Some idea of the market value of conspicuous insects, before they are sent over in numbers, may be gathered from the circumstance that a specimen of this butterfly recently sold for £15 at Stevens's auction rooms.

This is the last genus included in *Ornithoptera* which is met with in the East, but the two largest West African butterflies are likewise considered to belong to this group, and may receive a passing notice here. One of these is the famous *Drurya Antimachus*, which was brought by Smeathman from Sierra Leone, and figured by Drury in 1782, and, afterwards, by Donovan in his "Naturalists' Repository," but of which no second specimen was seen in Europe till 1864. It is an insect with very long and narrow wings, from seven to nearly nine inches in expanse, and much resembles some gigantic species of the very characteristic African genus *Acræa*. It is black, with large tawny spots and markings towards the base of the fore wings, the greater part of the hind wings is tawny, with a row of black submarginal spots. It has been suggested that this insect possibly mimics an extinct *Acræa*, for the largest known species of that genus are not much more than half the size of *D. Antimachus*. The female is considerably smaller than the male (a rather unusual character in butterflies), and has much shorter wings. There are two specimens in the Hewitson Collection in the British Museum, and it was one of these that Mr. Hewitson used to say cost him £500. The real explanation is probably that he spent that amount in sending out agents to collect butterflies in Africa, with special instructions to look for *D. Antimachus*. Of late years, many specimens have been brought to Europe, and the butterfly can now be bought at a comparatively reasonable price.

The other West African butterfly now recognised as belonging to the *Ornithoptera* group, but for which a new genus will probably be created before long, was described by Hewitson under the name of *Papilio Zalmoxis*. It measures about seven inches across the wings, which are broader and more rounded than in the typical Eastern butterflies of this group. The male is of a rather pale blue, with black borders, slightly spotted with blue on the hind wings, and with black marginal lines between the nervures, and a black costa on the fore wings. The male is fairly common in collections, but the female, which is of a dull yellowish grey instead of blue, is still very rare.

It is curious that, like the gorilla and chimpanzee, the nearest relatives of these two great West African butterflies (if we except *Papilio Ridleyanus*, White, a West African butterfly which has some resemblance to *D. Antimachus*, though it is much smaller and redder), are to be looked for in the islands of the Eastern Archipelago.

W. F. KIRBY.

A NEW ELEMENT IN THE NITROGEN GROUP.

A NEW element appears to have been discovered by Dr. Bayer in the residual liquors derived from the older process for the extraction of aluminium from red bauxite, and an account of it is communicated to the current issue of the *Bulletin de la Société Chimique*. The liquors in question consist chiefly of sulphate and carbonate of sodium, but there are also present considerable quantities of chromic and vanadic acids, and smaller quantities of molybdic, silicic, arsenic, phosphoric, and tungstic acids, together with alumina, magnesia, and lime, and an acid of the new element. In order to isolate the latter, the vanadium and chromium are first removed, the former as the difficultly soluble ammonium vanadate, and the latter as hydrated sesquioxide. The filtered liquid is then saturated with sulphuretted hydrogen, and the sulphides, all of which are soluble in the alkaline liquid, are precipitated by hydrochloric acid. This precipitate exhibits a deep brown colour, due to the new element. When dried it presents a brown earthy appearance, and burns readily with evolution of sulphur dioxide and formation of a bright brown powder. Concentrated nitric acid instantly causes ignition, and formation of a deep brown solution, from which a small quantity of a yellow precipitate of a compound of molybdic and arsenic acids is deposited. The brown liquid contains no tin, antimony, or tellurium, but still retains traces of vanadium, molybdenum, and selenium. These elements are best removed by calcination of the sulphides immediately after their precipitation with hydrochloric acid when selenium is volatilised, treatment of the residue with ammonia and ammonium nitrate, which precipitate the last traces of vanadium as ammonium vanadate, and concentration of the filtered liquid which causes deposition of ammonium molybdate. During the concentration two distinct crops of different crystals are obtained, the first and most sparingly soluble being cubic crystals of an olive-brown colour, and the second the much more soluble ammonium molybdate. The olive-brown cubic crystals contain the new element, together with a little molybdenum. The latter is readily removed by dissolving the crystals in dilute hydrochloric acid, and passing a current of sulphuretted hydrogen through the liquid heated to about 70°. The new element is not precipitated by sulphuretted hydrogen in an acid solution. The filtered liquid is then allowed to evaporate in the air. At first it is bluish-violet in colour, and contains the new element in a low state of oxidation; subsequently it becomes oxidised, and the colour changes to lemon yellow. The oxide in the latter stage possesses marked acid proclivities, and probably corresponds to the formula R_2O_5. The acid itself is soluble in water, from which it is deposited in yellow crystals, which at a red heat fuse to a brownish yellow mass. Ammonia transforms the acid into a crystalline powder of olive colour, presumably an ammonium salt, which readily dissolves in hot water and crystallises from the solution in cubes on cooling. The solution is olive green and is precipitated by strong ammonia. The solution of the acid after reduction with sulphuretted hydrogen in presence of hydrochloric acid yields with ammonia a voluminous deep violet-brown precipitate, which rapidly becomes crystalline. The precipitation is not complete, hence the supernatant liquid is coloured violet. Caustic soda and sodium carbonate likewise incompletely precipitate it, owing to solubility of the precipitate in excess of the reagent with formation of a soluble salt. Chlorides of barium and calcium produce greyish-violet precipitates of the salts of those metals.

An especially interesting reaction is that with ammonium sulphide, with which the highly oxidised yellow solution of the acid yields a deep cherry-red colouration, due to a sulfosalt. Acids precipitate from this solution a sulphide of the colour of iron rust. Silver nitrate produces a green precipitate of the silver salt, soluble both in nitric acid and in ammonia, and if the solution in the latter solvent is effected at a moderately elevated temperature the silver salt is deposited in crystals upon cooling. Magnesia mixture gives after standing a few minutes a green precipitate analogous to ammonium magnesium phosphate, and owing to the slowness of the precipitation the latter occurs in the form of relatively large crystals; moreover, the precipitation is complete after a short time, for the liquid which at first is green becomes colourless. A yellow precipitate is likewise afforded with a nitric acid solution of ammonium molybdate, as in the case of phosphoric acid. The chlorides of the new element appear to be volatile, for very considerable loss occurs on attempting to remove by ignition any admixed ammonium salts, for instance from the solution obtained after removal of the vanadium as previously described. A yellow sublimate is produced having all the characters of a chloride of the new element, and which is readily soluble in water.

A sufficient quantity of the new element in the form of any of its compounds has not yet been accumulated to enable exact quantitative analyses to be carried out, but Dr. Bayer hopes shortly to have obtained the amount requisite for this purpose and for the determination of the atomic weight of the element. There appears to be little room for doubt that it will prove to be one of the missing elements predicted by Prof. Mendeléeff in the nitrogen-phosphorus group. It exhibits characteristic spectroscopic lines in the green, blue, and violet.

A. E. TUTTON.

SCIENCE IN THE MAGAZINES.

A FULLY illustrated description of Mr. Maxim's experiments in aerial navigation is contributed to the *Century* by Mr. Maxim himself. The account of the new flying machine and its various parts is the best we have seen. The total result of Mr. Maxim's experiments is now fairly well known. It has been proved that a machine, carrying its own engine, fuel, and passengers, can be made powerful and light enough to lift itself in the air. The experiments also prove that an aëroplane will lift a great deal more than a balloon of the same weight, and that it may be driven through the air at a very high velocity, and with an expenditure of power very much less than that required to drive a balloon at even a moderate pace. In addition to this, they have clearly shown that a well-made screw propeller obtains sufficient grip on the air to propel a machine at almost any speed, and that the greater the speed the higher the efficiency of the screw. These results have certainly forwarded the problem of aerial navigation. The *Century* also contains an article on customs, fêtes, and celebrations in American Colleges for Women; and, in the same magazine, a brief description is given of the new anti-toxin treatment of diphtheria.

In the *National*, Mr. Stanley Lane-Poole pays tribute to the memory of the late Sir Charles Newton. (A notice of some of the researches of this distinguished archæologist will be found on p. 250.) Prof. Foxwell replies, on behalf of professed economists, to Lord Farrer's article in the October number of the same review, upon the Standard of Value. Towards the end of a contribution on the present state of the Royal Navy, Mr. W. Laird Clowes expresses himself upon the subject of the education of naval officers. Referring to the training of a naval officer, he remarks: "A century ago . . . it was not necessary that he should know anything of chemistry, of engineering, of hydraulics, of pneumatics, of electricity, and of half a dozen other subjects concerning which he must now know more than a little. . . . But at present, if an officer goes to sea, he has to suspend, in a great measure, the progress of his education. Theory is at the base of nearly all of it, and the theory is just as requisite as the practical experience, and, indeed, in some matters, even more so. . . . The seaman is in process of becoming the engineer; every year he becomes more and more the engineer; and I am certain that a much briefer experience of the sea than was formerly needed is now required towards the formation of a good officer. *Per contra*, he who would be a good officer requires very many things which are more easily obtainable at Portsmouth than in mid-Atlantic. We may regret the change, but we must not shut our eyes to facts. And I think the sooner the change is fully recognised, and the whole scheme of the education of naval officers is radically altered, the better will it be for the service." Mr. Clowes, however, does not seem to have sufficiently taken into account the difference between the duties of the navigating officers of the navy, and the engineers. Naval engineers at the present time receive admirable training in both the theory and the practice of the machinery with which a modern battleship is equipped. Does Mr. Clowes hold that navigating officers should receive the same kind of training? The statement that the seaman is in process of becoming the engineer, will hardly be accepted literally by those acquainted with the naval service. The engineers and engine-room artificers are fast becoming the most important men on board, but the distinction between them and the navigating staff is as hard and fast as ever it was.

In the *New Review* are some verses having a singularly strange and appropriate rhythm, by the late R. L. Stevenson, in which he has expressed his keen sense of the struggle for existence; and we find in the critical article upon this last among the many losses of 1894, by Mr. Archer, how profoundly modern scientific thought had affected his philosophy. There is also the first instalment of an eccentric story by Mr. H. G. Wells, in which, after certain rather paradoxical dealings with the four dimensions, a "Time Traveller" starts into futurity upon a *Time Machine*. What he found there remains to be told in a subsequent number, but there certainly seems scope for the scientific imagination in such a story.

A paper on "Feeling of Beauty in Animals," in *Chambers's Journal*, will interest students of nature. So long ago as 1866 a letter was published in the *Athenæum* under the same title, and attracted the notice of Charles Darwin. Birds offer, perhaps, the best proofs of a feeling for beauty exterior to themselves. There are the Bower Birds of Australia, and the Gardener Bower Bird of New Guinea, each of which decorates its bower with various objects. The Hammerkop or Hammerhead also nourishes æsthetic tastes, and other instances of birds showing a decided taste for ornament are described in the article referred to.

A passing notice will suffice for the remaining articles on scientific subjects in the magazines received by us. Some interesting reminiscences of the late Oliver Wendell Holmes as professor of anatomy, are given by Dr. T. Dwight in *Scribner*. *Good Words*—the first number of a new series—contains the first part of a paper on Sir Isaac Newton, by Sir Robert Ball; and some speculations by the Rev. Canon Scott on the physiographical consequences that would have resulted if the earth rotated from east to west instead of west to east. Mr. Grant Allen writes another "Moorland Idyll," in the *English Illustrated*. To the *Humanitarian*, St. George Mivart contributes the concluding part of his popular exposition of the doctrine of heredity. We are glad to note that the second number of the *Phonographic Quarterly Review* contains several scientific articles, each of which will help to familiarise phonographers with scientific phrases. The *Contemporary* has an article on the London County Council, by Mr. Sydney Webb, in which the work of the Technical Education Board is incidentally referred to. In addition to the magazines and reviews named in the foregoing, we have received the *Fortnightly*, *Longman's*, *Cornhill*, and the *Sunday Magazine*; but in none of these is science given a place.

SEASONAL CHANGES ON MARS.[1]

FOR the substantiation of changes on the surface of Mars, it is of paramount importance that the drawings to be compared should all have been made by the same person at the same telescope, under as nearly as possible the same atmospheric conditions. So much, at least, is fulfilled by the drawings referred to in this paper. For they were all made by Mr. Lowell at the same instrument, under the same general atmospheric conditions. Even the different eye-pieces used vary chiefly in a manner to minimise, if anything, and so emphasise the differences observed. For with increasing image the higher power used tends to decrease the contrast. The result is that it largely offsets the difference in contrast due to nearer approach, and leaves simply a case of magnification, with the values untouched.

Since, furthermore, the drawings were all made in the months preceding and following one opposition, secular changes are practically out of the question; and any changes that appear, are presumably of a seasonal character. They constitute of themselves a kinematical as opposed to a statical study of the planet's surface.

The resulting phenomena are much more evident than might be supposed; indeed, they are quite unmistakable. As for their importance, it need only be said that deduction from them furnishes, in the first place, strong inference that Mars is a very living world subject to an annual cycle of surface growth, activity, and decay; showing, in the second place, that this Martian yearly round of life must differ in certain interesting particulars from that which forms our terrestrial experience.

The phenomena evidently make part of a definite chain of changes of annual development. So consequent and, in their broad characteristics, apparently so regular are these changes, that it is not difficult to find corroboration of what appears to be their general scheme in drawings made at previous oppositions. In consequence it will be possible in future to foretell, to some extent, the aspect of any part of the planet at any given time.

The changes in appearance presented by the planet described by Mr. Lowell, refer primarily not to the melting of the polar snows, except as such melting forms the necessary preliminary to what follows, but to the subsequent changes in appearance of the surface itself. To their exposition, however, the polar phenomena become inseparable adjuncts, since they are inevitable auxiliaries to the result.

With the familiar melting of the polar snow-cap, therefore, this account properly begins, since with it begins the yearly round of the planet's life. With the melting of the Earth's Arctic or Antarctic cap might, similarly, be said to begin the

1 Abstract of a paper by Mr. Percival Lowell, in *Astronomy and Astro-Physics* for December.

Earth's annual activity. But there appears to be one important difference here at the very outset between the two planets. In the case of the Earth, the relation of the melting of its polar snows to the awakening of surface activity is chiefly one of *post hoc* simply; in the case of Mars, it seems to be one of *propter hoc* as well. For unlike the Earth, which has water to spare, Mars is apparently in straits for the article, and has to draw on its polar reservoir for its annual supply. To the melting of its polar cap, and to the transference of the water thus annually set free to go its rounds, seems to depend all the phenomena upon the surface of the planet.

The observations upon which this deduction is based extend over a period of more than five months; from the last day of May, 1894, to the 7th of November. They cover the regions from the south pole to about latitude thirty degrees north. It is probable that analogous changes to those recorded, differing, however, in certain marked particulars, occur six Martian months later in the planet's northern hemisphere. For though it is likely that the general system is one for the whole planet, it is also likely that the distribution of the planet's surface details alters the action to some extent.

In order to appreciate the meaning of the changes, it should be borne in mind that the vernal equinox of Mars' southern hemisphere occurred on April 7, 1894; the summer solstice of the same hemisphere on August 31; and that its autumnal equinox will take place on February 7.

On the 31st of last May, therefore, it was toward the end of April on Mars. The south polar cap was then very large, upwards of 45° across, and already in active process of melting. The tilt of the planet's axis towards the Earth enabled it to be well seen, and disclosed the fact that it was bordered persistently by a dark band, broader in some places than in others, but keeping pace with the snow's retreat. The average breadth of the dark band was, in June, 220 miles. It was the darkest marking on the disc, and was blue.

As the season advanced and the snow cap diminished, its dark girdle diminished in breadth, with fluctuations dependent, doubtless, on the draining capacity of the ground. In August it showed as a slender dark thread.

This formation was water, beyond a doubt; for it was of the colour of water, it faithfully followed the melting of the snow, and it subsequently vanished—three independent facts mutually confirmatory to this conclusion.

That it was the darkest blue marking on the disc, implies that it was the deepest body of water on the planet. That it subsequently entirely drained off, implies that its depth could not have been very great. Both facts together make a first presumption in favour of its being not only the chief body of water on the planet, but the only one of any size.

This polar sea plays *deus ex machina* to all that follows.

So soon as the melting of the snow was well under way, long straits of deeper tint than their surroundings made their appearance in the midst of the dark areas. They were already there on the last day of May. The most conspicuous of them lay between Noachis and Hellas in the Mare Australe, and thence through the Mare Erythæum to the Hour-glass Sea (Syrtis Major). The next most conspicuous one came down between Hellas and Ansonia. Although these straits were very distinguishably darker than the rest of the seas through which they ran, the seas themselves were then at their darkest. The fact that these straits ran through the seas, suffices to raise a second doubt whether the seas be seas. The subsequent behaviour of the so-called seas renders their aquatic character still more doubtful.

At the initial stage of the Martian Nile-like inundation, the seas were at their darkest. This is probably due both to the fact that some water had already found its way down from the pole, and also to the fact that moisture had been deposited there on the water's journey up, and had quickened the vegetation of those relatively amphibious lands.

For some time the dark areas continued largely unchanged in appearance; that is, during the earlier and most extensive part of the melting of the snow-cap. After this, their history became one long chronicle of drying up. Their lighter parts grew lighter, and their darker ones less dark. For even to start with, they were composed of every grade of tint. Indeed, one of the most significant features about them was that at this epoch it was impossible to fix any definite boundaries to the south temperate chain of islands. The light areas and the dark ones merged indistinguishably into each other. Viewed from the standpoint of maps of Mars, the landmarks of this whole region lay obliterated by a deluge; not directly, but indirectly. Probably the region was in various stages of vegetal fertility in consequence of a comparatively small body of water then inundating it. The colour of the dark areas was then, and is now, to my eye, a bluish-green; quite unmistakably so. This tint gradually faded out to give place to orange-yellow.

The first marked sign of change was the reappearance of Hesperia; this took place in July. It was not till the end of October, on the 30 h, that Atlantis was caught sight of. About the same time the straits between the islands, Zanthus, Scamander, Ascanias and Simois, came out saliently dark, a darkness due to contrast.

Meanwhile the history of Hesperia continued to be instructive. From having been invisible in June, and conspicuous in August, it returned in October to a mid-position between the two. Vacillating as these fluctuations may seem at first sight, they will all be found to be due to one progressive change in the same direction, a change that showed itself first in Hesperia itself, and then in the regions round about it. From June to August, Hesperia changed from a previous blue green, indistinguishable from its surroundings, to yellow, the parts adjacent remaining much as before. In consequence the peninsula stood out in marked contrast to the still deep blue-green regions by its side. Later the surroundings themselves faded, and their change had the effect of once more partially obliterating Hesperia.

While Hesperia was thus causing itself to be noticed, all the rest of the south temperate zone, as we may call it for identification's sake, was unobtrusively pursuing the same course. Whereas in June all that part of the disc comprising the two Thyle, Argyre II. and like latitudes was chiefly blue-green, by October it had become chiefly yellow. The separate identity of these islands became then for the first time apparent. Still further south, what had been first snow and then water turned to yellow land. This metamorphosis went on till, on October 13, the remains of the snow-cap entirely, or practically entirely, disappeared—the first complete disappearance of it on record. After this event the whole south polar region was one yellow stretch.

Toward the end of October a strange and, for observational purposes, distressing phenomenon took place. What remained of the more southern dark regions proceeded unexpectedly to fade in tint throughout. This was first noticeable in the Cimmerium Sea; then in the Sea of the Sirens, and in November in the Mare Erythræum about the Lake of the Sun. This fading steadily progressed until it got so far that in poor seeing the markings were almost imperceptible, and the planet presented a nearly uniform yellow disc.

Now, this fading out of the dark areas is a highly significant fact, with a direct bearing upon their constitution. For it is not simply that portions of the planet's surface have changed tint, but that, taking the disc in its entirety, the amount of the blue-green upon it has diminished, and that of the orange-yellow proportionately increased. Mars appears more Martian than he did in June. Now, if the blue-green areas represent water, where has this water gone? Nowhere on the visible disc. That is certain. For in that case the amount of the dark areas should not be perceptibly lessened—which it is. Nor can it all very well have gone to that part of the planet that is hidden from view. For Schiaparelli's observations in 1882 go to show that the northern snow-cap forms late—one month *after* the vernal equinox of the northern hemisphere on that year. Since, therefore, the water fails to prove an *alibi*, presumption is instantly raised in favour of the alternate hypothesis, that the blue-green areas represent vegetation, fertilised by a comparatively small amount of water whose direct presence or absence is not very perceptible to us, but whose indirect effects are. For vegetation might change from green to yellow without requiring any corresponding inverse change elsewhere.

Now, though the passage of the water may not be traced by its amount, there is a further change which has lately appeared on the disc which hints at what has become of it. The canals have darkened. What is more, their darkening has pursued a perfectly definite course, proceeding steadily from south to north.

The following observations show, first, that the canals are not equally visible at all times; and secondly, that their invisibility is a matter of the Martian seasons.

In June the canals were very faint markings indeed. The least faint were those in the Solis Lacus region. As the planet approached us, they all became naturally easier to make out; but until October no change apparently occurred in any of them, except those in the region about the Lake of the Sun. These by September were already dark. In October they began to show symptoms of growing lighter again. At the next presentation, in November, they showed further signs of change, though not differing as yet very unmistakably in tint. Meanwhile, when the Sinus Titanum region came round in November, I found that its canals had begun likewise to darken. The canals were not only darker relatively to the Mare Cimmerium and the Mare Sirenum than they had been, but actually darker themselves. In the next few nights the more northern canals about Ceraunius had followed suit. They had darkened relatively to the southern ones about the Lake of the Sun.

Now, on looking at a map of Mars, it will be seen that the Solis Lacus region is that part of the continental areas which lies nearest the south pole. Similarly, that the region about Sinus Titanum is the next farthest south. The matter of latitude therefore affects the point.

The canals and so-called lakes share, therefore, in the annual metamorphosis, with a season change dependent in a general way upon their latitudes. A wave of deepening tint passes successively through the blue-green regions from south to north, timed to the seasonal wave that travels from pole to pole. From being pale in winter, their colour comes with the spring, deepens through the summer, and dies out again in the autumn. In any given locality the change comes early or late, in proportion as the place lies, other things equal, distant from the pole.

That this change of tint is due indirectly to water, and directly to the vegetation that water induces, seems probable. For just as there is great difficulty in disposing of the water on the first supposition, so the second would lead us to expect just the phenomena observed. It may therefore be concluded that the formations known as the seas of Mars are probably midway in evolution between the seas of Earth and the seas of the Moon. That is to say, they are not barren ocean beds, but are in that half-way stage of the process when their low-level helps them catch what water still voyages upon the planet's surface, though they have long since parted with their own.

Throughout all these interesting changes that follow the seasons across the face of Mars, there is but one feature approaching permanence—the great continental areas. Except for a possible variation in brightness here and there, this great area has remained unchanged. Like the reddish desert regions of our Earth, its colour and immutability point to like character for cause. It does not change because it is already past such possibility. It is one vast desert waste.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A NEW post has been created under the Education Department for the purpose of obtaining special information and issuing special reports, from time to time, in relation to educational work at home and abroad. The frequent demand for fuller information on many educational subjects, and the great increase of purely administrative work, both at the Education Department in Whitehall and at the Science and Art Department, have made it desirable to have a separate officer in charge of a small additional branch for the above-named purpose, who will be designated "Director of Special Inquiries and Reports." This appointment has been accepted by Mr. M. E. Sadler, Student of Christ Church, and Secretary of the University Extension Delegacy at Oxford.

THE Technical Education Board of the London County Council will be prepared early in July, 1895, to award not more than five Senior County Scholarships of the annual value of £60 in addition to the payment of college fees, tenable for three years, and subject to annual renewal. The scholarships are intended to provide the means of obtaining advanced technical training in a university, university college, or technical institute of university rank for students (young men or women) of exceptional ability who would otherwise find it impossible to secure such training. Candidates must, as a rule, be under nineteen years of age on September 1, 1895, but the Board is prepared to consider very special cases in which the candidates are above that age. The scholarships are offered with the view of encouraging the study of science or art, with special reference to industrial requirements, and will be tenable at such institutions giving appropriate instruction within the statutory definition of technical instruction as may be selected by the scholars and approved by the Board. In the selection of scholars the Board will have regard, in the first instance, to the past achievements of the candidates, but the Board reserves the right to require any or all of the candidates to undertake an examination if it think fit. No candidate will be eligible whose parents have an income from all sources of more than £400 per annum.

SINCE November 1893, the Technical Education Board of the London County Council have awarded 721 Junior County Scholarships, each of the value of £20 and two years' free schooling. More than three thousand candidates presented themselves in competition for the scholarships, which are restricted to children whose parents are in receipt of not more than £150 a year. A detailed analysis of the occupations of the persons whose children competed for these scholarships is given in the *London Technical Education Gazette*. It indicates that the highest percentage of candidates who received scholarships is to be found in the leather trades, and next to these in the printing trades and jewellery and fine instrument trades. After these come the artistic trades and crafts, but the most remarkable feature is the comparatively poor results obtained by the children of clerks, agents and warehousemen, and the very poor success achieved by the professional classes. The time is not far distant when the scholarships granted by the Board will amount to the value of £30,000 per annum.

SCIENTIFIC SERIALS.

The Mathematical Gazette, No. 3, December, 1894.—The eccentric circle of Boscovich. In this continuation the editor considers a special case in which the centre of the eccentric circle lies on the straight line whose points of intersection with the conic are required. He then discusses the method as one of transformation, and finally points out a connection between reversion and perspective projection.—Dr. Mackay, in Greek Geometers before Euclid, writes upon Pythagoras and the Italic school.—Cajori's "History of Mathematics" is an all too short notice, by Dr. G. B. Halsted, of a book that has come in for a fair amount of praise and blame. There are some very interesting problems, solutions of examination questions, and questions for solution.—Prof. A. Lodge supplies an addition to his previous article on approximations and reductions.—We note, with pleasure, that in future the *Gazette* is to be enlarged to twelve pages. This additional space will greatly help to increase the use of this journal, which has so quickly made its way in school circles.

Bulletin of the American Mathematical Society (2nd series, vol. i. No. 3, December, 1894).—The group of Holoedric Transformation into itself of a given group, by Prof. E. H. Moore, is a paper read before the Society at its November meeting. The remaining article is by Dr. G. A. Miller, on the non-primitive substitution-groups of degree ten. A list of these was given in the *Quarterly Journal of Mathematics*, vol. xxvii. pp. 40–42. A result of the article before us is that the following six groups should be deleted from that list, viz. 20_3, 20_7, 20_8, 10_3, 5_2, 5_3.—In the *Briefer Notices* short accounts are given of H. Hertz, "Gesammelte Werke," Band iii. This volume, the first one as yet issued, contains a memoir on the principles of theoretical mechanics and mathematical physics, which was composed during the last three years of the author's life. The next notice gives a sketch of a new edition of Grassmann's mathematical works. It is to be hoped that, as was recently suggested in NATURE by Prof. Genese, a translation into English of the *Ausdehnungslehre* may soon be made, for the convenience of many students in this country. The other notices summarise the contents of the *Jahresberichte der Deutschen Mathematiker-Vereinigung* (vol. iii. 1893), of the *Proceedings* of the American Association—for the forty-second meeting, held at Madison, Wis. (August, 1893); of "Le Livret de l'étudiant de Paris" (Paris, 1894).—The *Notes* comprise accounts of the November meetings of the American and London Mathematical Societies. By the way, the reporter, who is a member of the latter Society, gives one of the names of the Council incorrectly. There is also an account of the meeting, in September last, at Vienna, of the German Mathematical Association. The *Bulletin* well maintains its position, and closes with its useful lists of new publications.

SOCIETIES AND ACADEMIES.

LONDON.

Mathematical Society, Dec. 13, 1894.—Major Macmahon, F.R.S., President, and subsequently Mr. A. E. H. Love, F.R.S., Vice-President, in the chair.—The following communications were made:—On Maxwell's law of partition of energy, by Mr. G. H. Bryan. In his recent report to the British Association, the author had shown that if a large number of dynamical systems of any kind be taken, all similar in every respect, it is always possible to distribute their coordinates and momenta so that the distribution shall remain permanent, and shall satisfy Maxwell's law of partition of energy. By this is meant that if the kinetic energy of each system be reduced to a sum of squares, the mean values of these squares are equal. But the author had doubted whether it was possible in any case to infer that the *time averages* of the squares forming the kinetic energy of a single system were equal. In the present paper the connection between *time averages*, and *averages taken over a large number of different systems*, is examined more fully by means of an artifice suggested by Prof. Boltzmann's paper "On the application of the determinantal relation to the theory of polyatomic gases" (published as an appendix to Mr. Bryan's report). Instead of a vessel containing gas (as taken by Prof. Boltzmann), any single dynamical system is taken whose coordinates and momenta return to their original values after a long time T. If the time be divided into an infinitely large number (n) of infinitely short intervals (i), we can derive a stationary distribution by taking n systems and starting them, the first at time 0, the second at time i, the third at time $2i$, and so on, giving every system the same coordinates and momenta at the time of starting it. At the end of the time T, we shall have the systems distributed according to a permanent or stationary law, and at any subsequent instant the mean value of any function of the coordinates and momenta for the different systems will be equal to the time average of the corresponding function for the original single system. If, however, we *start* with a number of systems distributed according to a permanent law, we *cannot pass back to the original single system unless we can show that the law of permanent distribution is unique.* Now in any simple test case, such as that afforded by rigid bodies movable about fixed points or particles moving in planes after the manner of a Lissajou's curve tracer, *a* stationary distribution exists satisfying Maxwell's Law of Partition, but other stationary distributions are possible which do not satisfy the law. Hence the author concludes that the time averages of the squares into which the kinetic energy of a single system can be divided, are *not* in general equal, at any rate independently of initial circumstances.—The Spherical Catenary, by Prof. A. G. Greenhill, F.R.S. The pseudo-elliptic integrals developed in the *Proc.* L.M.S. xxv. are applied in this paper to the construction of solvable cases of the spherical catenary, given by the relation

$$\psi = \int \frac{A\,dz}{(1 - z^2)\sqrt{Z}},$$

where

$$Z = (1 - z^2)(z - h)^2 - A^2,$$

connecting ψ the azimuth, and $z = \cos\theta$, where θ denotes the angular distance from the lowest point of the sphere, the tension being $w(z - h)$ (Clebsch, *Crelle*, 57). Putting

$$u = \int \frac{dz}{\sqrt{Z}},$$

and

$$\chi = \psi - fu = \int \frac{-f(1 - z^2) + A}{(1 - z^2)\sqrt{Z}}\,dz,$$

then χ can be identified with the standard form of the pseudo-elliptic of the third kind, of order μ,

$$I = \tfrac{1}{2}\int \frac{\rho(s - \sigma) - \mu\sqrt{(-\Sigma)}}{(s - \sigma)\sqrt{S}}\,ds,$$

where

$$S = 4s(s + x)^2 - \{(y + 1)s + xy\}^2$$

by putting

$$\chi = \frac{1}{\mu},\ p = \tfrac{1}{2}\left(\frac{M\rho}{\mu} + A\right), A = M(y + 1), h^2 = A^2 - 2y - 1,$$

where

$$M^2 = -\frac{y + 1}{2x},$$

and x, y are Halphen's functions, defined in his "Fonctions Elliptiques," I. p. 102. If $u = a$ when $z = 1$, and $u = b$ when $z = -1$, then $u = \frac{1}{2}(a - b)$ when $z = h$; a and b are each of the form $f\omega_3$, a fraction of the imaginary period ω_3. Also $M^2\wp(a + b) = -\frac{1}{6}(1 - h^2) - \frac{1}{4}A^2$, or $12\wp(a + b) = 8x - (y + 1)^2$, so that $\sigma = 0$, and

$$a + b = \frac{4\omega_3}{\mu}.$$

Thus, for instance, when

$$a + b = \omega_3,\ A = h^2 - 1,\ p = \tfrac{1}{2}A;$$

and the corresponding spherical catenary is given by

$$(1 - z^2)^{\frac{1}{2}} e^{\chi i} = \sqrt{\frac{h - 1}{2}}\sqrt{\{z^2 - (h + 1)z - 1\}} + i\sqrt{\frac{h + 1}{2}}\sqrt{\{-z^2 + (h - 1)z - 1\}}.$$

With

$$\mu = 3,\ a + b = \tfrac{4}{3}\omega_3,\ A^2 = h^2 - 1,\ p = \tfrac{1}{3}A;$$

and

$$(1 - z^2)^{\frac{3}{2}} e^{3\chi i} = A(z^3 - hz^2 - 2z) + i(hz + 1)\sqrt{Z}.$$

With

$$\mu = 5,\ a + b = \tfrac{4}{5}\omega_3,$$

then $y = x = -c$, suppose;

$$M^2 = \frac{1 - c}{2c},\ p = \tfrac{1}{5}(3 - c)M;$$

and

$$(1 - z^2)^{\frac{5}{2}} e^{5\chi i} = Hz^5 + \ldots + H_5 + i(Lz^3 + \ldots + L_3)\sqrt{Z},$$

where

$$H = \frac{2 - 5c + c^2}{c}M,\ L = \frac{2 - c}{c}h,\ \&c.$$

With

$$\mu + b = \frac{1}{2}\omega_3$$

the calculation is rather more complicated, as this case must be derived from $\mu = 8$; but the result is of the form

$$(1 - z^2)e^{2\chi i} = (Hz - H_1)\sqrt{(z_3 - z \cdot z - z_0)} + i(Lz - L_1)\sqrt{(z - z_2 \cdot z - z_1)}$$

with

$$z_3 > z > z_2 > z_1 > z > s > z_0,$$

$$z_0,\ z_1,\ z_2,\ z_3$$

denoting the roots of the quartic $Z = 0$.—The Transformation of Elliptic Functions, by Prof. A. G. Greenhill, F.R.S. The function z_a, introduced by Prof. Klein in his paper on the transformation of elliptic functions (*Proc.* L.M.S. xi. p. 151), and developed in Klein and Fricke's "Modulfunctionen," ii. part v., is shown here to be connected with Halphen's γ function by the relation

$$\rho(-1)^a z_a = \lambda^{\frac{a^2}{n}}\gamma_a,$$

for a transformation of the nth order; and for an odd value of n,

$$\lambda^{2p+1} = \frac{\gamma_{\frac{n-2p+1}{2}}}{\gamma_{\frac{n+2p-1}{2}}},\ p = 1, 2, 3 \ldots \frac{n - 1}{2};$$

in this manner the relation $\gamma_n = 0$ is satisfied.

The biquadratic relations satisfied by the function z are now derived from Halphen's formula

$$\gamma_{m+n}\gamma_{m-n} = \gamma_{m+1}\gamma_{m-1}\gamma_n^2 - \gamma_{n+1}\gamma_{n-1}\gamma_m^2.$$

The relation $\gamma_n = 0$ is treated as the equation of a curve with coordinates x and y; and when x and y can be expressed as functions of a parameter c, the quantities γ_a and z_a can also be expressed as functions of this parameter. For instance, $\gamma_{13} = 0$ reduces to the quadratic in p

$$p^2 - (1 - c^2 - c^3)p - c(1 + c)^2 = 0$$

by means of the substitutions

$$x = y(1 - z), \quad y = z\left(1 - \frac{z}{p}\right), \quad z = c(p - 1);$$

and now in Klein's Modular Equation of the Thirteenth Order, given in the *Proc.* L.M.S. ix. p. 126, it is found that

$$\tau = \frac{1 - c - 4c^2 - c^3}{c(1 + c)} = \frac{1}{c} + \frac{1}{1 + c} - c - 3.$$

When one root τ_∞ of this modular equation is given by

$$\tau_\infty = \frac{13c(1 + c)}{1 - c - 4c^2 - c^3} = \frac{13}{\frac{1}{c} + \frac{1}{1 + c} - c - 3},$$

the remaining 13 roots, typified by τ_r, are given by

$$\tau_r = \frac{\left(1 + \sum \frac{z_{2a}}{z_a} \epsilon^{36a^2 r}\right)^2}{\frac{1}{c} + \frac{1}{1 + c} - c - 3}, \quad \epsilon = e^{\frac{2\pi i}{13}},$$

where $a = 1, 2, 3, 4, 5, 6$; $r = 0, 1, 2, \ldots 12$,

(Klein, *Math. Ann.* xvii. p. 567).

It has been shown in the *Proc.* L.M.S. xxv. p. 252, that

$$\lambda = -\frac{cx^{\frac{1}{3}}}{yz};$$

and now, putting

$$\rho = \sigma x^{\frac{1}{4}},$$

$$(\sigma z_1)^{13} = \frac{c}{x^4 y z}, \quad (\sigma z_2)^{13} = \frac{c^4}{x^3 y^4 z^4}, \quad (\sigma z_3)^{13} = \frac{x^3 c^9}{y^9 z^9},$$

$$(\sigma z_4)^{13} = \frac{z^{16} c^{16}}{xy^3}, \quad (\sigma z_5)^{13} = \frac{c^{25}}{x^4 y^{12} z^{12}}, \quad (\sigma z_6)^{13} = \frac{c^{36}}{x^{12} y^{23} z^{10} f},$$

all functions of c and $\sqrt{C}$, where

$$C = 1 + 4c + 6c^2 + 2c^3 + c^4 + 2c^5 + c^6.$$

The solution in the same manner of the Modular Equation of the Seventh Order has already been given in the *Proc.* L.M.S. xxv. p. 224; while the Fifth Order introduces Klein's icosahedron function. A similar procedure will serve for the Eleventh Order.—On certain definite theta-function integrals, by Prof. L. J. Rogers.—On a class of groups defined by congruences (second paper), by Prof. W. Burnside, F.R.S.—Electrical vibrations in condensing systems, by Dr. J. Larmor, F.R.S. It is only by the introduction of considerable capacity that the vibrations of electrical systems of simple geometrical form can assume a character at all simple and steady; for this reason it is of practical importance to be able to estimate the periods of vibrations in the dielectric plates of condensers. It is shown that the modes and periods for such a plate are precisely the same as those of the acoustical vibrations of a plate of air of the same form and the same law of thickness, enclosed on both faces, and also round its edge, by rigid walls, the only difference being that the velocity of electric propagation replaces the velocity of sound. For example, if the condenser is a spherical one, the periods of the free vibrations are equal to the time required for an electric pulse to travel round its circumference, divided by $(m^2 + m)^{\frac{1}{2}}$, where m is any integer; and this result will also practically hold good for a condenser of this form which is not a complete sphere, but has a hole through it at the point opposite to the place where the inner coating is connected with the exciter. The periods for a flat condenser of uniform thickness correspond to the well-known ones of standing water-waves in a cylindrical vessel of the same form of contour. If a condenser is divided by cutting across its conducting coats, as is done in the ordinary guard-ring, the separate parts will vibrate without interfering with each others periods. Various other cases are treated; for example, the propagation of electric waves in a compound plate composed, say, of air above and a liquid below.—On the integration of Allegret's integral, by Mr. A. E. Daniels.—On the complex number formed by two quaternary matrices, by Dr. G. G. Morrice.

Linnean Society, December 20, 1894.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. W. B. Hemsley exhibited a series of specimens and figures illustrating parasitism of *Loranthus aphyllus* and other plants, from the Herbarium, Kew.—Mr. J. E. Harting exhibited a specimen of a small Siberian warbler, *Phylloscopus superciliosus*, which had been obtained near Beverley, Yorkshire, in October last, and made some remarks on its haunts, habits, and migration, and upon the previous instances which had been noted of its accidental occurrence in the British Islands.—Mr. H. M. Bernard gave the substance of a paper on the spinning glands in *Phrynus*, not previously known, and described their position and their morphological importance in Arachnidan phylogen. The penis was described as a pair of rudimentary filamentous appendages of the genital segment, and consequently of importance as bearing further testimony to the view that the limbs on the abdomen of the ancestral form were not plates as in *Limulus*, but appendages like those on the thorax. The presence of these limbs explains the curious genital operculum of the *Pedipalpi*, which is not a primitive feature derived from Eurypterine ancestors, as some would maintain, but a purely secondary specialisation acquired within the Arachnid phylism.—A paper was then read by Mr. Percy Groom, entitled "Contributions to the knowledge of Monocotyledonous saprophytes," or plants which are dependent for their existence on the presence in the substratum of decaying organic matter. He observed that, like parasites, they may be divided into those which possess chlorophyll (*hemisaprophytes*) and those which have none (*holosaprophytes*). Hitherto very few experiments, he said, had been made on *hemisaprophytes*, and hence our acquaintance with them was largely speculative. The remarks which he had now to offer referred almost entirely to *holosaprophytes*, or at least to plants with very little trace of chlorophyll. After an interesting discussion, in which Sir D. Brandis, Mr. H. N. Ridley, and others took part, the Society adjourned to January 17.

PARIS.

Academy of Sciences, December 31, 1894.—M. Lœwy in the chair.—A study of graphites from iron, by M. Henri Moissan. At the ordinary pressure, the graphite is purer when formed at a higher temperature. The graphite produced at the highest temperature is the most stable in presence of nitric acid and potassium chlorate. Under pressure, the crystals and masses of graphite appear to have suffered incipient fusion. During the solution of the cast-iron by acids, hydroxy compounds are formed, which resist a dull red heat, but burn like the graphite itself.—Report was made favourably on a memoir by M. Riquier, to be printed in the *Recueil des Mémoires des Savants étrangers*, under the title "On the existence of integrals in any differential system, and on the reduction of such a system to a completely integrable linear form of the first order."—On the radial velocity of ζ Hercules, by M. H. Deslandres. A spectrophotographic determination in which the line displacements are measured on photographs taken with comparison spectra on each side of the star spectrum. The mean value of the radial velocity of this star is −70 km., as determined by M. Belopolsky; the author confirms this exceptional value, finding −60·41, a second observer finds the velocity −62·97.—On the determination of the number of roots common to a system of simultaneous equations, and on the calculation of the sum of the values of a function in these points, by M. Walther Dyck.—On the solution of numerical equations by means of recurring series, by M. R. Perrin.—On definite integrals of divisors, by M. N. Bougaïef.—On certain conditions to be realised for the measurement of electrical resistances by means of alternating currents and the telephone, by M. R. Colson.—On the sulphides of nickel and cobalt, by M. A. Villiers. This is a study of the conditions of precipitation of nickel and cobalt sulphides, and of the means whereby the precipitation may be wholly or partly prevented.—On calcium ethoxide, by M. de Forcrand. Calcium carbide, C_2Ca, gives with ethyl alcohol compounds of the type $n\,CaO + n'\,C_2H_6O$, and not an ethoxide. The compounds obtained are (1) $3CaO.4C_2H_6O$ and (2) $CaO.C_2H_6O$. At the same time gas is disengaged, consisting chiefly of acetylene (80 per cent.), and an easily liquefied ethylenic hydrocarbon (10 per cent.).—On β-oxycinchonine, by MM. E. Jungfleisch and E. Léger. The preparation and properties of this compound are given in detail, and thirteen of its salts are described. β-oxycinchonine is an energetic diacid base; it turns litmus blue, and reddens phenolphthalein.—Action of chlorine on the secondary alcohols, by M. A. Brochet. The action of chlorine on alcohols of the type $R.CHOH.CH_3$ yields ketones of the form $R.CO.CCl_3$, the radical R being also chlorinated to the extent characteristic of the radical.—On the industrial preparation and physiological properties of the oxalate and of the crystallised salts of nicotine, by MM. H. Parenty and E. Grasset. The mortal dose of pure nicotine is 20–21 mgm. per kilogram weight of animal. The fatal dose in the combined state is much larger. An animal slowly accustomed to the action of the poison can support daily a dose greater than that fatal in ordinary cases.—On pine tar, by M. Adolphe Renard.—Remarks on the muscles and bones of the hind limb of *Hatteria punctata*, by M. A. Perrin.—Comparative study of the lobed and reticulated Rhizopoda of fresh water, by M. Félix Le Dantec.—On the nests of *Vespa crabro*, L.; order of appearance of the earlier cells, by M. Charles Janet.—The fragments of the uppermost stratum of Ubaye, by MM. E. Haug and W. Kilian.—On the conditions of propagation of typhoid fever, cholera, and exanthematous typhus, by M. Renard.

NEW SOUTH WALES.

Linnean Society, November 28, 1894.—The President, Prof. David, in the chair.—Re-description of *Aspidites ramsayi*, Macl., by Edgar R. Waite.—A review of the fossil jaws of the *Macropodidæ* in the Queensland Museum., by C. W. De Vis. The very fine collection of over eleven hundred dissociated jaws or portions of jaws in the Queensland Museum has been studied in the light of a knowledge of the nature and range of the variations, individual and specific, presented by the skulls of 479 individuals referable to sixteen existing species. The following species were described as new: *Palorchestes parvus*, *Sthenurus pales*, *S. oreas*. *Halmaturus vinceus*, *H. thor*, *H. dryas*, *H. odin*, *H. indra*, *H. siva*, *H. vishnu*, *Macropus magister*, *M. pan*, and *M. faunus*.—Notes on some Land Planarians collected by Thos. Steel, Esq., on the Blue Mountains, N.S.W., by Dr. A. Dendy.—On a British bivalve mollusc found in Australia and Tasmania, with its distribution; and on a new sub-genus of *Trochidæ*, by J. Brazier.—*Cryptodon flexuosa*, Montagu, was recorded for the first time from Port Stephens, N.S.W., and Esperance Bay, Tasmania.—The name *Solanderia*, Fischer (1880), being preoccupied by Duchassaing and Michelotti (1846), it was proposed to replace it by *Rossiteria*.—Description of a new Australian eel, by J. Douglas Ogilby.—*Gymnothorax prionodon*, sp.n., from Port Jackson, appeared to be closely allied to the Atlantic species *G ocellatus*.—On a new Typhlops previously confounded with *T. unguirostris*, Peters, by G. A. Boulenger, F.R.S.—Botanical notes from the Technological Museum (part iii.), by J. H. Maiden and R. T. Baker The writers gave a list, with localities, of plants new to New South Wales; also notes on some rare or little known plants indigenous to the colony.—On a new species of *Enteropneusta* from the coast of New South Wales, by James P. Hill. The name *Ptychodera australiensis* was proposed for the first described Australian species of Enteropneusta. It is specially characterised externally by the great development of the genital wings which completely hide the gill-area, and extend far into the hepatic region, and by the presence of two longitudinal epidermal stripes overlying the two ciliated bands of the intestine. In the mode of formation of the proboscis pore, it appears to be the most variable of all *Enteropneusta* hitherto described. The most interesting points in its internal anatomy are the presence of a median longitudinal infolding of the ventral wall of the heart bladder into the cavity of the same. the presence of a transverse vessel between the different proboscis vessels, and the much branched condition of the gonads.—On a Platypus embryo from the intrauterine egg by J. P. Hill and C. J. Martin. The embryo described was taken from one of two eggs just ready to be laid. The eggs measured 18 mm. by 13·5—being somewhat larger than the eggs described by Caldwell. The embryo more nearly resembled that of the Virginian opossum (Didelphys) of seventy-three hours, described by Selenka, than any other embryo known to the authors. The Platypus embryo is, however, much longer.

EPIGENESIS OR EVOLUTION.

Zeit- und Straitfragen der Biologie. Von Prof. Dr. Oscar Hertwig. Heft 1: Präformation oder Epigenese? Grundzüge einer Entwicklungs-theorie der Organismen. (Jena: Gustav Fischer, 1894.)

THE theory of preformation, or rather let us say predetermination, as revived at the close of the nineteenth century, is much more formidable than its prototype of the eighteenth century. Not only is it stripped of all its earlier crudities, such as the doctrine of *émboitement*, but it is supported by a mass of evidence accumulated by the researches of the last quarter of a century. Its fundamental assumption, that of the existence of minute, qualitatively unlike, ultimate particles of living matter, is strengthened, if not supported, by the analogy of the atomic theory, and the observed phenomena of mitosis accompanying the maturation of the ovum and spermatozoon, and the subsequent acts of impregnation and segmentation have been skilfully blended with the fundamental assumption in such a way that they are made to seem to be a proof of it. This strong position is now assailed by Dr. Oscar Hertwig, who is in many respects peculiarly well fitted to the task. He is the master of a simple, lucid and logical style, he has himself been, in conjunction with his brother, a pioneer in many of the discoveries on which the doctrine of predetermination is founded, and he has recently set himself to the task of verifying the experiments of Roux and others, and of examining the evidence which they afford for or against the doctrine which he attacks. His answer is unequivocal. The phenomena of development are to be explained on epigenetic, not on evolutionary grounds, and the latter hypothesis is contradicted by a number of well-ascertained facts.

In an introductory chapter Dr. Hertwig refers to and accepts Roux's definition of development, evolution, and epigenesis, which may be repeated here, as they give precision to terms which are often loosely used or little understood. By "development" is meant the origin of perceptible heterogeneity. Epigenesis means, not merely the formal increase of perceptible heterogeneity in a substance apparently similar but possibly extremely complex, but a real increase of pre-existing heterogeneity. Evolution means, the becoming perceptible of pre-existing latent imperceptible differences. Dr. Hertwig goes on to describe the positions taken up by Weismann and Roux, and deals particularly with the former, who, as he shows, regards the germ as a veritable microcosm, in which every separate variable part which appears in the course of the whole ontogeny is represented by a living particle; on the characters of these particles the characters of the parts of the adult organism, whether composed of one cell or many, depend. The sum of these particles forms the germ-plasm. Agreeing with Weismann that a theory of heredity must be founded on and brought into harmony with the cell theory (and therefore rejecting the opposite view of Nägeli), Dr. Hertwig proceeds to attack Weismann's fundamental assumptions. As he rightly says, the foundation and corner-stone of Weismann's theory is the assumption of differential or anisocleronomic[1] division of the cell nucleus. All-important as this assumption is, there is no foundation of fact to be found for it in all Weismann's work. Instead we find purely dialectical argument, and more than this, we find that Weismann has attributed the most opposite characters to his "idioplasm," declaring it, in one place, to be stable and unchangeable, in another to be labile and changeable. But, Hertwig points out, the facts are directly opposed to the assumption of anisocleronomic division of the germ substance. In the Protozoa the division is clearly isocleronomic, and we know of no instance among them in which the act of division, as such, is a means of producing new species. Moreover, the numerous cases (*e.g. Podophrya gemmipara*) of complicated life histories among Protoza show that the dissimilarity which may at first obtain between the two products of cell division is no indication of permanent and essential difference. The case of the lowest multicellular organisms is adduced as showing that in these also the cell division is isocleronomic, for each cell of which the soma of many of these organisms is composed, retains the power of giving rise to the whole organism. The phenomena of regeneration and heteromorphosis afford evidence that there are in the tissues of many highly differentiated organisms cells, or groups of cells, which retain, in a high degree, the power of giving rise to new and complicated structures, and this is particularly exemplified in cases of heteromorphosis, which is to be distinguished from regeneration by the fact that, in the former case, lost organs are replaced by organs which differ in form and function from those which were lost, or organs are, as a result of special conditions, produced in abnormal positions on the body. Under this head of phenomena of heteromorphosis, Dr. Hertwig groups the extraordinary phenomena which have been brought to light by his own researches and those of Driesch and E. B. Wilson on the segmenting ova of such different animals as frogs, echinids, and amphioxus, and these observations have been extended, since the publication of Dr. Hertwig's book, by the researches of Prof. Rafaello Zoja on the developing ova of cœlenterates. Briefly stated, the results of these experiments are as follows: In the case of echinids, amphioxus, and cœlenterates, the first two, four, or even eight blastomeres may, by suitable means, be isolated without impairing their vitality. Each blastomere, instead of giving rise to an incomplete embryo, or a portion of an embryo, begins the developmental course afresh, as it were, and produces an embryo perfect in all its parts, but one-half, one-fourth, or one-eighth the size, as the case may be, of the normal embryo. In the case of the frog it was not possible to isolate the blastomeres; but Hertwig was able, by pressure, to so alter the segmentation, that the normal relations of the blastomeres, one to another, were completely changed, and yet a perfectly normal embryo resulted. Unquestionably this proves that, in the first stages of segmentation, at any rate, the division of the germ substance is not differen-

[1] The German words "erbgleich" and "erbungleich" being untranslatable into English, I have coined the equivalents isocleronomic and anisocleronomic from the Greek Κληρόνομος an heir.—G. C. B.

N

tial but integral, not qualitative but quantitative, and this undermines the most important of Weismann's positions.

Very important are Dr. Hertwig's criticisms on the doctrine of determinants, so sharply and clearly defined by Weismann. This doctrine is inseparably connected with that of the anisocleronomic division of the germ-plasm, and it might appear that if the latter is disproved, it is unnecessary to enter into a detailed criticism of what depends upon it. But the criticism is not without its utility, since, Dr. Hertwig shows us, the conception of determinants is only an extreme instance of a false conception of causality common in current biological literature. Weismann has supposed that the ultimate vital particles, which he calls biophors, are grouped in the germ-plasm into "determinants," and that every smallest cell-group in the adult organism which has definite characteristics and a definite situation is represented in the germ-plasm, both of ovum and spermatozoon, by a definite determinant. These last are so arranged in the germ-plasm, and are endowed with such special forces, that they are able, in the course of ontogeny, to move at the right time into the right place—this movement being effected by the almost purposive anisocleronomic division of the germ-plasm. This very definite idea is founded on an erroneous conception of the relations between primordium (Anlage) and primordial product, which are supposed to stand in relation to one another as cause and effect. More or less unconsciously, the biologist commonly assumes that, because a given animal proceeds of necessity from a given egg, there is an identity between primordium and primordial product; so much so, that the developing organism is often spoken of as if it were a self-contained system of forces, a sort of organic perpetuum mobile. He overlooks the fact that for the fulfilment of the developmental processes many other conditions are necessary, without which the primordium could never arrive at the condition of its final product. Between the two there is clearly no identity, and it is false and mischievous to suppose, as the older evolutionists did, and the new evolutionists are again trying to make us believe, that the perceptible heterogeneity of the last stage of the developmental process is only the final expression of an invisible corresponding heterogeneity of the first stage. Throughout the whole of the ontogeny there is an exchange of material taking place, the adult has arrived not only to its bulk, but to its complexity as the result of metabolism; inorganic material is perpetually changed into organic, and serves for the growth and development of the primordia. It is true that the form changes are constant and invariable for the species, from a certain kind of germ a certain kind of animal is invariably produced; but is not this largely because, in the ordinary course of events, the ovicell is always subject to similar conditions of assimilation and excretion, and to similar conditions of gravity, light, temperature, &c.? Throughout the course of organic development things which were external are transformed into things internal, and the primordium grows and is changed at the expense of the environment. In thus recalling to our attention the fact that an organism is above all things metabolic, that its growth and changes are the result of its metabolic activity, and that its ultimate mass is the result of assimilation, of the taking up and making an integral part of itself of matter which was previously apart and different from itself, Dr. Hertwig does a real service to biology. He forces us back to the consideration that physiology and morphology are not two separate and independent lines of study, but that they are so closely interdependent that no generalisations can be made on the evidence of one kind of observation alone; they must be supported by equally cogent arguments from the other side. The theories of the evolutionists are essentially morphological, and in this they resemble the theories of the last century, that they take no account of one of the most wonderful of all vital phenomena, that of metabolism, but strive to find an explanation of the ultimate perceptible differences in form by asserting that the differences were always there, and have only expanded so as to become perceptible. Weismann's attempt to deal with this question by assigning the power of change as the result of metabolism to the biophors, does not really offer more than a purely formal explanation of the question, for what he predicates of the biophors may very well be predicated of the whole cell. Our ideas of increase of complexity as the result of metabolism are made none the clearer by shifting the responsibility of the change, if one may express oneself so, to subordinate parts.

It is indeed apparent, on reflection, that the characters of the perfected organism are not and cannot be the characters of a single cell—or even of a cell fusion such as the oosperm—and the converse of this is true that the characters of a cell cannot be the characters of the perfected organism. For what is a perfected metazoon or metaphyte but an aggregation of cells of most numerous and unlike characters? The characteristics of the perfected organism are the result of the correlation of all its parts, of the relations of cell to cell and of groups of cells to groups of cells; and are we to attribute to a single cell which has no relations characters which are essentially the results of the relations of innumerable cells one to another? Of the importance of the correlation of the parts of the perfected organism we can have no doubt, nor can we escape from the corollary that the characteristics of the organism reside not so much in the cells themselves as in the aggregation and interdependence of the cells, and if we may demur to the suggestion of the *colonial* character of the metazoa which is contained in the sentence, we must at least admit much of the truth of Hertwig's statement (p. 85):

> "That the ovum is an organism which multiplies itself by division into many organisms similar to itself, and that it is through the reciprocal action (Wechselwirkung) of all these many elementary organisms at each stage of the development that the organism as a whole is gradually and progressively established."

Dr. Hertwig institutes the comparison which was made long ago by Herbert Spencer, between an organism and a human society, and it is worth while mentioning his illustration as showing his conception of the relations of the cell to the organism. The organisation of a complex human society, he says, is something new, and not to be thought of as existing beforehand in the organisation of an individual man. It is nevertheless founded in human nature, but we cannot in gross, mechanical fashion seek for the organisation of a society in the primitive nature of man. In a like manner the character of the perfected organism is founded on the nature of the cells which compose it, but it contains in itself a new element, a heterogeneity due to correlation and reciprocity, which is limited by the specific nature of the cell substance, but is not to be sought for as a specific constituent of the substance of any individual cell. Starting from this point of view, we may consider Dr. Hertwig's own doctrines which he sets forth in the second part of his work entitled "Gedanken zu einer Entwicklungstheorie der Organismen." Whereas Weismann seeks the cause of the orderly development of the primordium in the primordial substance itself, Hertwig considers that the development of the primordium is dependent on conditions or causes which lie outside of the primordial substance of the ovicell, but are none the less produced in regular succession during the process of ontogeny. Such are, in the first instance, the reciprocal relations in which cells stand one to another in increasing degrees of complexity, whilst they increase in number by division; and in the second place, the action of the external environment on the organism. The argument in support of this proposition is given in so condensed a form that it is almost impossible to give any part or abstract of it without giving the whole. The following sentence is so important that it may be quoted at length, and the reader should refer to the work itself for the rest of the argument and the conclusion: –

"One of the most important and essential causes of the appearance of heterogeneity in the course of development is to be found in the specific power of the ovicell, to multiply itself by division. From this fact alone, that the nuclear substance is able, in the course of most manifold chemical processes, to assimilate, step by step, matter from the reserve material stored up in the egg, and oxygen from the surrounding atmosphere, it is able at the same time to evoke an ever-increasing heterogeneity. The increase of mass of the nuclear substance involves its progressive division into 2, 4, 8, 16 parts, and so forth. But the division is again the cause of a constantly changing spatial distribution of the substance. The 2, 4, 8, 16 and following nuclei which arise by division give way to one another in opposite directions, and attain to new positions at definite distances from one another within the limits of the egg. Whilst all the material particles of the ovum were at first arranged round the fertilised nucleus as a single centre of force, they are now grouped around as many individual centres as there are new nuclei, and they segregate themselves around these as cells. It is therefore clear that the ovum as an unicellular organism, when compared with the ovum as a multicellular organism, has altered its quality to an important extent, and that merely by the process of isocleronomic division."

This is what Hertwig calls the function of growth as a form-producing principle. The other principles which he invokes are the relations of the cells to external conditions, or the function of their position, and finally the reciprocal influence of the parts of the whole on one another and on the whole, or the function of correlation. It is not to be denied that these are principles of considerable importance, and it may be said that their importance has never quite been lost sight of, but they do not bring us any nearer to the explanation of the totally different reaction of apparently similar substances to the same stimuli. What we want to know is why, when we place under a hen her own eggs and those of a duck, and so expose them to identical conditions, chickens and ducklings are hatched as unlike one another as may be. The answer given, "the difference can be due to nothing else than to the different nature (the different micellar structure) of the substance," is unsatisfactory, in that it is only a restatement of the fact, and is not an explanation at all. In attempting to give a more definite account of the different natures of the egg substance, Hertwig is obliged to take his stand upon much the same ground as the evolutionists. "In the hen's egg the species is present as fully as in the hen, and the hen's egg is as different from the frog's egg as the hen is from from the frog." He is compelled to agree with the evolutionists in assuming the existence of a specific, and even of a very highly organised primordial substance as a basis of developmental processes, but he claims that his concept of this substance is different from and better than theirs, in that he ascribes to the primordial substance or germ-plasm characters which are congruous with the concept and character of a cell, and does not ascribe to it the innumerable characteristics which are only evoked through the union of many cells and the concomitant action of external conditions. The distinction appears to be a slight one, yet on careful consideration it assumes more important dimensions. Hertwig, if I interpret him rightly, conceives of the germ-plasm as a substance of many and definite potentialities. He does not attribute this potentiality to one part, and that to another part of the germ-plasm, but argues that as a result of multiplication by division the relations of the cells with their contained germ-plasm are continually undergoing change, both with regard to one another and to the environment. In consequence of the different conditions thus induced, this potentiality is evoked in the germ-plasm of one cell, that in the germ-plasm of another, and so on in ever-increasing grades of complexity. The differentiation of any cell is the result of its position, which determines which of its many potentialities shall be called into action. It is the reaction of the living substance to the stimulus which evokes a particular potentiality, which brings about its form changes, and it may be supposed that a profound form change following on constant action in one direction incapacitates the cell in question for the performance of any of the many other duties for which it was primitively fitted. This conception is epigenetic in that it admits the coming into being of a new heterogeneity which was not pre-existent in the ovum as such; that which was present was a capacity for certain kinds of heterogeneity. Very different is the conception of the evolutionists, who define the exact potentialities of the germ-plasm, and assign each to a given material particle or group of particles. The heterogeneity is already present; thenceforward there is no room for the increase of complexity in response to external stimuli. Dr. Hertwig rightly says that Weismann's explanation amounts to nothing more than a renunciation of an explanation. His doctrine of determinants leads us into an invisible world in which there is no foothold for research. For this reason, if for no other, we should welcome Dr. Oscar Hertwig's invitation to return to the paths of epigenesis. A theory which has a formal answer for every question, which regards everything that we can see and lay hold of as predetermined and unalterable, which relegates the causes of phenomena to the unseen and unknowable—such a theory, if accepted as true, does not stimulate, but stifles inquiry. Fortunately it has had the opposite result. It has not been accepted, and it has developed an attack of a brilliant and overwhelming character. All the best arguments which Dr. Hertwig can bring against the theory of predetermination are derived, not from simple observation, but from experiment. A few simply conceived interferences with the normal course of the segmentation of the ovum have sufficed to strike down the doctrine of determinants. May we not hope that an extension of these methods may illuminate the regions which are still hidden from us? After all his attempts to supply an acceptable alternative to Weismann's scheme, Dr. O. Hertwig makes a partial confession of failure. To many his failure will seem complete, and it must be so since the evidence derived from experiment is as yet wholly inadequate. But his attempts indicate the paths along which research may be conducted, and he is very right when he claims, in conclusion, that it is the great merit of his conception of the developmental processes, that it opens the gates once more to research, with some brighter hope of results than the formal theory of predetermination afforded us.

G. C. Bourne.

COAL-DUST AND COLLIERY EXPLOSIONS.

Coal-Dust an Explosive Agent, as shown by an Examination of the Camerton Explosion. By Donald M. D. Stuart. (London: Office of the *Colliery Manager*, and E. and F. N. Spon.)

IT is significant of the conservatism—not always wholly disinterested—that surrounds an old-established industry that, in spite of all that has been written and said on the action of coal-dust as an explosive agent during the last twenty years, we should still find people persistently clinging to the belief that the only possible cause of a colliery explosion *must* be fire-damp. It would be amusing, were the matter less serious, to note the extraordinary hypotheses and absurd surmises to which the believers in this time-honoured doctrine are occasionally driven in order to account for the existence of fire-damp in places where the common testimony of unbiassed people affords no proof of its presence. The hard logic of facts is, however, surely, even if slowly, undermining the mass of prejudice with which this question has been surrounded, and we may hope that before the close of the century the action of the Legislature will compel these people, whose obstinate unbelief jeopardises men's lives, to give practical heed, even more directly than at present, to the teachings of intelligent observation and inspection. The causes and conditions which lead to a colliery explosion are now so well understood that such a catastrophe ought to be no longer possible. If it does occur, we must lay the blame on the management and discipline of the mine, and it should not be difficult, under these circumstances, to fix the responsibility. The master of a vessel who carelessly navigates his ship, is liable to have his certificate dealt with in a very summary fashion. It does not avail him to plead that his crew are picked from a class that is proverbially reckless and foolhardy, and that his "look-out," therefore, was probably in fault. The Assessors take it for granted that he has a proper knowledge of his business, and they hold him responsible for the discipline on his vessel. Public opinion demands that a mine-manager should be treated in a similar manner. How difficult it is for the the law, in spite of the length of its arm, to get at a manager who has been guilty of culpable carelessness, has been shown in more than one inquiry that could be named.

As an illustration of the mental attitude to which we allude, we may refer to a recent report on the cause of the explosion at the Albion Colliery, South Wales, in June last. All the circumstances connected with that explosion seemed to indicate that it was due to the same cause as that which accounted for the explosions at the Park Slip, Apedale, and Malago Collieries, viz. the presence of coal-dust, and this conclusion was confirmed by the report of the inspectors appointed by the Home Office to inspect the colliery.

In a report prepared for the colliery proprietors by six engineers, we find that these gentlemen are unanimously of opinion that the disaster was caused by an outburst of fire-damp, and they have great satisfaction in stating that no blame in the matter can be attributed to any of the officials or employés. There is no wonder, in view of this conflict of testimony, that the men of the Rhondda district should have demanded a fresh inquiry by the Government into the cause of the disaster.

The changes of opinion among "practical" men on this question of coal-dust are very suggestive, and strikingly exemplify the course through which a new truth has to run when it is in conflict with the settled conviction of interested persons. Like the course of true love, it does not run at all smooth under these circumstances. The idea that coal-dust could be the cause of a colliery explosion was, in the outset, scouted as absurd. Then, as facts multiplied, the dust was allowed to have a share in the catastrophe: it aggravated the violence of a fire-damp explosion. Next, the proportion of the fire-damp became smaller by degrees, until it reached the vanishing-point. Now we have reached the stage that all dusts are not explosive, and the colliery manager is satisfied that his dust is not as other men's dust. Even in the case of those who were more receptive of the teaching of experiment and of trained observation, the recognition of the real facts has had to run the conventional course. First they were not true, then they were not new, and we knew of them before; for did not Faraday and Lyell tell us all about the matter in the Haswell report? In a question of this kind, colliery management ought to be in advance of public opinion. That it has not always been so in the past, the history of coal-mining shows only too plainly. It was the shock to public sentiment, caused by a succession of disastrous explosions, which occurred in the early part of this century, that indirectly brought about a revolution in the art of coal-getting. People in the colliery districts, who were witnesses of the terrible loss of human life, and of the misery and destitution that followed it, asked their fellows if this ought to be part of the price to be paid for coal, and the answer was given in no uncertain tones. Government inspection was insisted upon, and, in spite of persistent opposition, eventually obtained. In the outset, the character of the inspection was not always what it should be; but, little by little, this has improved. We have a better trained class of men sent out by the Home Office now than formerly, and their hands have been gradually strengthened by the Legislature, although, perhaps, not to the extent that is desirable.

Statistics show that this intelligent inspection is gradually making its influence felt. Tested by the ratio of fatalities to number of men employed, and to amount of material raised, there is a slow but decided improvement. Of course, even under the most ideal system of inspection, coal-mining will continue to be a hazardous occupation; but this at least we may hope, that the steady sacrifice of 1000 victims a year, which that ruthless potentate, Old King Coal, seems to demand, shall not continue to be augmented by catastrophes that ought to be considered as preventable.

Mr. Stuart's book is to be welcomed, therefore, as adding one more link to the chain of evidence which establishes the fact that coal-dust may be the most important and, at times, even the only agent in bringing about a colliery explosion. About a year ago an explosion occurred at the Camerton Collieries in Somersetshire, the significant feature of which was that it took place in a mine wholly free from fire-damp. All the circumstances connected with this explosion were brought to the knowledge of Mr. Chamberlain's Commission by Mr. Garthwaite, the general manager, and were fully inquired into by H.M.'s inspectors. Mr. Stuart's examination was made independently of the official investigation, and it is satisfactory to note that as regards the main conclusion there is absolute unanimity on all sides. There can be no possible doubt, therefore, that the explosion of November 14, 1893, at the New Collieries, Camerton Court, was due to coal-dust, and to coal-dust alone, initiated by a gunpowder shot, and most probably by what is technically known as a "blown-out shot." Mr. Stuart's examination showed that there were no "extraordinary circumstances" present; the shot-firing was an ordinary operation, the presence of coal-dust was a normal circumstance, and the work was being done by a competent man. "The angle and declivity of the hole were such, that if the gunpowder were expelled, it would directly strike the dust; but it was so placed in the judgment of an experienced miner. . . . In the presence of this explosion, therefore, conjecture upon the supposed innocuousness of a gunpowder shot in a dry and dusty non-gaseous mine is at an end."

Whilst we wholly agree with Mr. Stuart in this conclusion, we are not altogether at one with him in regard to his explanation of the chemical process of a coal-dust explosion. Mr. Stuart appears to be of opinion that a coal-dust explosion is in reality only another form of a gas explosion. The action of the heated products of the exploded gunpowder is, he assumes, to cause the dust to experience a kind of destructive distillation whereby hydrogen and gaseous hydrocarbons are formed, which at the high temperature combine explosively with the oxygen of the air of the mine. Whether there is any necessity to invoke this distillatory process as an explanation of the phenomena, is extremely doubtful. Without expressing any final opinion on this point, it may be pointed out that no definite relation between the bituminous character of the dust and its "sensitiveness" as an explosive agent has been established. The dry mines of South Wales, where some of the most formidable explosions of recent times have occurred, yield a dust which is relatively rich in carbon, and which affords no very large quantity of gas on distillation.

We would commend this book to the thoughtful attention of every colliery manager, with, however, the reservation that Mr. Stuart's theories are not to be accepted as of the same value as his facts. So long as he confines himself to the orderly arrangement and analysis of these facts he is on perfectly safe ground. The weakest portion of the book is that in which the author seeks to elucidate the chemical and physical phenomena of a coal-dust explosion, by the application of imperfect thermal data and of irrelevant chemical observations.

THE MODE OF LIFE OF MARINE ANIMALS.

Die Lebensweise der Meeresthiere. Beobachtungen über das Leben der geologischwichtigen Thiere. Von Johannes Walther. Zweiter Theil einer Einleitung in die Geologie als historische Wissenschaft. (Jena: Gustav Fischer, 1893.)

THIS is the second part of Prof. Walther's projected extensive geological treatise, the first part of which—on the Bionomy of the Sea—appeared some time ago. Of the three titles given, the second, or subsidiary one, seems best to describe the scope of the present book. It is not, as might be supposed from the primary title, a treatise on the physiology of marine animals—would that it were! that is still a great desideratum in biology—but is rather some observations on certain points in the life-relations, or mode of occurrence, of certain marine animals, viz. those which are of importance to the geologist [and no less to the biologist] as being the present-day representatives of former animals now preserved as fossils. Walther's idea is that we must study the relations of organisms to their environment at the present day, before drawing deductions from fossil remains as to the physical conditions of past geological periods. His object is to lay a sound foundation of fact, as to the mode of occurrence of particular sets of animals, upon which to base an account of the history or development of the events chronicled in the rocks. The idea is a sound enough one, if not very original—it must surely have been present, consciously or not, in the minds of various geological and biological writers—and the conclusions arrived at, if really based upon a sufficiently large accumulation of statistics, will no doubt be a valuable guide to the geologist in forming his opinions. The book, if very complete in its series of facts, would also be a useful reference work to the zoologist; but it may be doubted, on an examination of the lists given by

Walther, whether they are a sufficiently exhaustive compilation to inspire thorough confidence.

For example, the information as to the geographical distribution of species is rather unequal, being detailed in some cases, and decidedly meagre in others, as when for *Lagena sulcata* is given only "im Mittelmeer," and when for *Crania anomala* the only north-west European locality is the Clyde! While, on the other hand, such minute local detail is given as that *Globigerina bulloides* is not uncommon in the brackish water of the Dee from Chester to Hilbre Island. A number of detailed criticisms of this kind might be made, such as the extraordinary entry "*Lafoëa*, 450 faths." when several species of the genus are found in quite shallow water. But probably enough has been said to show that the lists are by no means complete.

The plan of the book is, briefly, as follows: first, the gaps in the palæontological record, and their causes, are discussed; then the following groups are treated in succession: Foraminifera, Radiolaria, Spongia, Anthozoa, Crinoidea, Asteroidea, Echinoidea, Holothuroidea, Bryozoa, Brachiopoda, Lamellibranchiata, Gastropoda, Cephalopoda, and Crustacea. A few general questions are discussed. The author alludes to the well-known fact that some of the most abundant groups in the sea are almost unrepresented in the fossil series, and that even amongst animals with hard parts the fossils of a particular bed might inadequately represent what had been the living assemblage at that spot. He quotes Edward Forbes' account of the natural history of a shell-bed off the north-west of the Isle of Man, and his later observations in the Ægean Sea, to show that even the fresh dead remains of organisms on the sea-floor do not always correctly show the relative abundance of the living species.

In each group, after a short account of the characters, mode of occurrence, &c., there follows a list of genera and species, with an indication of the distribution and range in depth, compiled from *Challenger* reports, monographs, and other sources; but there is a want of correlation and digestion of the facts, the nomenclature is not up to date, and the same species sometimes occurs several times under different names; *e.g.* on p. 308, *Ophiothrix fragilis* appears three times under the names *Ophiocoma rosula*, *Ophiothrix fragilis*, and *Ophiothrix rosula*, with a different range in depth each time. Occasionally an animal is found in the wrong group altogether, as, a Holothurian amongst the Asterids, and an Ascidian in the Gastropods. However, Prof. Walther has brought together a considerable amount of material which those who are interested in the distribution of animals in the sea, and the association of species to form "faunas" characteristic of particular regions, will have to utilise. For this the marine zoologists and the geologists will no doubt be grateful, and will, with profit, consult the lists; but I fear they will also sometimes regret that the author had not taken more pains to digest his facts and to correct his proofs. Many odd pieces of interesting information are given; but there is still room in some book on marine faunas for a detailed account of characteristic assemblages of animals with as full a description as can be given of their physical surroundings and their variations. W. A. H.

OUR BOOK SHELF.

Elementary Qualitative Chemical Analysis. By Prof. Frank Clowes, D.Sc., and J. B. Coleman. Pp. 180. (London: J. and A. Churchill, 1894.)

Tables and Directions for the Qualitative Chemical Analysis of Moderately Complex Mixtures of Salts. By M. M. Pattison Muir, M.A. Pp. 44. (London: Longmans, Green, and Co., 1895.)

Laboratory Exercise Book for Chemical Students. By E. Francis, F.C.S. (London: Blackie and Son.)

THE first of these books is an abridgement of Prof. Clowes' text-book on qualitative analysis, adapted for use in the laboratories of schools and colleges. For the most part, the book is like a host of others of the same kind. It differs from many of them, however, in the fact that the first fifty pages is devoted to instructions on the preparation of apparatus, to experiments illustrating the preparation and properties of certain gases and liquids, to descriptions of analytical operations, and directions for the performance of ordinary processes of chemical manipulation. Work of this character forms by far the best introduction to a course of practical chemistry, and it has an educational value, which is more than can be said for mere test-tubing. On account of this and one or two other notable features, the book will probably take a permanent place among laboratory guides.

"These tables and directions" (writes Mr. Pattison Muir) "are intended for the guidance of students who are acquainted with the principles of qualitative analysis, and who are able to make a qualitative analysis of a simple salt, and of a mixture of salts containing not more than a single metal in any one group, and three or four of the common acids." The student who has passed through an elementary course of practical chemistry is frequently puzzled how to conduct an analysis of moderately complex mixtures of salts and the commoner metals and acids, or an analysis of metals and alloys. Mr. Muir's book tells exactly what to do in such cases. By following the directions given, it would hardly be possible for the young analyst to go wrong. The processes described are easily carried out, and are concisely stated. A point worth noting is that the formulæ of solids are printed in heavy type; of liquids or substances in solution, in ordinary type; and of gases, in italics. This method of indicating the physical states of substances certainly possesses advantages. Altogether the book is a handy and trustworthy manual for analytical chemists.

The exercise book arranged by Mr. Francis has apparently been designed to take the place of the laboratory note-book. It opens with a few exercises in practical chemistry, the experiments being briefly—sometimes too briefly—described; and blank spaces are left for the entry of results. Then come a set of analytical tables, and a number of blank forms in which all the steps in the analysis of a mixture of two simple salts are indicated, spaces being left for the student to fill up with his inferences. The average student of practical chemistry works like a machine now, and we have no doubt that these tables will be after his own heart, for they only leave him to fill in his observations as if he were answering the questions in a census paper. The book may serve to drill the student into carrying out his tests in the proper order, but it will not benefit him mentally.

Elements of Astronomy. By G. W. Parker, M.A. (London: Longmans, Green, and Co., 1894.)

THIS is one of the books in which astronomy seems to be regarded as a subject which is to be studied much in the same way as one would take up an additional book of Euclid. It abounds in definitions, propositions, and corollaries; the diagrams of instruments scarcely give any ideas of what they are intended to represent; and the descriptive part of the subject might have been omitted without much sacrifice. The ground covered is that which is ordinarily understood by an elementary treatment of mathematical astronomy, dealing chiefly with the considerations relating to the positions, movements, dimensions, and distances of the various heavenly bodies, but includes also some very scanty references to their telescopic appearances. On the whole, the various points are clearly, though shortly, explained, but there is much to suggest that the author would be all the better for some little observatory practice; for example, his method of determining the angular value of a micrometer by means of the sun (p. 48) is scarcely practicable, and a sun-spot 13,000 miles long is by no means to be classed as one of the largest spots (p. 68). It may be pointed out, also, that a single observer, by observing at intervals of twelve hours, gets better results for the parallax of Mars than two working in the way indicated on p. 115. A ship's mean time at sea, too, is usually determined by one observation near the prime-vertical, and not by the method of equal altitudes.

In less than a dozen pages the author attempts to give an idea of the classification of the stars, and of "the principal discoveries which have been made in modern times, chiefly by means of spectroscopic analysis, with their nature and physical condition" (p. 203). The omission of the solar prominences in an account of the phenomena of a solar eclipse, is a good indication of the very feeble character of this chapter.

The book is intended specially for students preparing for University examinations, and by such it may be found useful.

LETTERS TO THE EDITOR.

Exploration at Ruwenzori.

PERHAPS it may interest your readers to give a short account of Ruwenzori, where I have now spent four months. The mountain is a very difficult one to study, on account of the difficulty of reaching the most interesting part. Taking a sort of botanical section from the shore of the Albert Edward Nyanza, one finds first a series of grassy plains covered with Andropogous some two feet high, and in certain months supporting large herds of elephants, Kudu, and Lurwali antelopes. This is in part the old level of the lake, and in part gravel and sand brought by the numerous rivers; in places it is dotted by Acacia and the tree Euphorbia, which has something of the appearance of an enormous chandelier. After leaving this plain, one comes to a series of small hills from 4000 to 5000 feet in height, which have been apparently cut out of the mountain by the numerous rivers and streams. Some of these are covered with patches of cultivation, banana plantations, &c.; usually these are hidden from the main road. When one reaches the mountain proper, one finds up to 7000 feet a steep ascent covered with grass and small shrubs, usually three to four feet high. The valleys in this part are usually very steep V-shaped trenches, and cultivation is abundant everywhere, sometimes over 7000 feet, and in the Wakondja country the edible Arum is grown up to 7400 feet or more. This height, 7000 to 8000 feet, marks the beginning of the forest. It is composed of deciduous trees, sometimes with a very thick undergrowth; sometimes it is pretty open, with a profusion of fern and moss on the old trunks, and creepers in some places. I have found tree ferns and Begonia, but usually the flowers are rather pale in colour, or quite inconspicuous. At 8600 feet another distinct change takes place, and a wilderness of decaying young and mature bamboos replaces the trees. Here and there these are hung with creepers, but the predominant feature is the wetness of everything. Moss covers almost every trunk below, and amongst the roots are only very watery plants, such as Urticaceæ. At 9600 feet another change takes place; bamboos disappear completely, and tree heather takes its place. In a dry part of the mountain one finds a charming little violet, a Cardamine, Galiums, Epilobium, Rubus, &c. In wetter places one finds a regular peat-moss with Sphagnum, beautiful orchids, and short heather; in another place one will find enormous trees of heather, usually gnarled and twisted in growth—tree Senecios, tree Hypericums, &c. This region seems to extend to the snow (which, I am sorry to say, I have not been able to reach). On my highest attempt, I could see the heather trees apparently higher than the snow. On another attempt to get to the summit, I found what seems to me *Alchemilla alpina!* One feature of the mountain is the extreme scarcity of animals and birds. In the lower forest there are bushbuck, baboons, and two other sorts of monkeys; one the magnificent black and white-furred kind from which grenadiers' shakos were made, and another with short slatey fur, which is new to me.

Perhaps the commonest birds are the sunbirds; one green, yellow, and crimson, I have seen above 10,000 feet, and I have also seen (though I am almost afraid to say it) a robin, and a goldfinch.

As to the geology of the mountain, I do not care to risk an opinion at present, but I have taken many specimens which I hope may solve some of the questions. I think glaciers must have extended seven to eight miles down two of the valleys, but there was no evidence to my mind of any extensive glaciation. I think I am right in saying that the Salt Lake is nothing but an extinct volcanic crater, and in several places along the east side of the mountain there are others, or a small chain of volcanoes; usually the chain radiates from the centre of the mountain.

I hope to start to-morrow for Ujiji, my object being to see whether a practicable route exists from Tanganyika to the Albert Edward Nyanza. I only hope I shall be able to bring my collections safely home. G. F. SCOTT ELLIOT.

Salt Lake, Ruwenzori, August 2, 1894.

The Alleged Absoluteness of Motions of Rotation.

I MUST confess that discussions upon mathematical metaphysics appear to me to be somewhat unpractical. They are suggestive of the case upon which Serjeant Snubbin was engaged, which related to a right of way "leading from some place which nobody ever came from, to some other place which nobody ever went to." Nevertheless, I propose to offer some remarks upon this subject.

That *absolute* motions of translation and rotation exist appears to me too clear for argument; but whether our senses are capable of taking cognisance of them and reducing them to exact measurement, is quite another matter. The view advocated by Prof. Greenhill appears to be that motions of rotation are determinate—that is to say, they are capable of exact measurement within the limits of experimental error; whereas the contrary is the case with motions of translation. Mr. Love, on the other hand, holds that neither kind of motion is determinate in the above sense. Now a knowledge of the absolute value of the velocity of translation of any object involves a knowledge of the magnitude and direction of the sun's velocity in space; and until the latter has been determined, which has not yet been done, the former is necessarily unknown. It therefore follows that all motions of translation of which our senses are capable of taking cognisance are *relative*.

On the other hand, the motion of rotation of any object is independent of the motion of translation of the sun or any other body. If, therefore, it were in our power to construct a system of axes which either move parallel to themselves or whose angular motion is known, it would be possible to determine the absolute value of the angular velocity of any object. But even if it were possible to devise an experiment by which such a system of axes could be obtained, our results would only be accurate within the limits of experimental error. It may, therefore, be well to point out that, without inventing any new experiment, the angular velocity of any object may be accurately determined *within the limits of experimental error* in the following manner.

Select two stars, X and Y, whose proper motions are so minute that they have never been detected by the most refined observations. Through the sun and the two stars draw a plane, S X Y, and through the sun draw a line, S Z, perpendicular to this plane; and let the motion be referred to S X, S Z, and a line perpendicular to them as axes. Now in consequence of the proper motions of the sun and the two stars, these lines will not constitute a system of axes which are either fixed in space or which move parallel to themselves; consequently, if these lines be taken as axes of reference the observed (or calculated) value of the motion of rotation of any object will necessarily be *relative* to these axes, and its *absolute* value cannot be determined without ascertaining the angular motion of the axes of reference. But since the two stars have been specially selected from amongst those whose proper motions have eluded detection, the angular motions of the axes will be so small compared with ordinary standards that the error caused by neglecting them will lie within the limits of experimental error. If, for example, we were to endeavour to calculate by the above method, or some similar one, the *absolute* angular velocities of the hands of a clock, or of a fly-wheel, the value which we should thereby obtain would be as exact as the existing state of mechanical and instrumental appliances admits.

A series of observations extending over several thousand years might of course reveal a proper motion of any two selected stars; but in the case of angular motions whose periods do not extend much beyond a century, the above method leads to results which are for most practical purposes exact.

I am therefore disposed to think that all motions of rotation of which our senses are capable of taking cognisance are *relative*; but with the exception of certain astronomical motions of very long periods, the *absolute* value of any motion of rotation which can be observed may be accurately determined within the limits of experimental error. A. B. BASSET.

Fledborough Hall, Holyport, Berks.

THE gist of Mr. Love's long letter, on pp. 198–9, seems to be that since the specification of a force or a motion depends upon the choice of axes, therefore the force or motion itself is similarly dependent. A slight extension of the same principle would make a velocity—say the velocity of light—depend upon whether it was to be expressed in miles per second or in centimetres per hour; and no extension at all is necessary to make it depend on whether it is referred to Groombridge 1830, or to some more quiescent body, if indeed the term quiescence may be allowed henceforth to have any meaning.

Tycho Brahé is said to have held that there was only a question of language between the Copernican and the Ptolemaic systems; but, with the exception of a semi-ironical Church compromise attributed to Descartes, he has been unfortunate in not finding a disciple of importance until the present moment.

It appears now to be equally true to say that the earth rises to meet a stone, as to say that a stone falls to meet the earth; and considerations of energy are of no consequence!

I just want to add one word of my own on the subject, to the effect that whereas the *position* of a body in an infinite homogeneous stagnant ocean would be unmeaning and unspecifiable, except by reference to boundaries or other bodies, yet it does not follow that the *velocity* of a body through such an ocean would be either unmeaning, unspecifiable, or undiscoverable by experiment. It may be replied that such motion would still be relative to something; and to that I say by all means, but it is not relative to other bodies such as are competent to fix *position*, which is what Mr. Love is contending for.

As to the other question, about absoluteness of rotation, I shall be much interested in seeing what Prof. Greenhill, and with him Profs. Mach and Karl Pearson, have to say on the point. OLIVER J. LODGE.

Liverpool, December 29, 1894.

The Quarrying of Granite in India.

At Bangalore, in Southern India, the quarrying of granite slabs by means of wood fire has been brought to such perfection, that an account of the method may not be out of place. The rock is a grey gneissose granite of very irregular composition through unequal segregation of hornblende and the presence of numerous felspathic veins. But it is otherwise very compact, and forms solid masses uninterrupted by cracks for several hundreds of feet. Only near the surface the rock is found split parallel to the surface. In one quarry there is thus, for instance, a 4-feet thick horizontal layer of rather weathered rock, underneath this another layer of fresh rock 3 feet thick; but below this the rock is entirely fresh, and not split. These layers are probably due to the variations of temperature, daily and seasonal.

The undisturbed rock is quarried by means of fire, and it is remarkable what large plates may be detached. I saw one plate of 60 feet greatest length, and 40 feet greatest width, and half a foot thickness. This thickness varied only one inch over the greater part of the area. The whole plate had been detached in one piece by means of wood-fire. Afterwards the plate was cut with blunt chisels into strips of 2¼ feet width. So easily are these strips and slabs obtained, that it is quite common to see palisades of them used instead of boundary walls, and also to see them used as posts for huts, for telegraphs, and for railings and posts in gardens.

In one case, I observed the operation of burning over an area. A narrow line of wood-fire, perhaps 7 feet long, was gradually elongated, and at the same time moved forward over the tolerably even surface of solid rock. The line of fire was produced by dry logs of light wood, which were left burning in their position until strokes with a hammer indicated that the rock in front of the fire had become detached from the main mass underneath. The burning wood was then pushed forward a few inches, and left until the hammer again indicated that the slit had extended. Thus the fire was moved on, and at the same time the length of the line of fire was increased and made to be convex on the side of the fresh rock. The maximum length of the arc amounted to about 25 feet. It was only on this advancing line of fire that any heating took place, the portion which had been traversed being left to itself. This latter portion was covered with the ashes left by the wood, and with thin splinters which had been burst off. These splinters were only of about ⅛th inch thickness, and a few inches across. They were quite independent of the general splitting of the rock, which was all the time going on at a depth of about five inches from the surface. The burning lasted eight hours, and the line of fire advanced at the average rate of nearly 6 feet an hour. The area actually passed over by the line of fire was 460 square feet, but as the crack extended about 3 feet on either side beyond the fire, the area of the entire slab which was set free measured about 740 square feet. All this was done with, may be, about 15 cwt. of wood. Taking the average thickness of the stone at 5 inches, and its specific gravity as 2·62, the result is 30 lbs. of stone quarried with 1 lb. of wood.

The old quarries have sloping sides formed of steps left by each successively split plate, each new plate extending to within about 2 feet of the step left by the preceding plate. Many plates are taken out in an inclined position, and as the directions of inclination differ, it follows that the action of the fire is quite independent of the original surface of the rock, and also of the direction of lamination and of the numerous veins in the rock. The action of the fire is thus very similar to that action which produces dykes and faults on a large scale, more or less independent of the nature of the rocks which are passed through.

The great uniformity of the thickness of the slabs formed by the above process is probably due to a regulating influence of the pre-existing crack. When the action of the fire is somewhat slower, it takes longer for the heat to penetrate down to the crack; when the action is quicker, there will be enough expansion produced in the upper layers, and the lower layers transmit the tension to the plane of the crack. Perhaps it will be possible some day to measure the temperature of the heated rock, when a certain agreement ought to be found between the tensile strength of the rock and the strain which the expansion by the heat produces in the so-far elastic rock.

Bangalore, December 19, 1894. H. WARTH.

Storm Statistics at Bidston.

THE Liverpool Observatory, erected at Bidston, on the Cheshire side of the estuary of the Mersey, stands on a slight eminence about 200 feet above the sea-level. The ascent is tolerably steep on each side except from the south, and with the Irish Sea on the north, and the rivers Mersey and Dee on the east and west sides respectively, there is nothing to obstruct or diminish the force of a passing storm. Self-recording anemometers of the Robinson and Osler types have been in position since 1867, and it is from the records of these instruments that these statistics have been prepared. How far these records are absolutely correct is beside the present question; all the data have been obtained with the same instruments, and are strictly comparable between themselves.

It has been the custom at the observatory to treat as storms or gales, all occasions in which the Robinson anemometer recorded the horizontal velocity of the atmosphere as equal to or exceeding fifty miles an hour. The total number of instances in the twenty-eight years under consideration is 321, or an average slightly below one a month. It will frequently happen in stormy periods that the critical velocity will be registered, and be followed by a partial lull in the storm, to be succeeded by gusts of greater force. If these periods of comparative calm have lasted for about twenty-four hours, the disturbance would count as two storms, although probably both are parts of the same atmospheric disturbance.

The greatest number recorded in a year is in 1868, when no less than twenty-eight gales were reported; and the least occurs in 1880, when there were only two, and these neither long in continuance nor great in violence. It is not without significance—though, of course, it is not intended to insist upon the coincidence—that when the number of storms is plotted as an ordinate with the time for abscissa, a rough curve can be drawn among them giving maxima at practically equal intervals of five years, from 1868, with minima at intermediate dates. Or, if we take the sums of the maximum years 1868, 1873, 1878, &c., it is found that in the six we have records of eighty-three storms; while in the six years of minimum, 1871, 1875, 1880, &c., we have only thirty-seven.

It is scarcely necessary to refer to the direction in which storms approach the observatory, after what has been said of its geographical position. Roughly, they are all from the west, with slight deflections to the north and south. As a matter of fact, only five have deviated from this rule, and they have been either east or south-east, and have been comparatively slight in their character.

The time scale on which the velocities have been registered is not a very open one. The recording drum moves through rather less than one inch in an hour, and the habit has been to read and record the distance travelled from the commencement of one hour to the beginning of the next. The maximum hourly velocity is, therefore, not to be understood as the greatest in any sixty consecutive minutes, but as the greatest in one whole hour as marked by the clock. In this sense the following table, which exhibits the number of times the greatest hourly velocity has exceeded noticeable amounts, is to be understood:—

Recorded hourly velocity in miles.	No. of instances.
50–60	220
60–70	68
70–80	21
80–90	10
Exceeding 90	2

Here again, curiously enough, we find some slight evidence in favour of a five-year period. Not only do the two instances of the greatest velocity recorded in the observatory occur in years already noticed as those of maximum disturbance, but the average velocity of all storms in the years 1868, 1873, &c., is 59·2 miles, as compared with 57·9 miles in the years of minimum number.

Intimately connected with velocity, though probably a less accurate measure of the true force of a storm, is the pressure recorded per square foot. Here Bidston has long held a record for the British Isles, having placed to its credit a pressure of ninety pounds on March 9, 1871. The accuracy of this measure has often been questioned, and probably it is too great owing to the momentum in the moving parts of the machinery, but it is certainly the record of a far greater pressure than has ever been witnessed since. Considering over what small areas these excessive pressures are exercised, and the great variation that exists from moment to moment in the velocity of the wind when a storm is raging, it is not an impossible amount, but it would certainly be misleading to conclude that such a pressure was a measure of the force of the wind a few feet, or even a few inches, away from the pressure-plate. The hourly velocity on the occasion when this pressure was registered has frequently been exceeded, without reproducing similar pressures. Herein is represented the great difficulty in determining a simple relation between pressure and velocity, or, rather, the square of the velocity; for one may regard Hutton's law of wind-pressure on a given obstructing surface as satisfactorily proved. The fact of such accidents as that referred to destroys any value that can be drawn from averages, but as a mere matter of figures, it appears that the average maximum hourly velocity for all storms is 58·4 miles, and the mean of the maximum pressures 37·6 lbs. This would require the factor for multiplying the square of the velocity in miles, to obtain the pressure per square foot, to be greater than one-tenth, which is evidently and necessarily erroneous, since we are comparing the accidental momentary pressure with the average velocity obtained throughout the entire hour. Taking the extreme pressures for what they are worth, the numbers come out as follows:—

Pressure in lbs. on sq. ft.	Number of instances.
20–30	132
30–40	111
40–50	50
50–60	11
60–70	12

On two occasions the pressure registered was greater than 70 lbs. to the square foot, and on three did not reach twenty. Since the extreme pressures are in a sense accidental, and do not represent with any accuracy the force of a storm, it does not seem desirable to determine the relative pressures in what have been called years of maximum and minimum storm occurrence. But the general features are again borne out. The explanation here is probably that the greater the number of storms the greater the chance of finding a high pressure. It seems more profitable to inquire what is the average length of a storm, how long may a violent disturbance be expected to last. This question is unfortunately complicated by the fact already alluded to, that a storm may subside for a few hours and then reappear with its original violence. If the interruption is only for an hour or two, as already explained, the depression is considered as one, but only those hours are counted in which the registered velocity exceeds fifty miles. There are only two instances in which this amount of violence has been maintained for thirty consecutive hours, viz. in February, 1868, and again last February. The total number of stormy hours in the twenty-eight years is 1732, giving an average of 5·4 hours for each storm. Our local disturbances are therefore not of long duration.

An examination of the dates when gusty weather is most prevalent, goes neither to substantiate the ancient myth of the equinoctial gales, nor to uphold the evil supremacy which has long been assigned to the winds of March. Since no attempt has been made to equalise the lengths of the months, February has been somewhat unfairly treated in the following table; but notwithstanding this handicap, it possesses the unenviable privilege of compressing within its shortened limits more tempestuous weather than any other month.

Month.	No. of storms.	No. of stormy hours.
January	47	260
February	42	281
March	47	238
April	14	63
May	7	27
June	3	19
July	7	21
August	17	65
September	16	77
October	26	180
November	44	254
December	51	247
Total	321	1732

Of course one would expect to find the greatest number of storms in the winter; but that three-fourths of the whole should be compressed within five months of the year, is a greater disproportion than was expected. The variations of the barometer during these storms, and the dependence of this variation upon the direction of the wind, are of considerable interest, but may not very well be entered upon here while treating simply of numerical statistics. WILLIAM E. PLUMMER.

Peculiarities of Psychical Research.

MR. DIXON asks in his first letter: Could an abnormal distribution of the cards affect the result, if certain precautions were taken? In his second letter he says there was nothing in his first letter to indicate that he under-estimated the importance of "abnormal distributions." Well and good, if the S.P.R. have not under-estimated the importance of examining the actual distribution of cards cut and of cards guessed, they will have kept a record of each card cut and each card guessed, card for card. If they have not done so, then their experiment is scientifically of no value; if they have done so, then the analysis of the distributions of the cards cut and the cards guessed ought to have accompanied any publication of these experiments. It is an obvious, but by *no means sufficient*, condition for a proper experiment. If the Secretary of the S.P.R. will place in my hands the actual analyses of the cards cut and the cards guessed made by a competent mathematician, *before* the publication in their *Proceedings* of the card guesses, and proving that they did at that time fully consider the point, and take this obvious precaution against deception, my estimation of the "scientific acumen" of the S.P.R. will at any rate on this point be modified.

I, of course, do not refer to my friend Prof. Edgeworth's investigations, which do not touch the question of the distributions of cards cut and cards guessed. KARL PEARSON.

MAY I call attention to Prof. Lodge's method of "silencing" me in your issue of January 10. It bears very closely upon this question of the effect of psychical research upon the investigator's reasoning. He quotes the preface of Mr. Podmore's book to show that that gentleman is not a "bigoted upholder of the certainty of telepathy," and the casual reader would scarcely guess that, in truth, I never asserted that he was. I complained of the very air of open-mindedness in that preface to which Prof. Lodge's quotation witnesses, and showed by an instance, that in the body of the book question-begging occurred which was all the more dangerous on account of the liberal tone of the opening portion. I made no objection to the individual prosecution of psychical research—only to its public recognition before it has produced more definite results than it has done so far. So much for the "silencing." It shows either that Prof. Lodge has not read my review, or that he has misunderstood it; and in either case it enforces my contention that these investigators are over-hasty. The phrase "irresponsible detractor," points in the same direction. H. G. WELLS.

The Suspended Animation of Snakes.

IN NATURE of December 6, p. 128, Mr. G. E. Hadow asks whether the snakes feign death for protective purposes, with intent to deceive, or whether the strange action is the result of a general nervous inhibition, produced reflexly by the action of fright, which would render it more or less analogous to a fainting fit. He and others of your readers will be interested in an additional observation that, in a measure, answers his question. The snake, a "hognose," "spreading adder," or "blowing viper," *Heterodon platyrhinus*, upon which Dr. L. C. Jones based his note in NATURE, November 29, p. 107, the origin of the discussion, was presented to me about five months ago. While in my possession it has repeatedly verified Dr. Jones's statements; and, besides, it has proved that it does not depend upon the feint alone. The latter is preceded by another action that apparently has not been published hitherto. After being teased a little, the animal, vigorously bending from side to side, the tail abruptly raised and the vent slightly protruded, begins to smear itself over the back with urine and excrement, the odour of which is so excessively nauseous that observers are quickly driven back, the better satisfied if they escape without a spatter in their faces. If the teasing stops with this, the victim glides away to hide; but if still more worried, it takes up the contortions that end in the trance-like condition, lasting ten minutes to half an hour, or until the creature feels that it may safely revive. The specimen still lives, and does not discard its filthy habit on prolonged acquaintance Much handling and familiarity with annoyance make little difference in behaviour, or in disposition to take advantage of the peculiar tactics. In the inception of the habits these actions most likely were due to terror; possibly the trance was a real faint; but, however their utility may have been discovered, it is evident at the present time that confidence in them as means of securing immunity from torment induces their practice on occasions when the existence of actual fright is hardly possible. At such times it would be difficult to convince witnesses that the snake is not intelligently employing what it knows to be its best methods of protection.

Cambridge, Mass., Dec. 27, 1894. S. GARMAN.

I DO not think that Mr. Vincent can be right in supposing that the suspended animation of grass snakes has nothing to do with simulation. I have never observed it in the case of a snake when unmolested in a glass case (as he has), though I have kept hundreds so, but noticed it first when catching snakes in the New Forest. After much struggling and the usual offensive methods of defence had proved vain, one has, in several instances, suddenly hung limp and apparently lifeless on my hand. It could hardly be a faint or anything but death-feigning, for as soon as I put it on the ground, or allowed it no longer to feel my hand, it recovered at once, and was off like a shot. I took particular pains to test this, as I was much surprised at the circumstance, which I did not remember having seen mentioned in any book. In all cases it was a *dernier ressort*, the ejection of food and the effusion of smell having preceded. W. KENNEDY.

"Finger-Print" Method.

IN my letter on the subject (NATURE, December 27, 1894, p. 199), I have introduced my assertion of the old Japanese usage of the "thumb-stamps" on legal papers, with a qualifying clause—"although at present I have no record to refer to." Continuing in my search, I have come across a passage which gives confirmation to the statement. It is in the *Fûzoku Gwahō*, No. 50, p. 6, Tōkyō, February 10, 1893, where the details of the bastinado inflicted on criminals during the *ancien régime* are given, and reads as follows:—"When the criminals' guilt was ascertained, and they signed with '*thumb-stamps*' on papers in the Court, they were sent to prison with the magistrate's words, 'Sentence shall follow,' which they used to understand as the signal of the approach of the day of punishment."

December 31, 1894. KUMAGUSU MINAKATA.

A White Rainbow.

THE white rainbow is so rare as to deserve noting. One was visible at Westnewton, Aspatria, for more than half an hour on Saturday, January 5. The band was much broader than in the ordinary bow, and the arc was formed in the upper intermediate cloud drift. This drift consisted of a light pallium of irregular cirro cumulus. It is important to observe that cumulus was forming, from above, at the time; *i.e.* the cirro cumulus was melting and descending into ordinary cumulus. A patch of this cumulus formed (under observation) and crossed beneath the bow. It then became coterminous with the western section of the arc, which blended with the cloud, and was of similar tint. Hard, dry frost continued and lasted till January 13. Barometer steady at time.

SAMUEL BARBER.

Westnewton, Aspatria, January 9.

P.S.—Connote with the above the condition of the weather on the Continent; also violent thunderstorms on following day in Cornwall; also snowstorms in Cumberland and Scotland within few days.—S. B.

AMERICAN TOPOGRAPHY.[1]

WE have it on the authority of Prof. Gannett that, at the present rate of progress, the series of topographical maps of the United States, which was commenced in 1882, will require no less than fifty years for completion, and that the cost of this great undertaking will not fall far short of twenty million dollars. The map is primarily intended to meet the needs of the geologists of the Survey; but it has been thought economical to make such arrangements that the resulting map may be adequate to serve all purposes for which general topographic maps are used. Its scope is limited to the representation of the larger natural features, and the artificial features which are of general or public interest, to the exclusion of those which are purely of a private character, and therefore liable to rapid changes.

In the vast area covered by the United States, there is a great diversity both of natural and cultural features, and the extent of the survey and the scales of the maps

[1] "United States Geological Survey. A Manual of Topographic Methods." By Henry Gannett, Chief Topographer. (Washington: Government Printing Office, 1893.)

are varied accordingly. The scales adopted at the commencement of the work were 1 : 62,500, 1 : 125,000, and 1 : 250,000; or very nearly 1, 2, and 4 miles to the inch respectively. With the progress of industrial development, the maps came to be in great demand in connection with all sorts of enterprises in which the nature of the ground required consideration, as in the projection of railways, water-works, drainages, and the like. Maps on a larger scale, and showing more detail, have in many instances become necessary, so that it has been determined to altogether discontinue the four miles to the inch map, but only to make new maps of the areas already represented on this scale in cases where they are specially required. It is believed that on the scales of one and two miles to the inch, it is possible to represent with faithfulness all necessary details.

The relief of the maps is represented by contours, or lines of equal elevation; in the larger scale maps the intervals range from 5 to 50 feet, and in the smaller ones from 10 to 100 feet, according to the nature of the area mapped. For the now discarded scale the intervals are from 200 to 250 feet.

The methods adopted in the preparation of these maps form the subject of the twenty-second monograph of the United States Geological Survey, which constitutes an excellent manual of topography. It is not intended as an elementary treatise on surveying, nor as a general treatise on topographic work, "although it may, to a certain extent, supply the existing need of such a work." It is primarily intended for the information of the men actually engaged upon the survey; but we believe that it will have a much larger field of usefulness.

We may look upon this manual as consisting of two essential parts: first, that dealing with the methods employed in the surveys; second, that giving a brief account of the origin of the various topographical features. The latter part we hope to refer to on another occasion, and for the present it is sufficient to say that its object is to act as a guide to correct delineation in filling in the details of the sketching.

A map, whatever its character, is defined as a sketch, corrected by locations. "The work of making locations is geometric, while that of sketching is artistic, and however numerous the locations may be, they form no part of the map itself, but serve only to correct the sketch, while the sketch supplies all the material for the map." Hence, the education of the topographer, as Prof. Gannett tells us, should consist of two parts, the mathematical and the artistic. "The first may be acquired from books, and this book knowledge must be supplemented by practice in the field. The second, if not inherited, can be acquired only by long experience in the field, and by many can be acquired only imperfectly. In fact, the sketching makes the map, and therefore, the sketching upon the Geological Survey is executed by the best topographer in the party, usually its chief, whenever practicable to do so."

In making a map, four principal operations are involved. (1) Astronomical observations for locating the map upon the earth's surface; (2) the horizontal location of points; (3) the measurement of heights; (4) the sketching of the map.

With regard to the methods now employed, "it is to be understood that they are not fixed, but are subject to change and development, and that this manual describes the stage of development reached at present." Five principal instruments have been employed in the Survey: theodolites of a powerful and compact form, for use in the primary triangulation; plane tables of the best type with telescopic alidades, for secondary triangulation and height measurements; plane tables of simple form with sighted alidades, used for traversing and minor triangulations; "odometers," for measuring distances; aneroids, for the measurement of details of heights.

All these instruments are described with sufficient fulness, while other instruments, such as transits, chains, tapes, and telemeters, which are commonly figured and described in all works on surveying, receive no special attention.

A single instrument of a very convenient form suffices for the astronomical determinations of position. This is a combined transit and zenith telescope, and consists of an ordinary transit instrument provided with a zenith micrometer eye-piece, and resting on a graduated circular base in such a way that the whole instrument can be made to revolve when using it as a zenith telescope. The telescope has an aperture of two and a half inches, and a focal length of twenty-seven inches. We are not acquainted with any other instrument so convenient for the double purpose of finding latitudes and longitudes with accuracy. Examples of the observations made with the instrument are given, and these, with the various steps in the reductions, form an admirable guide to the astronomical work.

Triangulation is employed in preference to primary traversing wherever the country presents sufficient relief for the purpose, as it is more accurate and cheaper. The initial step in this process is, of course, the measurement of a base line, and in our British survey this was accomplished by Colby's compensation bars. This method of measurement was also employed in the United States up to 1887, when it was decided to adopt a system of measurement by steel tapes. The tape in use has a length of 300 feet, and it is claimed that it is easy to obtain the required degree of accuracy in a far shorter time and at much less expense. A special apparatus for using this tape has been devised, and full instructions for its use and reduction to standard are given.

The description of the base-line measurement is naturally followed by hints as to the selection of stations and the erection of signals for triangulation. A very convenient form of observing tower, or combined instrument support and signal, for use when surrounding objects have to be overlooked, is figured and described. We learn that vernier theodolites have now been discarded in favour of others in which the circles are read by micrometer microscopes, although the circles are only 8 inches in diameter. An excellent and concise account is given of the various errors to which angular measurements are liable, and of the methods of eliminating them from the final results. Some of these errors are instrumental, others personal; and in this connection, Prof. Gannett remarks that, "after learning how to make good observations, the observer should place the utmost confidence in them, and never yield to the temptation of changing them because they disagree with some preceding observations. Such discrepancies are in general an indication of good, rather than poor, work."

In some districts it is almost impossible to carry on a triangulation, and in such cases primary traverse lines are resorted to, these simply differing from ordinary traverse lines in being more elaborately and carefully executed. These traverse lines, it may be said, consist of a series of measurements of distance and directions, and when they are intended to replace the triangulation, they are made with the steel tape, to which reference has already been made, and theodolites.

The account of the secondary triangulation is remarkable chiefly for the great prominence given to the plane table. Speaking of this, Prof. Gannett says that "much misapprehension exists, especially in this country [the United States], regarding the character and application of this instrument. This arises, apparently, from the fact that it is little known. For making a map the plane table is a universal instrument. It is applicable to all kinds of country, to all methods of work, and to all scales. For making a map it is the most simple, direct, and economic instrument; its use renders possible the making of the map directly from the country as copy, and renders unnecessary the making of elaborate notes, sketches, photographs, &c., which is not only more expensive, but produces inferior results." As the instrument is perhaps not widely known in our own country, we may say that it consists of a drawing-board mounted on a tripod in such a way that it can be levelled, turned in azimuth, and clamped in any position. At the centre of the board is pivoted the alidade, consisting of a ruler with a graduated bevelled edge, to which is attached a pair of sights for rough work, or a telescope for work of a higher class. A small graduated arc is provided in the better-class instrument for the measurement of vertical angles, but the horizontal directions are plotted directly, by means of the alidade, on a sheet of paper stretched on the board. The edge of the board is set in the same direction when the instrument is in use at different points in the area being mapped, and horizontal locations are thus readily determined by intersections.

The simple form of plane table is now exclusively used by the Survey for the ordinary traverse work. Distance measurements in this class of work are made in the usual way by counting the revolutions of a wheel, an "odometer" being used for this purpose.

The manual abounds in practical hints on the various points connected with surveying, and concludes with a brief account of the office work which is so important a supplement to work in the field.

The numerous appendices consist of tables to be used in the various computations, and are complete enough to include even a table of logarithms.

It is not too much to say that Prof. Gannett has produced a manual which will be of interest to many not actually engaged in surveying, while at the same time it forms a very valuable supplement to the ordinary works on the subject.

A. FOWLER.

LIFE AT THE ZOO.[1]

A SIGN of the increasing interest shown by the outside world in all questions concerning life, and more especially animal life, is evidenced by the far greater number of books published every year on popular natural history.

The past year witnessed the commencement of several large works, such as the "Royal Natural History," edited by Mr. Lydekker; the republication of "Jardine's Naturalists' Library," edited by Dr. R. B. Sharpe; and the "Cambridge Natural History," of which, so far, only one volume has appeared. Besides these there have been issued a number of smaller works, not extending over so wide a ground.

The present volume consists of a number of short articles on various natural history topics more or less directly connected with the Zoological Society's Gardens, illustrated with reproductions of some of Gambier Bolton's successful photographs of the animals found there. A considerable number of these sketches have already appeared before in the pages of the *Spectator*, but many chapters have been added, and the whole forms a very agreeable *repertoire* of gossip, with, in some cases, pretensions to higher things in the shape of accounts of experiments on the æsthetics of the animal world.

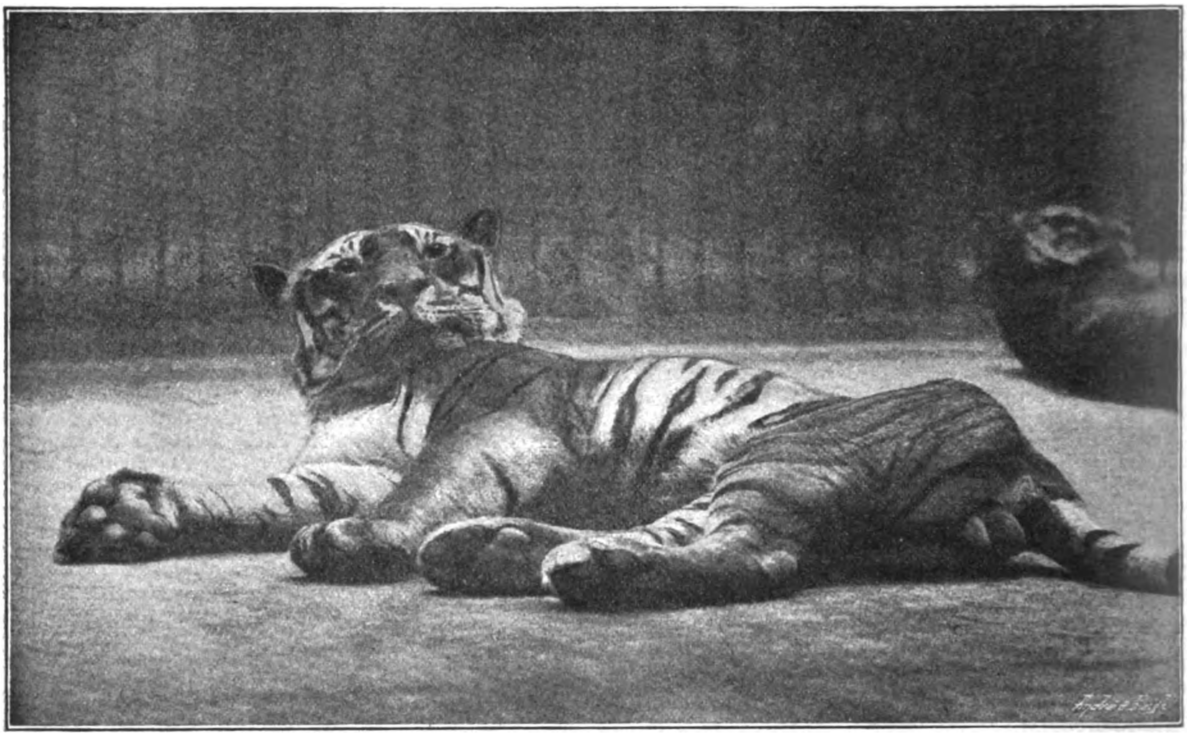

FIG. 1.—The Tiger listening to soft music.

One of the most interesting of the articles directly connected with the Zoo is that on "Elephant Life in England." The number of elephants now in Europe, chiefly in circuses and menageries, is considerable. Mr. Cornish gives it at about 120, of which England possesses about thirty-four. With some half-dozen exceptions, all these elephants belong to the Indian species, and are mostly imported from Burma, where they are bred in a half-wild state. The African elephant, according to our

[1] "Life at the Zoo. Notes and Traditions of the Regent's Park Gardens." By C. J. Cornish. 8vo. (London: Seeley and Co., 1895.)

author, does not appear to possess quite so even a temper or so docile a nature as the Indian species, but still, judging from what has been done with them in our Zoological Gardens, there seems to be no reason why they should not be caught and tamed exactly in the same manner as their Indian relatives. Indeed, a few years ago an officer, in the service of the German colony of East Africa, made a special tour in India for the purpose of investigating whether it would be possible to introduce the *keddah* system into East Africa. Whether this enterprise has ever come to anything, does not appear to have transpired. It is also known that the subject occupied the attention of General Gordon shortly before his death.

In an article on the Wild Cats of the Zoo, Mr. Cornish discusses the origin of our domestic tabby. Besides the European Wild Cat (*Felis catus*), which now appears to be increasing slightly in numbers in Scotland, owing, doubtless, to the increased reservation of so much of the area of that country for deer-forests, he suggests the Chaus Cat of India and Northern Africa as a possible ancestor of our domestic form. There are, however, two other species, which both seem in many respects to have greater claims. One of these is the Cat of North Africa (*Felis caffra* or *maniculata*), a species held in veneration by the ancient Egyptians, large quantities of the mummified remains of which have been imported to this country for manure. An argument in support of the opinion that this is the true ancestor of the domestic cat, is the fact that the sole of the hindfoot of this species, like that of most varieties of domestic cats, is black, and not spotted, as in the European Wild Cat (*Felis catus*).

Another possible candidate for the ancestry of the domestic cat is the Waved Cat (*Felis torquata*); this cat has been obtained in various parts of India, but is never very common. It resembles very closely the Indian domestic breed. It is, however, more than probable that whatever the origin of the domestic cat may have been, it has interbred with the wild cats of the various countries to which it has been conveyed by man. This has certainly been the case in India, where hybrids between the native domestic cats and both the Jungle Cat (*Felis chaus*) and the Leopard Cat (*Felis bengalensis*) are fairly well known.

A plea for the repeal of the absurd and oppressive Act of Parliament that prohibits the use of dogs for draught purposes, forms another short essay. This Act was based entirely on the *à priori* and ridiculous argument that dogs "were not created" for such a purpose. Mr. Cornish shows that on the Continent, where dogs are freely used in this way, no ill effects ensue to them, and that their employment is an enormous boon to the poorer classes, who are unable to afford horses.

Several chapters of this work are devoted to the inhabitants of the Reptile House at the Zoo, and among them is specially mentioned the Heloderm, the only known poisonous lizard in existence. A recent memoir by Dr. Shufeldt (*P.Z.S.* 1890, p. 148) has supplied a good deal of information respecting the anatomy of this lizard. The large poison glands are shown to lie on either side of the lower jaw, their ducts opening into the floor of the mouth, whence it is surmised that the poisonous secretion finds its way along the grooved teeth of the mandible to the inflicted wound. It is a curious fact that although some of the teeth of the upper jaw of this Lizard are also grooved, no trace of any poison gland has been found here. An interesting account of the effects of the bite of the Heloderm on the human subject has been already recorded in our pages (NATURE, vol. xxvii. p. 154), and it has been shown that its effects on man, though painful at the time, are not of a serious nature.

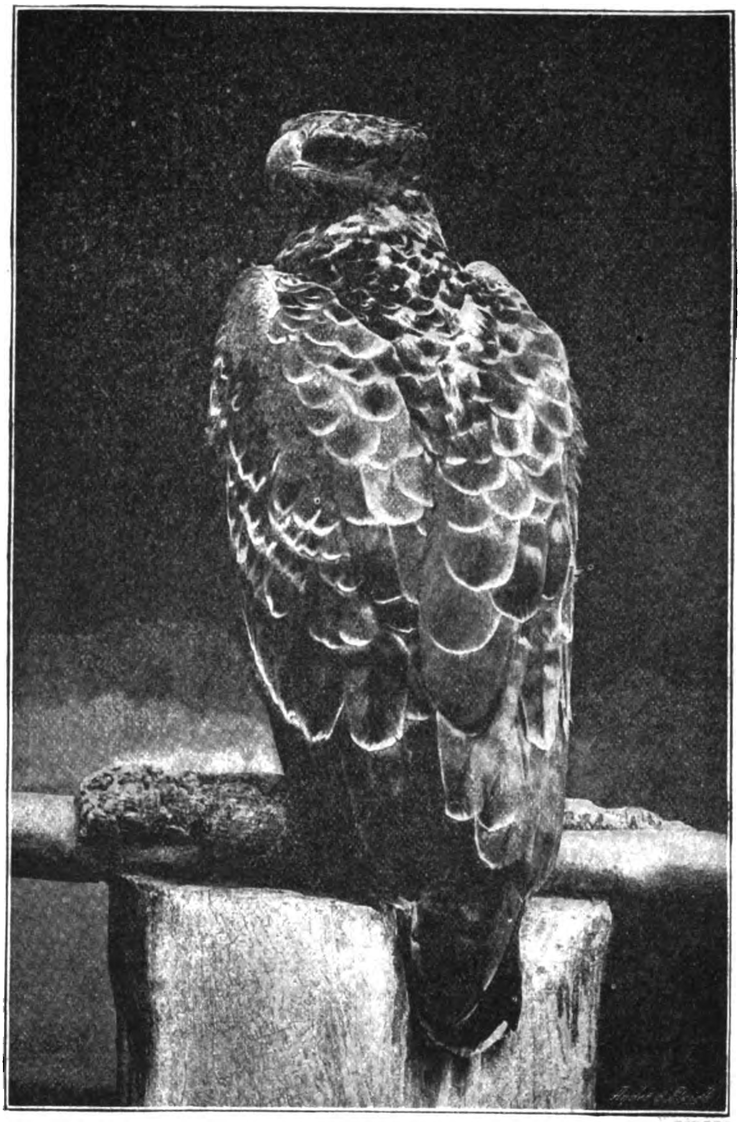

FIG. 2.—The Martial Hawk Eagle.

One of the very few statements in this work with which we are unable to agree, is to be found in the account of the diving birds at the Zoo. With regard to the Penguin, Mr. Cornish says: "It cannot fly in the air; it cannot walk, but hops as if its feet were tied together; it cannot even swim." If Mr. Cornish will turn to the account of the expedition of the Dundee whalers to the Antarctic Seas, given in the *Scottish*

Geographical Magazine for February 1894, he will find the following passage: "On one occasion, in the north of the Erebus-and-Terror Gulf, we saw large schools, numbering 300 to 500, of the common black-throated Penguin, swimming together; the movements of each school being controlled by a single individual of larger size, which followed in the rear." It is quite possible that this error may have arisen through the fact that, as a rule, the Penguins, when allowed, in the Zoological Gardens, to enter their tank, dive straight off the board leading into the water, and remain under water until all the fishes in the tank are caught and devoured. After that they usually betake themselves straight back to the board. But that they can swim duck fashion, when they wish to do so, admits of no doubt whatever.

The volume is illustrated by a series of Gambier Bolton's photographs, which are certainly the best ever taken of "Life at the Zoo." Of these we are kindly permitted to reproduce two. One of them represents the Tiger "listening to soft music," and forms part of a series made to illustrate "Æsthetics at the Zoo." The other shows the Martial Hawk Eagle, a rather rare bird from South Africa. On the whole, we can cordially recommend this volume for readers of the lighter literature of Natural History, and even as containing a certain amount of novel information on "Life at the Zoo."

INTERCOLONIAL ASTRONOMY AND METEOROLOGY.

WE learn from Mr. R. L. J. Ellery, F.R.S, that a conference representing the three colonies of New South Wales, South Australia, and Victoria, met at the Observatory, Melbourne, on October 29. Mr. H. C. Russell, F.R.S., from Sydney, and Sir Charles Todd, F.R.S., from Adelaide, were present.

(1) As regards Australian standard time, it was resolved to advise the respective Governments to adopt for that purpose the time of the meridian of 150° E.

It was also agreed to advise that the changes from one hour zone to another shall take place at the eastern and western boundaries of the several colonies.

(2) A proposal, by Sir C. Todd, was adopted to the effect that the three observatories should co-operate in a special series of observations for determination of co-latitude, and for testing the applicability of the present refraction tables to astronomical work at the various observatories.

(3) It was resolved, at Mr. Russell's suggestion, to carry out systematic cloud photography at each observatory, as an aid to weather forecasting.

(4) As to agricultural forecasts, it was agreed to: "That in each of the colonies represented a forecast of the weather shall be sent to all the principal telegraph stations each day, except Sunday (Saturday's forecast being for 48 hours), and that forms to contain a week's forecasts be used, which it is proposed shall be posted on a special board at the station receiving forecasts."

(5) It was resolved that the storm signals to be used be the same as used in England.

(6) On the suggestion of Mr. Russell, it was agreed that further determination of the differences of longitude of Adelaide, Melbourne, and Sydney, should be carried out, and that periods when there was high atmospheric pressure at one place, and low at another, be selected for the operations, with the view of ascertaining if large differences of atmospheric pressure between the eastern and western stations had any influence on the longitude results. Mr. Russell undertook to draw up a programme for this undertaking.

NOTES.

ENGLISH geologists will be gratified to learn that the veteran Prof. Prestwich has been elected a Vice-President of the Geological Society of France. It is, we believe, the second time only that this honour has been conferred on one who was not a French subject. The Council of the Geological Society of London has formally offered to Prof. Prestwich its congratulations on the distinction thus received.

M. MASCART has succeeded M. Tisserand as President of the Paris Société d'Encouragement.

THE death is announced of Prof. Karl v. Haushofer, Director of the Technische Hochschule at Munich, and Professor of Mineralogy in the University of that city.

DR. G. M. DAWSON, C.M.G., F.R.S., has been appointed Director of the Geographical Survey of Canada, in succession to Dr. A. R. C. Selwyn, who has been superannuated.

WE regret to note that the Duke of Argyll was attacked by sudden indisposition while addressing a meeting at Glasgow on Tuesday evening. His condition at first gave rise to serious concern, and it was not till a late hour that he recovered sufficiently to be conveyed to the residence of Lord Kelvin, where he is staying.

AT Fishmongers' Hall, this evening, the Marquis of Lorne will present the prizes and certificates obtained by students in connection with the City and Guilds of London Institute.

THE twenty-second annual dinner of the old students of the Royal School of Mines will be held on Friday, January 25, at the Criterion Restaurant. A number of distinguished visitors are expected to be present, and arrangements have been made for a large gathering of associates and old students.

THE annual meeting of the People's Palace Chemical Society will be held on Thursday, January 24, when Dr. T. E. Thorpe, F.R.S., will give an address on "Some causes and conditions of chemical change." The chair will be taken by Prof. Tilden at 8 p.m. Tickets may be obtained by application to the hon. sec., Mr. Thomas Yetton.

THE Association for the Improvement of Geometrical Teaching will hold a general meeting at University College, Gower Street, next Saturday. In the morning, the report of the council will be read, and the new officers will be proposed for election. During the day, papers will be read on "Algebra in Schools," "The Association's Syllabus of Geometrical Conics," "The Conics of Apollonius," and "Notes on Mensuration."

THE forty-eighth annual general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, January 31, and Friday evening, February 1. The annual report of the Council will then be presented, and the election of the President, Vice-Presidents, and Members of Council will take place. The following papers will also be read and discussed, as far as time permits:—"The Determination of the Dryness of Steam," by Prof. W. Cawthorne Unwin, F.R.S.; "Comparison between Governing by Throttling and by Variable Expansion," by Captain H. Riall Sankey.

THE freshwater biological station, which was established at Plön three years ago through the efforts of Dr. Otto Zacharias, seems to be assuming quite an international character. From a recent report of the director, we learn that nine investigators worked at the station during the summer semester of last year, and of these four were German, two English, two French, and one Russian. Much interesting work seems to have been accomplished, the results of which have been partially published in the *Forschungsberichte* of the station, while others are already in the press.

THE death of Mr. Thomas Andrews at Guildford (says the *Times*) removes one of the best-known and most successful pisciculturists of the day. His breeding ponds at Haslemere, on the borders of Surrey and Hants, are perhaps, next to Sir James Maitland's famous establishment at Howietown, near Stirling, the most important trout-rearing fishery in the kingdom. The series of ponds are picturesquely situated on the side of a hill, and were all planned under the immediate direction of the late owner, who was a keen observer and an enthusiastic naturalist. They afforded every facility for studying the various points in connection with the artificial cultivation of trout. Mr. Andrews had brought this particular branch of pisciculture (to which he had devoted many years of his life) to a very high state of perfection. The distribution of ova and fish from the Surrey ponds was not merely confined to our home waters. At various times consignments were despatched to foreign countries, Ceylon, Buenos Ayres, Mauritius, and elsewhere. Mr. Andrews contributed many important papers on fishery matters to various periodicals.

THE St. Petersburg Academy of Sciences has recently made some changes in the system of publishing papers communicated to it. In September 1894, it commenced the publication of a monthly number, under the title *Bulletin de l'Académie Impériale des Sciences*, which serves as the organ of the three classes of the Academy. This *Bulletin* is intended to include the *procès-verbaux* of the meetings, annual reports on scientific researches, reports on prizes conferred by the Academy, notes on the work of the museums, &c. In addition to notices of this kind, the *Bulletin* will contain short scientific papers. The *Mémoires de l'Académie Impériale des Sciences* will form in future the second means of publication. It will be divided into two independent series, dealing respectively with the physico-mathematical section of the Academy's papers, and the historical and philological section. The publication of the *Mélanges, tirés du Bulletin*, has been discontinued.

SOME very low temperatures were reported to the Meteorological Office during the recent frost. At Braemar, in the east of Scotland, the sheltered thermometer fell below zero on four consecutive days, the lowest value being $-5°$ on the 9th instant. At Hillington, in the east of England, the lowest reading was 2° on the 12th instant; in other districts the minima varied considerably, being 8° or 9° in the north of Scotland and the north-east and midland parts of England. This severe weather came to a sudden termination on the night of the 12th–13th instant, owing to the approach of a serious disturbance from the Atlantic, which arrived off the Irish coast on Saturday, and remained comparatively stationary during Sunday and Monday. Strong easterly gales were experienced on the Scotch coasts, and very strong winds in other places. The gale was accompanied by a very high sea on our north and east coasts, and, as usual with easterly gales, many shipping casualties occurred.

WE learn from an article in *Das Wetter*, that a permanent meteorological station has been established by the Danish authorities at Angmagsalik, on the east coast of Greenland (Lat. 65° 37′ N., Long. 37° 16′ W.), and has been provided with self-recording instruments, in addition to the usual ones. This station will be of much importance, as it forms a link between those on the west coast of Greenland and the stations in Iceland, and as it is between Iceland and Greenland that the centre of the Icelandic barometric low-pressure lies, the varying position of which exercises a great influence on the weather conditions of Europe. It is known, from a year's observations made there by Holm ten years ago, that the climate is very rough and stormy; during the year in question the mean temperature was 5° below the freezing point, while the minimum reached $-13°$ of Fahrenheit's scale. Meteorologists may well be grateful to men who have undertaken to make observations in a place where, in all probability, they will be cut off from all other human intercourse for some years. Dr Nansen only succeeded, after considerable difficulty, in reaching Lat. 63½° along this coast in the year 1888.

IT will be news to most people that dealers in drugs, both wholesale and retail, cannot legally use kilogramme weights, or any of the metric system of weights and measures, for the export trade, though orders received from continental countries are given in that system. A short draft Bill has been prepared to amend the law, and will be presented to Parliament in the coming session. The chief clause reads as follows:—"That, on and after the passing of this Act, wherever the word 'trade' occurs in the Weights and Measures Acts of 1878 and 1889, it shall be so construed as not to prohibit or penalise the use of metric weights and measures, verified by the Board of Trade or local authorities, by export traders." The Acts of 1876 and 1889 have been disregarded by many traders, but the London County Council having recently intimated that they must enforce the law, the passing of an amendment such as that proposed has become necessary.

ON Tuesday, January 8, a paper was read before the Anthropological Institute, on the Samoyad race, by Mr. Arthur Montefiore. After dealing in some detail with the geographical distribution of the various branches of the Samoyads, Mr. Montefiore proceeded to give evidence of their affinity with the Finns, and, following Castrèn, placed them in the group which that authority called Ural-Altaic. The evidence consisted partly of physical measurements and characteristics, partly of similarity in ideas, habits and customs, and partly of identity in language. It was shown in the course of the paper that the language of the Samoyads is highly agglutinative and so inflectional as to form a link, as it were, between the Mongol and Indo-Germanic groups. After dealing with the myths and conceptions of deity held by this curious race, Mr. Montefiore read a number of notes made by Mr. Frederick G. Jackson (the leader of the Jackson-Harmsworth Polar expedition) during his sojourn among the Samoyads in the autumn and winter of 1893-94, and his subsequent journey across the Great Tundra between the Kara Sea and the Pechora River. Mr. Jackson's notes were very full, and contained some remarkable evidence of the completeness with which the Samoyad has adapted himself to the rigorous requirements of his environment. A number of Samoyad implements and other articles (including a highly curious Samoyad doll and some calculating sticks) were exhibited, together with a series of lantern slides from photographs, which are necessarily new to English students of anthropology.

DOES atmospheric dust exercise any perceptible influence on the intensity of the sun's rays transmitted through it? is the question which Prof. A. Bartoli answers in the *Nuovo Cimento*. He studied the effect of different thicknesses of air upon the sun's heat by measuring the heating power of the sun at various altitudes with the pyrheliometer, after the great eruption of Etna in July 1892. On July 25, the air was filled with an impalpable dust, which fell very gently, and gave to the sun a slight reddish tinge. There were no clouds, and there was a dead calm. By comparing the absorptive influence of the air under these conditions with that in a clear atmosphere, Prof. Bartoli found that 28 per cent. of the heat transmitted by the pure air was intercepted by the volcanic dust.

A FURTHER instalment of M. Raoul Pictet's fascinating experiments at very low temperatures is published in the *Comptes rendus*. The object of the experiments was to test the power of cotton-wool and other bad conductors to prevent the passage of low-temperature radiation. Copper cylinders were cooled down to – 170° C. and packed in layers of cotton-wool of various thicknesses. It was found that the cylinders rose to about – 80° very rapidly, and that the rate of warming was the same whether the cylinders were naked or packed in cotton-wool of 20 inches thick. The "bad conductor" behaved, in fact, like a perfect conductor transparent to heat radiation. Above – 80° the influence of the packing began to make itself felt, the rate of warming varying with the thickness of the layer.

IN the current number of *Natural Science*, Captain Marshall-Hall urges the importance of a fuller study of existing glaciers, as the necessary basis for any attempt at setting in order the chaos of opinion on the nature and causes of the Glacial period. He gives an account of the steps recently taken by the Alpine Club and the Glacier Committee of the International Geological Congress towards drawing up a systematic statement of the methods of observation, for the use of those who can visit and examine modern glaciers in any part of the world. For fuller details, readers are referred to papers in the *Alpine Journal* (February 1891, and November 1894); but a number of subjects for careful observation are suggested, and some necessary precautions mentioned. It is very satisfactory to see that the members of the Alpine Club, if primarily climbers, are able incidentally to do useful service to Geology.

IN the last number of the *Records* of the Geological Survey of India, Dr. Noetling announces an interesting discovery from Baluchistán. Certain beds which Mr. Oldham had recently described as intermediate between Cretaceous and Tertiary he finds really belong to the *Danian*—a stage to which the English chalk nowhere reaches (except perhaps in Norfolk), but which forms the summit of the Cretaceous in various parts of Europe. In examining the Echinoids from the Baluchistán beds, Dr. Noetling found a striking resemblance to those from the Danian beds in the Pyrenees. That the Pyrenean fauna should resemble that of such a distant region more than the nearer ones of Northern Europe, is another of the many pieces of evidence of ancient life-provinces—not improbably climatic in this case—that accumulate as geological research is extended into distant parts of the world. It must be coupled with the further fact that the Baluchistán Echinoids have little in common with those of the same age in Southern India.

THE last number of the *Comptes rendus* contains a paper by R. Colson, on the conditions which have to be fulfilled in order to obtain correct results when measuring liquid resistances with alternating currents and a telephone. The author, while working on the propagation of electrical waves of slow period, obtained results which have an important bearing on the above method of measuring liquid resistances. The results obtained depend on the supposition that, even in the case of alternating currents in liquid resistances, Ohm's law holds. However, this law does not hold good in the case of the propagation of waves of high potential, such as are furnished by the secondary of an induction coil in high resistances, such as threads saturated with a solution of calcium chloride, or capillary tubes filled with water. The author gives a series of tests which, when applied to any given arrangement of conductors, will show whether the above effects will have any influence on the result.

MR. B. D. PEIRCE has contributed a paper to the *American Journal of Science* (vol. xlviii. p. 312), on the thermo-electric properties of platinoid and manganine. Since platinoid and manganine wires are often used in potentiometers and slide wire Wheatstone's Bridges, the thermo-electric properties of these metals are of considerable interest. The author has primarily determined the electromotive force of the above metals and copper, since this is the most interesting case from a practical point of view. He finds that after the manganine wire has been well annealed, the thermo-electric phenomena are quite regular. While the mean electromotive force for a difference of 10° C. between the hot and cold junctions of a copper manganine couple is about 5·5 microvolts, in the case of a platinoid-copper couple the mean electromotive force for the same difference of temperature is about 170 microvolts. Incidentally the author has examined the thermo-electromotive force of couples consisting of different samples of commercial copper, and he finds that two specimens of annealed copper wire bought from different makers hardly ever yielded more than one or two C.G.S. units of E.M.F. per degree Centigrade.

A FEW particulars concerning the earthquake felt in Nicaragua and Honduras in November 1894, have been sent to us from Managua, by Mr. J. Crawford. Shocks were felt for twenty seconds at Managua, about 9h. 36m., and another series, lasting about thirty seconds, at eleven in the evening of November 19. Mr. Crawford has been able to trace the course of the waves for about 120 miles to the north-west and south-east of the city. At Managua, the undulations were short and rapid; they were stronger at the city of Masaya—twelve miles to the eastward, and still stronger at Granada—about twenty-four miles eastward. In the latter place, houses were thrown down by the vibrations, and also at Chinandega—seventy miles west of Managua, though at Managua itself the shocks were not of sufficient severity to fracture any of the walls of the houses, or displace any of the tiles on the roofs. It is remarkable that the earthquakes were most violent both east and west of the city.

MR. J. C. SHENSTONE has taken a census of remarkable oak trees in Essex, and he gives, in the *Essex Naturalist*, descriptions and illustrations of noteworthy specimens found by him; together with notes on a few oak trees outside the county The five trees with the largest trunks in Great Britain, stated in "Loudon's Arboretum," are: Cowthorpe Oak, Yorkshire, 78 feet; Merton Oak, Norfolk, 63 feet; Hempstead Oak, Essex, 53 feet; Grimstone Oak, Surrey, 48 feet; Salsey Oak, Northampton, 46 feet. Among trees having the widest stretch of boughs, are the Worksop Oak, 180 feet; and the Oakley Oak, 110 feet. All these trees are not, however, standing at the present time. The Hempstead Oak fell about twenty-five years ago, and a mutilated and decayed trunk is all that remains of this forest giant. A fine tree, thirty-one feet in circumference, exists in the park at Danbury Palace. The inside of the bole was completely burnt out more than sixty years ago, but the tree has continued to grow, and will probably yet survive many years. Several of the trees mentioned are said to be from five hundred to a thousand years old, but there is not sufficient evidence to decide the point at all accurately.

BRITISH ornithologists have long been aware that the increase and extension of range of the starling presents some interesting and phenomenal facts. They will therefore follow with interest a paper on the increase and distribution of the bird in Scotland, contributed by Mr. J. A. Harvie-Brown to the *Annals of Scottish Natural History* for January. By looking up old records dating back to the end of last century, and by collecting information through a special circular, it has been possible to give a consecutive statement of the steps of advance. The account, and the map accompanying it, show that, as regards Scotland, the starling is almost omnipresent. The statistics indicate "that two great centres of habitation have influenced the dispersal of the species: an earlier one in the Shetlands, Orkney, and the Outer Hebrides, and north coasts and north-east of Caithness, from north-east towards south-west; and a later one, entering Scotland in the south and passing north through the south and central districts of Scotland. Moray appears to have drawn its supplies from the northward, in comparatively recent years; but the districts to the south of the Grampians mostly, if not entirely, from the southwards. . . . It might not, perhaps, be too rash to predict that the day may yet arrive when the starling having increased still more prodigiously, and every crevice and cranny having become populated by these cosmopolites, a great struggle for existence even amongst themselves may become necessary to preserve the balance of nature. Before this can take place, however, the probability exists that some other weaker species may have to go to the wall. Indeed, there are already indications of such a fact in at least one instance and locality—by sheer force of numbers."

IN the eighth annual report of the Liverpool Marine Biology Committee, edited by Prof. Herdman, there is an interesting account of the work carried on during the past year at the biological station at Port Erin. A number of important additions to the fauna already known in that neighbourhood are recorded, including *Dicoryne conferta*, *Crisia ramosa*, *Amphicodon fritillaria*, and some forms of Copepoda new to science, *Pseudocyclopia stephoides* and several species of the genus *Ectinosoma*. Many observations have been made on the submarine deposits of the Irish Sea, and a preliminary general account is given in the report. The bottom, down to the depth of 10 fathoms, is chiefly covered with sand; at a greater depth, between 10 and 20 fathoms, there is a large admixture of mud; from 20 to 50 fathoms the bottom deposits are greatly varied, and here the richest fauna occurs; below 50 fathoms is found a bluish-grey tenacious mud, with a peculiar and characteristic fauna. Prof. Herdman very justly points out the importance of a thorough investigation of the submarine deposits round our coast; he regards the nature of these deposits as probably the most important of the various factors that determine the distribution of animals over the sea-bottom within one zoological area. "In practically the same water, identical in temperature, salinity, and transparency, at the same depth, with, so far as one can see, all the other surrounding conditions the same, the fauna varies from place to place with changes in the bottom—mud, sand, nullipores, and shell-beds, all have their characteristic assemblages of animals." The concluding part of the report contains a short account of a plan for the distribution of drift-bottles in order to obtain information with regard to the currents in the Irish Sea which affect small floating bodies; this experiment is based upon the plan employed by Prince Monaco in the Atlantic a few years ago. The observations made on the course of the drift-bottles up to the present have already been described in our columns by Prof. Herdman (NATURE, December 13, 1894, p. 151).

WITH the January *Journal* of the Chemical Society, we have received a supplementary number, containing title-pages, contents, and indexes of volumes lxv. and lxvi. (parts i. and ii.) of the *Journal*.

THE resolutions accepted by the International Congress of Hygiene and Demography, held at Budapest in September last, have just been published in the form of a pamphlet. They are printed in four languages—Hungarian, French, German, and English.

THE first part of a new catalogue of entomological works offered for sale, has been issued by R. Friedländer and Son, Berlin. The list, which is No. 416 of the "Bücher-Verzeichniss," published by Friedländer, is devoted to fossil insects, Coleoptera, and miscellaneous works on entomology.

WE regret to announce that, owing to the death of Father Denza, the publication of the *Bollettino Mensuale*, issued by the Moncalieri Observatory for the last fourteen years, is to be discontinued, and that the Italian Meteorological Society is to be dissolved. We hope that some other pioneer of Italian meteorology will take up the good work left by Father Denza.

THE publication of "The Cambridge Natural History" will shortly be commenced by Messrs. Macmillan and Co. The first volume to appear will contain "Molluscs," by the Rev. A. H. Cooke; "Brachiopods (Recent)," by Mr. A. E. Shipley; and "Brachiopods (Fossil)," by Mr. F. R. C. Reed. This will be followed, in the course of a few months, by two other volumes in the same series, on "Insects," by Dr. David Sharp, F.R.S. The whole series, which will include ten volumes, fully illustrated, is intended, in the first instance, for those who have not had any special scientific training; but an attempt will be made to combine popular treatment and popular language with the most modern results of scientific research.

REFERRING to the announcement that ten Surinam water-toads had been received at the Zoological Society's Gardens (NATURE, p. 85), Dr. C. Kerbert, the Director of the Koninklijk Zoölogisch Genootschap, informs us that a number of these interesting animals were received at Amsterdam in October 1893, and are still living.

THE Royal Horticultural Society has been established for ninety years, and there are at present three thousand Fellows on its roll. It works in various ways "for the improvement of horticulture in all its branches, ornamental as well as useful." The *Journal* of the Society usually contains much valuable information on scientific and practical gardening. In the January issue, there are a number of papers read at a conference on trees, and others read at a conference on British-grown fruit. Perhaps the most important section of the Society is the strong Scientific Committee appointed to examine and report upon instances, submitted by the Fellows, of diseases and injuries of plants, caused by insects or otherwise. The Committee give their advice on all matters connected with the prevention or cure of disease, and are glad to receive specimens of malformation, or other subjects of horticultural or botanical interest.

A DEFINITE and trustworthy answer appears at last to be given to the long-standing question of the closely approximating atomic weights of nickel and cobalt, in a communication from Prof. Winkler to the *Zeitschrift für Anorganische Chemie*. The great difficulty in deciding the actual values of the atomic constants of these interesting metals has been largely owing to the fact that the methods of analysis hitherto adopted have not been free from all source of error. During the last few years, however, very considerable progress has been made in the chemistry of the compounds of nickel and cobalt, and the sources of error are now more correctly appreciated, and consequently more amenable to elimination. It is inconceivable, in the light of the ample verification which the periodic generalisation associated with the names of Newlands and Mendeléeff has received since its inception, by the subsequent accumulation of experimental facts, that the atoms of nickel and cobalt can both be endowed with the same relative weight, as was for so long supposed to be the case. A short time ago, Prof. Winkler carried out a series of analyses of the chlorides, prepared from the electrolytically deposited metals, and obtained the numbers Ni = 58·90 and Co = 59·67. Having, however, still some doubts as to the absolute accuracy of the decimal places, owing to the possibility of a minute source of error in the preparation of pure neutral chlorides, another series of experiments have been carried out by a method which Prof. Winkler states is in his opinion (and there can be none higher as regards work with the two metals in question) quite unimpeachable. The older methods based upon the electrolytic determination of the metals were found to lead to an error in the case of cobalt, owing to the fact that a small quantity of the hydrated oxide $Co_2O_3 \cdot 2H_2O$ is contained in the deposit upon the platinum electrode, while in the case of nickel no oxidation whatever occurs. This discovery was consequent upon another, namely, that a solution of iodine in potassium iodide of decinormal strength is capable of instantly dissolving the deposited metal from the platinum terminal without in the slightest attacking the latter, producing a solution of the iodide of the metal. In the case of nickel the platinum is left perfectly clean, while deposited cobalt invariably leaves a stain due to about half per cent. of oxide. The electrolytically-deposited cobalt employed by Prof. Winkler was therefore all reduced in pure hydrogen before use; when subsequently dissolved in the iodine solution, no trace of oxide was ever left. The method of analysis consisted in determining, by titration with pure sodium thiosulphate, the excess of iodine left after solution of the pure metals to form the iodides. Two complete series of analyses, each consisting of a considerable number of individual determinations, were carried out with an interval of some months, in order to employ metals from totally independent mineral deposits. The results are most concordant, and lead to the final numbers, Ni = 58·72 and Co = 59·37, when H = 1 and I = 126·53. The atomic weight of cobalt must therefore be accepted as at least half a unit higher than that of nickel, a result likewise in accordance with the work of Prof. Winkler published a short time ago.

OUR ASTRONOMICAL COLUMN.

δ CEPHEI.—Further particulars of Dr. Belopolsky's spectroscopic study of this variable star (NATURE, November 1, 1894, p. 21) are given in the *Bulletin* of the St. Petersburg Academy of Sciences, November, 1894, and some of his numerical results are slightly changed. He has shown for the first time that orbital movement is as closely associated with this class of short-period variable stars as with those of the Algol class, in which the minima are produced by eclipses. Although the spectrum of δ Cephei is described as of Vogel's Class II.*a*, it is pointed out that it differs from that of the sun in many respects, some of the lines which are narrow and feeble in the sun being strong in the star, and *vice versa*. There does not appear to be any change in the character of the spectrum, other than a variation of intensity, as the light of the star changes.

The displacements of the lines with respect to the comparison spectra of iron and hydrogen indicate that the star has an orbital movement in a period corresponding to that of the light changes (5d. 9h.), and that the eccentricity of the orbit is 0·514. The form of the curve of velocities which is given, indicates that the major axis of the orbit must be very nearly directed towards the earth, and the system is approaching the earth with a velocity of about 12 English miles per second. With reference to the centre of movement, the maximum velocities of approach and recession are about 13 English miles per second; the star is receding for about a day after minimum, approaching for nearly 3 days more, and receding until minimum again. Periastron is the point of the orbit farthest removed from us, and is passed about a day after minimum.

The apparent semi axis major is about 818,800 English miles, so that the whole orbit is less than twice the sun's diameter. We are not aware that any attempt has been made to determine the parallax of the star, but unless it has a very high emissive power, its small size would indicate that it must be relatively near to us.

Notwithstanding that the time of a possible eclipse is a day after the minimum of the light curve, Dr. Belopolsky seems to be of opinion that the variation may be due to eclipsing. He appears to believe that further work may show that there is some systematic error, and that periastron may really coincide with the minimum. As the light changes appear to be going on continuously throughout the period, it is clear that the eclipsing cannot be of the simple kind with which we are familiar in the case of Algol.

THE VATICAN OBSERVATORY.—A day after the death of Father Denza, we received the fourth volume of the "Pubblicazioni della Specola Vaticana." Every annual report of the work done at the Vatican Observatory is more voluminous than the one preceding it. The volume which came to us last month, and to which Father Denza's death gives a melancholy interest, runs into more than six hundred pages, and is illustrated by forty-two plates. Among these are illustrations of the Dumb-bell nebula in Vulpecula, the Pleiades nebula, the Orion nebula after exposures of thirty minutes and of nine hours, two photographs of the eclipse of April 1893, a photograph of the sun with the big spot of August 1893, together with two enlarged pictures of the spot, and a map showing the direction of motion of the meteors observed on August 10–11 of the same year. Papers on the subjects of the illustrations make up the greater part of the astronomical section of the report. Altogether, ten photographs were taken at Rome during the eclipse of April 1893, and contact observations were also made. The numerous meteor observations made under Father Denza's direction in Italy, in August and November 1893, are catalogued and commented upon. It is to be hoped that the system of meteor-observation which the late Director instituted will not be allowed to lapse. In celestial photography we note that in addition to the work for the photographic chart and catalogue, 248 photographs were taken of various celestial objects, 150 being photographs of the sun. But the astronomical results by no means represent the total work carried out at the observatory. Meteorology and terrestrial physics come in for a large share of attention. To us it seems that the only thing wanting to make the Vatican Observatory a true astro-physical observatory is a section for spectroscopic investigations.

Many astronomers will be interested to know that a full and appreciative notice of Father Denza's life and work has been written by P. Armani, of the Collegio dei S.S. Biagio e Carlo. Another full notice appeared in *Cosmos* of December 22.

AN INDISPENSABLE ANNUAIRE.—This year is the centenary of the creation of the Bureau des Longitudes, the invaluable *Annuaire* of which has been received for 1895. It is quite unnecessary to remind astronomers of the merits of this veritable *vade mecum*, for they know its usefulness better perhaps than workers in the other branches of physical science to which it appeals. A few changes have been made since the previous issue. M. Berthelot has completely revised and corrected the tables relating to thermo-chemistry. M. Moureaux has inserted in the tables of the magnetic elements in France, the values determined directly by him in 1894, at nearly six hundred places. Prof. Glasenapp has added five new stars to his table of the elements of the orbits of double stars. The list of comets has been brought up to the end of 1893, and that of minor planets up to November 1894. There are five articles in the volume, the subjects and authors being: Lunar atmospheric waves, by M. Bouquet de la Grye; the Geodetic Congress at Innsbruck, by M. Tisserand; the Observatory on Mont Blanc, by M. Janssen; photographic photometry, by the same author; and a report on the proposition to unify the astronomical and civil days, by M. Poincaré (see the next note).

THE UNIFICATION OF CIVIL AND ASTRONOMICAL DAYS.—It will be remembered that in 1893, the Astronomical and Physical Society of Toronto invited replies from astronomers to the question: "Is it desirable, all interests considered, that on and after the first day of January 1901, the Astronomical Day should everywhere begin at mean midnight?" The result of the voting was noted in NATURE, April 5, 1894, p. 542; and to this may now be added the following resolution adopted by the Bureau des Longitudes upon the question (*Annuaire* for 1895):—"The Bureau des Longitudes is favourable, in principle, to the reform proposed by the Canadian Institute to change the time from which to reckon the astronomical day. The Bureau thinks that this reform, as has been observed by the Lords of the Admiralty, will be of little avail unless an understanding is come to between the Governments publishing the principal ephemerides. Finally, considering that the unification will not really be complete until the civil hour is reckoned from 0 to 24 hours, as is the case in Italy, the Bureau is of the opinion that this reform ought to be realised as soon as possible."

THE FOUNDATIONS OF DYNAMICS.[1]

THIS posthumous volume of Hertz's works, edited by Prof. Lenard, with a preface by von Helmholtz, has a doubly melancholy interest. It is the last work of Hertz upon which he was engaged until a few days before his death, and it contains a preface which is almost the last work of von Helmholtz. The pupil died shortly before his master, and by the departure of such a pupil and of such a master, science, and with science mankind, have lost many prospects of advances in the near future.

In his preface, von Helmholtz pays a touching tribute to the genius of his favourite pupil, from whom he hoped most, and who had drunk most deeply of his master's thoughts. In 1878 their intimacy began. At that time difficulties connected with various electrical theories of action at a distance were occupying his thoughts, and he offered a prize for the best essay on induction in non-inductively wound coils. Weber's theory would have involved an inertia of the electric current distinct from the magnetic inertia. The question is still interesting in connection with discharges between two charged conductors, one of which completely surrounds the other when a dielectric between them is suddenly made conductive. There is then no magnetic force. Is there *no* inertia? Can a medium become *suddenly* conducting? Is a conducting medium homogeneous? Is there inertia of ionic charges which represent the non-homogeneity of the medium? These questions still require answering; but in the seventies, in Germany, Maxwell's idea of magnetic force accompanying displacement currents was not generally received, and Helmholtz's question as to the induction in non-inductively wound coils really had reference to these displacements. Hertz won the prize by showing that at most only 1/20th or 1/30th of the extra-current could be due to electric inertia. By subsequent experiments on the possible effect of centrifugal force on the current in rapidly rotating plates, he reduced this estimate to a very much smaller value. Mr. Larmor has suggested that any centrifugal force may be balanced by a tension in the length of the current, much in the same way that the tension of a running rope will balance centrifugal force in the curves round which it may be running. In every way the subject deserves further investigation, for it is intimately connected with the most fundamental questions as to the nature of electricity and its connection with matter.

The next thing to which Hertz devoted himself was a prize problem proposed, at von Helmholtz's suggestion, by the Berlin Academy. The problem was to investigate Maxwell's postulate that changing electric displacement was an electric current. This was the bud from which Hertz's great work sprang. Of it von Helmholtz says: "It is a pity we do not possess more such histories of the inner psychological development of knowledge. Its author deserves our sincerest thanks for letting us see so deeply into the inmost working of his thoughts, and for recording even his temporary mistakes. By this work Hertz has settled for ever the question as to electromagnetic actions being propagated by a medium, and the only outstanding question of the kind is as to gravitation, which we do not yet know how to logically explain as other than a pure action at a distance." It thus appears that von Helmholtz to the last was unconvinced as to the probability of any hypothesis like Le Sage's or Osborne Reynolds's. He seems, on the other hand, to have been satisfied with the possibility of chemical actions being explained either by electromagnetic actions or by actions not at a distance. This latter term, of course, requires explanation as to what "at a distance" means. Any actions other than those of absolutely rigid bodies, such, for instance, as the fairly well-established forces of attraction of gaseous molecules for one another, and some of which can hardly be explained either by electricity, magnetism, or gravitation, seem to be actions at a distance that require explanation just as much as gravitation.

Following this short history of the work of his pupil which, coming from such a master, must have a permanent interest to all, von Helmholtz gives a *résumé* of the last work of Hertz. In it there is attempted a continuously elaborated presentation of a complete and self-dependent system of mechanics, in which each particular application of this science is deduced from a single fundamental law which can of course be itself only assumed as a plausible hypothesis. In order to explain how this is required, von Helmholtz gives a short history of the development of the science of mechanics. The first developments arose from the study of the equilibrium and motion of solid bodies in direct contacts with one another, such as the simple machines, the lever, the inclined plane, the pulley. The law of virtual velocities gives the most fundamental general solution of all such problems. Galileo subsequently developed the knowledge of inertia and of moving force as an accelerating agent. It was, however, conceived by him as a succession of blows. Newton was the first who arrived at the notion of force acting at a distance, and its more accurate determination by the principle of action and reaction. It is well known how strenuously he and his contemporaries resisted this idea of pure action at a distance. From this men developed the methods of treating all problems of conservation forces with constant connections whose most general solution is given by D'Alembert's principle. All the general principles of dynamics have been developed from Newton's hypothesis of permanent forces between material points and permanent connections between them. It was subsequently found that these laws held even when these foundations could not be proved, and it was thence deduced that all the laws of nature agreed with certain general characteristics of Newton's conservative forces of attraction, although it was not found possible to deduce all these generalisations from one common fundamental principle. Hertz has devoted himself to discovering such a fundamental principle for mechanics, from which all the laws of mechanics hitherto known as universally valid can be deduced; and he has carried out this with great acuteness, and by means of a very remarkable presentation of a peculiarly general kinematic conception. In working it out, he returns to the oldest mechanical theories, and supposes all actions to be by means of rigid connections. Of course he has to assume that there are innumerable imperceptible masses and invisible motions of these, in order to explain the apparent actions upon one another of bodies that are not in immediate contact. Though he has not given examples of how this may be the case, he evidently builds his expectation of being thus able to explain natural actions upon the existence of cyclical systems, rollers, &c., with invisible motions. The justification of such an assumption can only be obtained by its success. Von Helmholtz concludes this interesting preface by remarking how English physicists have so often based their work on dynamical and geometrical suppositions, as for example Lord Kelvin and his vortex atoms, Maxwell and his cells with rotating contents. These physicists, he says, "have clearly been more satisfactorily helped by such illustrations, than by the mere most general representations of the facts and their laws as given by the system of physical differential equations. I must confess that I have restricted myself to this latter method of investigation, and have felt most confidence therein; and indeed I might not have arrived at any important results by the methods which eminent physicists such as the three mentioned have employed."

Although so far it seems as if there were very little to choose between the old methods of supposing that natural actions can be explained by conservative forces between molecules and by systems of rigid connections, Hertz in his introduction shows that he is dissatisfied with the hypotheses, of these forces as entities, while von Helmholtz, by his silence, seems to hold the view that the old method was good enough for him. Hertz's method has, however, the advantage of turning our attention to something definite to be investigated and invented, namely, the structure of these rigid connections. It is apparently very closely related to Osborne Reynolds's and "Waterdale's," suggestions as to the structure of the ether, namely, that it consists of perfectly rigid particles in almost complete juxtaposition which, whether by their smoothness or by their rolling upon one another, waste no energy in internal heat motions.

In his own preface, Hertz says that he has culled many things from many minds, nothing particular in his work is new; what he presents as new is the arrangement and collocation of the whole, and the logical, or rather philosophical, aspect thereby attained.

To these prefaces there follows a long introduction, in which Hertz reviews and criticises the present foundations of dynamics. The great road by which this domain is now entered is one that was laid by Archimedes, Galileo, Newton, and Lagrange. It is founded on our notions of space, time, force, and mass. Force is introduced prior to motion, as the independent cause thereof. Galileo's notion of inertia only involved space, time, and mass.

[1] "The Principles of Dynamics developed on new lines:—Hertz's Collected Works," vol. iii. Pp. 310. (Leipzig: Barth, 1894.)

Newton first introduced all four notions. To this D'Alembert's principle gave the analytical method of treating generally connected systems. Beyond it all is deduction. Here Hertz introduces a discussion as to the so-called forces of inertia. From his discussing the case of a solid subject to centripetal acceleration by means of a string, the question is much more intricate than if he had taken the case of a body falling freely under gravity, where the force is applied directly by the earth to each point of the body, and not, as in the case of the string, distributed to each part by stresses in the solid. Hertz seems to consider that there is some outstanding confusion in applying the principle of equality of action and reaction, and appears to hold that by this principle the action on the body requires some reaction *in the body* whose acceleration is the effect of the force. He does not seem fully to appreciate that action and reaction are always on *different* bodies. From his consideration of this, and from a general review of our conception of force, he concludes that there is something mysterious about it, that its nature is a problem in physics, like the nature of electricity. We have a quite distinct conception of velocity: why not of force? He concludes that the mystery is not due to our not having enough ideas to associate with the word, but to our trying to put too much into it. These mysteries, however, do not invalidate in any way the deductions that have been made; they only require us to seek out a new foundation for our dynamics. He goes on to criticise this method of filling nature with forces of which, being ultimately between molecules, we can have no direct experience. A piece of iron on a table is acted on by gravitation, cohesion, repulsion, magnetic, electromagnetic, electric, and chemical forces. Some of these would drag it to pieces if unbalanced to a nicety by others. Is this a sound view of nature? Can we not get some more attractive one?

A second view may be elaborated by making our fundamental quantities, space, time, mass, and energy. There is no book in which this view of nature is fully and consistently worked out, at least none that Hertz was acquainted with. He sketches how it might proceed. Besides the postulate of the conservation of energy we require some definition of potential energy and experimental relations connecting it with space, and in addition we have a choice of relations with kinetic energy, of which Hertz suggests the choice of the integral form of Hamilton's principle known as that of least action. This is, no doubt, a recondite idea to use as a fundamental postulate, but it only implicitly involves the idea of force, which then comes in merely as a definition. To this method, which certainly has several great advantages, Hertz makes a number of objections. In the first place he objects that it requires the equations of connection to be integral equations, and we know such actions as pure rolling of one hard body on another cannot be so expressed. We must, in order to specify the subsequent motion, know the rate of rotation round the normal axis through the point of contact, and this cannot be specified except in terms of differentials. To such motions we cannot apply the proposed principle of least action, and yet we can hardly dispute that such rolling is possible in nature. If we treat it as the limits of frictional sliding, we introduce the whole of the difficulties of force, or of the irregular heat actions which have not yet been fully made amenable to accurate dynamical treatment. Again, difficulties arise as to the foundation of this method. There is great difficulty in specifying energy itself. How can it be satisfactorily measured without returning to the first method, and introducing the idea of force? Some have conceived of energy as a sort of substance; but when we try to form concrete conceptions of what is occurring, we get involved in perplexities. The very existence of two forms of energy is a very serious difficulty. Again, it is doubtful whether it can be sound to consider the integral of least action as a *fundamental* principle. It makes the present depend on the future. It sets the problem to nature to make a certain integral the minimum.

A good many of these objections could be got over by making all energy kinetic, which is what Hertz himself practically assumes in his own method.

This third method begins by assuming only three fundamental quantities, time, space, and mass, and puts aside as non-fundamental, force and energy. In order to explain how nature works, we already do postulate invisible underlying structures in nature. We postulate these in the atoms and molecules of matter. Hertz sees in all actions the working of an underlying structure whose masses and motions are producing the effects on matter that we perceive, and what we call force and energy are due to the actions of these invisible structures, which he implicitly identifies with the ether.

We must, however, assume certain connections between the three quantities, time, space, and mass. Between time and mass there is no direct connection. Space and mass, Hertz considers, are connected by the existence of a given mass at each point of space. He cannot mean here to assume a complete plenum, which would make serious difficulties in the way of the working of what he subsequently assumes to be a structure of rigid bodies; he must include a vanishingly small density at some points, though perhaps he may have had in view the filling of the interstices between his rigid bodies with a fluid. Any way, he goes on to say that some connection is required between all three quantities, and for this purpose he postulates his great fundamental single law of motion, which he considers is an extension to systems of Newton's first law of motion for a single body; it is that a system, which is unconnected with any others, moves with constant swiftness along one of its straightest paths. "Systema omne liberum perseverare in statu quo quiescendi vel movendi uniformiter in directissimam." In order to understand what Hertz here means by the path of a system, and by its being straight or curved, requires further explanation; but from this principle, which is capable of analytical representation, and from the assumption that the connections of a system are all rigid, he deduces all the fundamental principles, conservation of areas, momentum, energy, least action, &c. In considering the motion of any part of a system, we find that we may conveniently introduce certain actions of the other parts of the system upon it which are measured by forces, which thus come in as mere definitions. He does not seem to investigate anywhere the question as to the danger of his rigid connections becoming tangled. Analytically a postulate that the points of two different bodies that act on one another are in contact is easily expressed, but it does not follow that when we come to invent actual rigid connections to produce the observed effects, they will do so for any length of time without jamming. It is a seductive theory that gravitation or electrical actions may be due to vortex filaments ending on atoms; but the tangling of the filaments is a very serious difficulty that has not been satisfactorily got over. Hertz does not seem to feel this as a serious difficulty, but he does notice an obvious objection that is sure to be raised, namely, that rigidity in itself postulates forces. To this he replies that rigidity in itself is merely a matter of definition and of fact. How is our view of the fact that two points are at a constant distance apart, improved by saying that there is a force between them? As, however, real bodies are only imperfectly rigid, Hertz concedes that it may be that when we learn more about these invisible connections, they may turn out not to be absolutely rigid. It is a matter for further investigation. This very same view might have been urged, and has been urged already with reference to actions like gravity. The *law* of gravity can be perfectly well described without any reference to the notion of force. We may say, every element of matter moves towards every other element in the universe with an acceleration inversely proportional to the square of their distances apart. We can describe the law kinetically, just as Hertz proposes to describe the law of motion of parts of a rigid body. There is no *necessity*, however convenient it may be, to introduce the notion of force; the other bodies in the universe are a sufficient cause for motion of each, without postulating an entity, force. The principal reason for introducing this notion was to account for a body acting where it was not; force was invented to get over this; the body produced force, and this force existed where the body did not, and there acted on other bodies. This whole difficulty seems, however, to be partly due to want of distinct ideas connected with the question of where a body *is*. We are so accustomed to consider a body as having a definite boundary, that we think there is a definite boundary in reality. All we know of the atoms and molecules, however, would lead us to conclude that round the centre of each there is a very complexly structured region which may or may not change abruptly in structure, but which often extends to considerable distances from the atom, so that it is practically impossible to state absolutely where the atom ends and where the empty space begins. With this view of matter there is no serious reason why we may not rightly consider each atom as existing everywhere that it acts, that is, throughout the whole of space, for its action in causing gravitional accelerations exists, so far as we know, throughout space. A view of this kind entirely gets over any difficulty of a body acting where it is not; for all bodies *are* everywhere, and if we consider matter to be the cause of motion of other matter, there seems no very imperious necessity for imagining another cause which we call force.

There are two assumptions that Hertz makes which he considers can only be proved by their success. One is that all the connections in nature can be represented by linear differential equations. There are plenty of cases imaginable in which this would not be true, as, for example, connections depending on the curvature of the path. The other assumption is that forces can be represented by force functions. This, again, may not be a complete representation of nature.

Following this introduction comes the book itself, which is divided into two parts. The first part is purely kinematical, the second deals with the deductions from Hertz's fundamental postulate of motion in the straightest possible path.

The first part begins by explaining what is meant by the path of a system of points. To get at this we calculate the mean square of the displacements of a system of points when they are displaced: the square root of this, Hertz calls the displacement of the system of points. If there is a mass at each point, then the displacement of the system is the square root of the mean squares of the displacements of the points, each multiplied by the mass at it. Thus, if s be the displacement of the system, and $s_1 s_2$, &c., the displacements of each point of masses $m_1 m_2$, &c. Then

$$(m_1 + m_2 + \ldots .)s^2 = m_1 s_1^2 + m_2 s_2^2 + \ldots$$

By taking s_1, s_2, &c., as the displacements in the element of time, we evidently get a similar expression for the velocity of the system, and for its acceleration. The mean square of the velocity of the parts of a system is well known in connection with the principle of least action. Further than this, however, Hertz defines the angle between two displacements. This is defined by the equation

$$(m_1 + m_2 + \ldots .)ss' \cos \epsilon = (m_1 s_1 s_1' \cos a_1 + m_2 s_2 s_2' \cos a_2 + \ldots .)$$

s and s' being the two displacements of the system as calculated above, and $s_1 s_1'$, &c., the two displacements of each point and a_1, a_2, the angles between these latter, then ϵ is the angle between s and s'. Hertz remarks that these can all be very interestingly expressed in terms of space of multiple dimensions, in which analytical diagrams are supposed to be drawn. This, however, represents the real by the unattainable. There follow, then, several chapters expressing these displacements in terms of various systems of coordinates, and discussions as to the conditions that the connections of a system should fulfil in order that they may be represented by equations not involving differentials. The curvature of the path is here studied. It is defined as $c = \frac{d\epsilon}{ds}$, and from this it follows that, representing $\frac{d^2x}{ds^2}$ by x'', &c.

$$(m_1 + m_2 + \ldots .)c^2 = \Sigma_1{}^1(m_1 x_1''^2 + y_1''^2 + z_1''^2).$$

The problem then of making the path of the system straightest, is to make c a minimum consistently with the connections of the system. Now, in accordance with his assumption that the connections of the system are linear differential equations of the form

$$\Sigma_1{}^1 P_1 x'_1 = 0,$$

whose differentiation gives

$$\Sigma_1{}^1 P_1 x'_1{}' + \Sigma^1\Sigma_1{}^1 . \frac{dP_1}{dx_2} x'_1 x'_2 = 0,$$

we are to determine the minimum value of

$$c^2 = \Sigma_1{}^1 \frac{m_1}{m} . x''_1{}^2,$$

when

$$m = m_1 + m_2 + \ldots .$$

In determining the variations of these, we must recollect that the positions and direction of displacement, *i.e.* the first differentials of the system, are supposed given, and that it is *only* the second differentials that can be varied in order to make c a minimum. Calling, then, a system of indeterminate coefficient λ, μ, &c., corresponding to the equations of condition, we evidently get a system of equations of the form

$$\frac{m_1}{m} x''_1 + \Sigma_1{}^1 P_1 \lambda = 0,$$

which are sufficient to determine the second differentials required.

From this form of result one can see how the ordinary equations of motion are derivable from the conception of the straightest path, and how, when dealing with part of a system, these indeterminate coefficients introduce what are equivalent to forces. This method of deducing the equations of motion lends itself particularly well to the deduction of the principles of least action, and the other general methods in dynamics. So far, he deals with free systems subject only to internal constraints. It is where he investigates how to deal with parts of systems that he requires to consider the nature of the constraints joining one part to another. For this purpose he defines two systems as coupled when coordinates can be so chosen that one or more of them are the same for both systems. Force is then defined as the action one system has on another. Now, when a coordinate is the same for two systems, one of the equations of condition is $p = p'$, p and p' being coordinates of the coupled systems, and for this equation the coefficient P becomes the same in the two systems, being unity for each, so that the equations of motion involve the indeterminate coefficient λ corresponding to this equation equally with reference to each system. It is thus that the equality of action and reaction appears, being thus bound up with the constant equality of the common coordinate. This seems to be where the assumption that the connections are rigid is introduced. When rigid bodies act upon one another by non-slipping contact, certainly the coordinates of the point of contact are common to the two systems. It is also quite evident that if we assume rigid bodies acting upon one another by contact only, we can have no potential energy, and all *necessity* for talking about the forces disappears. In Hertz's system there are no forces like Newton's acting between bodies which have no common coordinate, like the earth and the sun. We would have to invent connections to explain the motion before we could be certain that action and reaction are equal in this case.

The proof of the principle of virtual velocities by substituting for the forces between parts of a system a number of pulleys which produce the same effects, is quite analogous to Hertz's supposition that the actual connections are by rigid bodies. It is not, however, liable to the objection that the connections may become tangled, for it is only applied to the case of infinitesimal virtual displacements, while Hertz postulates the possibility of his connections existing as the real ones for all time, and throughout all finite displacements of the system.

The work considers many other matters, and shows how all the general methods in dynamics are deducible from his fundamental postulate of the straightest path. It includes discussions on how best to deal with systems whose connections do not involve differentials, how to treat cyclical coordinates, and many other matters. It is most philosophical and condensed, and gives one of the most—if not the most—philosophical presentations of dynamics that has been published. It is worthy of its author: what more can be said?

G. F. FITZGERALD.

PSEUDO-SATELLITES OF JUPITER IN THE SEVENTEENTH CENTURY.

IN the New York *Nation* for January 11, 1894, Dr. D. C. Gilman, President of the Johns Hopkins University, called attention to an interesting letter from John Winthrop, jun., to Sir Robert Moray, concerning the satellites of Jupiter. In this letter, which was written from Hartford, Connecticut, on January 27, 166⅘, Winthrop described an observation of Jupiter which he had made on the night of the previous 6th of August, when he had very distinctly seen five satellites about that planet. He was naturally "not with out some consideration whether that fifth might not be some fixt star with which Jupiter might at that tyme be in neare conjunction," and expressed the wish that more frequent observations might be made upon that planet with a view to ascertaining whether it is not impossible to discern a fixed star, when it is so near to the planet as to appear "within the periphery of that single *intuitus* by a tube which taketh in the body of Jupiter," and if so, whether his star is not a new satellite. He further proceeds:—"I am bold the rather to mention this as an inquiry whether any such number of Satellites or moons hath beene seene by your honor or Mr. Rooke [? Hooke] or any mathematitians or other gentlemen that have good tubes and often have the curiosity to view the planet, for possibly it may be new to me which hath beene more usually knowne by others, though the notion of such a thinge is not new to my selfe, for I remember I mett with the like narration many years since in a little booke intituled Philosophia Naturalis per Joh. Phociliden, though then I thought that was but a mistake of some fixed starrs." Now that Prof. Barnard has discovered a genuine fifth satellite of Jupiter after the lapse of nearly three centuries since Galileo's telescope detected the Medicean stars, a greater interest is given to those imaginary satellites which from time to time have claimed a place in the solar system. In a paper in the Johns Hopkins University *Circular* for last May (referred to in NATURE, vol. l. No. 1283, p. 113), Mr. Frank H. Clutz has given a probable identification of Winthrop's supposed satellite with B.A.C. 6448. In a postscript to his article it is pointed out that the work to which Winthrop refers is presumably the "Philosophia Naturalis, seu Physica Vetus-Nova" of Johann Fokkens (born at Holwarden in Friesland in 1618; died at Franeker, February 19, 1651). At President Gilman's suggestion, I have followed up this clue, and have succeeded in examining the work in question. I find that it contains more than a casual reference to additional satellites of Jupiter; in fact, a whole chapter is devoted to a discussion of certain observations, which seems to be sufficiently interesting to deserve a brief notice.

Phocylides' treatise was published at Franeker in 1651, shortly after the death of the author. On the title-page it is described as written "Ab Eximio Viro/JOH. PHOCYLIDE HOLWARDA/ L.A.M. Med. Doct. & Philosophiæ,/dum viveret, Profess. Ordinario." There is also a portrait. The third of the three parts into which the book is divided is entitled "Physica Cœlestis," and it is doubtless this portion of the Philosophia which Winthrop had in mind when writing his letter to Sir Robert Moray. It is not Phocylides himself who claims to have discovered new moons of Jupiter; nor does he believe in their existence. On the contrary, he treats the supposed observations with the severest disapprobation; and while in general he is enthusiastic over the revelations which the telescope had already made and was daily making, this particular discovery, which he regards as spurious, rouses him to the most strenuous exertions in order to effect its refutation. The discoverer, by name Antonius Maria Schyrleus de Rheita, stated that he had seen, not one, but five new satellites of Jupiter, all farther removed from the planet than the four Galilean moons, and revolving in a contrary direction. Phocylides' account of the matter may be briefly summarised as follows: First he refers to five stars near a certain known star of the fourth magnitude. They are "intra duodecimum & decimum quintum Piscium gradum" (p. 205) "versus sinistram secundum Signorum successionem." (p. 205 and p. 284.)

These stars, he continues, have given rise to no little controversy among learned and experienced astronomers (astrophilos) whether they are fixed stars or erratic, and, more particularly, whether they are companions (commilitones) of Jupiter. The discussion of this point is then postponed. Chapter xvi. treats of the number of the planets and their division in kind. Both satellites and planets proper are included in the term "planetæ." After rejecting the sun from his ancient place among the seven planets, and adding to their number the two *laterones* about Saturn and the four about Jupiter, discovered in the "current century by the aid of new and admirable instruments, such as Tubi Optici, specula, and others of the same sort," he adds the Earth to the twelve hitherto obtained. It is thus certain, he says, that there are at least thirteen planets, since it is not yet known whether Mars, Venus, and Mercury have any *laterones* revolving about them. "But as to the five other circumjoviales which P. Anton. Mar. de Rheitâ boasts that he has observed and called Urban Octavianæ, learned men are justly in doubt whether they should be referred to the fixed or to the wandering stars." Nothing further is added at this place, but he proceeds to divide the thirteen planets into primary and secondary. The former (six in number) are named in order from Mercury to Saturn, with the Earth in the Sun's former place. The latter are Saturn's two, and Jupiter's four satellites. The seventh is the Moon. Anyone who doubts this, he adds, will be convinced by what is soon to be said, as well as by the considerations contained in the chapter "De Lunæ corpore & motu." After several interesting chapters, including one on Saturn and his laterones, and another on Jupiter and the Medicean stars, we come to chapter xxi., entitled "De Pseudo-Jovialibus: & priorum consectaria." Phocylides' attitude is at once disclosed. He refers to the pseudo-discoverer as "quidam Antonius Maria de Rheita, (homo in Papatu arrogans, invidus, judicio præceps & fatuus, aliorum gloriam pro propriâ injustè & cum pudoris oblivione captans & vindicans)."

The discovery was alleged to have been made at Cologne near the end of the year 1642, and was announced in a letter to Puteanus. But it so happened that Hevelius had noticed and described these very stars several months previously. His observations were made in August 1642 and the succeeding months, and Phocylides regards the claims of Rheita to have been the first to discover them as "fœtidum mendacium," as, by his own admission, he did not observe them before the end of the year. The identity of Rheita's pseudo joviales with these fixed stars is shown by a comparison of the actual positions of Jupiter on the dates when the observations were made. Our author points out that on December 29, the day of Rheita's discovery, Jupiter occupied the same position as on the previous 4th of September, when Hevelius observed him and noticed the five stars. This position is defined by Phocylides in the words, "decimo tertio gradu Piscium, cum quindecem minutis." Again, Hevelius saw Jupiter on August 28 "in decimo quarto gradu Piscium, cum quindecem minutis," where Rheita observed him on January 4 of the following year (1643). The new circum-joviales are then, says Phocylides, none other than the stars recently discovered in Aquarius. They do not move round Jupiter, as they would do if they were secondary planets, and are therefore fixed stars, "manebuntque [fixæ] usque ad sæculi consummationem." They were observed by Hevelius to remain stationary, while Jupiter left them behind him. Phocylides challenges any doubter to look for these stars himself, when all five will be found in their original position and at the same distances one from another. He concludes with the words (p. 289): "Hallucinatur itaque crassè & inani nimis glorio â Rheita se ipsum titillat."

The following will throw further light on Rheita's tendency to form hasty conclusions. According to Phocylides he declared that he had observed three of the Medicean stars to be in a straight line, but the fourth "tantam obtinuisse latitudinem, quæ, si ex centro Jovis Eccentricum ad illum excurrentem metiamur, ad quindecem gradus excrescat." This, says our author, is contradictory to the observations of all "mathematicians," who unanimously agree that the Medicean stars never recede from Jupiter in latitude more than three minutes, whether to the north or to the south. He then states that this fourth star, so far from being a true Galilean satellite, was not even a pseudo-jovial, but another fixed star. Gassendi observed the satellites on the same night, and saw all four in a straight line, the second slightly to the north; but they were differently disposed with regard to Jupiter. In all probability, Phocylides concludes, the first (innermost) satellite was obscured by the planet, if, as is likely, the observations were not made at precisely the same hour; for Jovial Mercury (as he is called) runs his course round Jupiter in a few hours more than a whole day. Phocylides supposes that, as Rheita was well aware that there were four satellites, he mistook this fixed star for the fourth satellite.

The existence of Rheita's new satellites was opposed by Gassendi in his "Judicium de novem stellis circa Jovem visis" (see Delambre, "His. de l'Ast. Mod.," ii. p. 351), and by Hevelius in his "Selenographia," *ib.* p. 437). Lobkowitzius defended Rheita against Gassendi ("Phocylides," p. 295). Delambre devotes several pages to Rheita, or Schyrle, and gives some account of his work "Oculus Enoch et Eliæ, sive Radius sidereomysticus," Antwerp, 1645. In this book, according to Delambre, he admits that he has not succeeded in observing his satellites again, but asserts anew that he noticed changes in their mutual distances. He explains their disappearance by connecting them with variable stars, which he supposes to have large orbits and long revolutions. He believed, moreover, that the spots of the suns were planets, and that the sun itself rotated but once in a year.

Phocylides also mentions circum-martiales and circum-saturnales, which, no less than the circum-joviales, must be held to be fixed stars.

It will thus be seen that Winthrop was right in remembering

Phocylides' treatise as a work in which the discovery of new satellites was mentioned. But apparently he did not remember very accurately the position assumed by the author, for the book contains but little to encourage an observer in the belief that he has discovered new satellites.

It is perhaps worth noticing that the Philosophia was published less than fourteen years before the date of Winthrop's letter; it must therefore have been quite a new book when Winthrop perused it, as he says, "many years since."

CHARLES W. L. JOHNSON.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. J. Burdon Sanderson has been appointed Regius Professor of Medicine in succession to Sir Henry W. Acland, whose resignation was announced last Term. In accepting the Regius Professorship, Prof. Sanderson vacates the Waynflete Chair of Physiology, which is more valuable in a pecuniary sense. It is naturally a matter of regret that he should formally sever his connection with the school of Physiology which he may be said to have created in Oxford, but it is recognised that no better appointment could have been made to the headship of the Medical School which he has done so much to encourage, and whose interests he will have further opportunities of promoting in his new position.

At a meeting of the Royal Statistical Society held on Tuesday, a paper was read, by Mr. L. L. Price, on "The Colleges of Oxford and Agricultural Depression." The accounts of the Oxford and Cambridge Colleges have been published year by year for some time past, and in Mr. Price's paper the accounts of the Oxford Colleges for the years 1883–93 were brought under review. The gross external receipts of the Colleges were in 1893 some £11,000 less than in 1883, and the net external receipts some £13,000. Though the external receipts are not entirely derived from agricultural estates, it seems within the facts to regard agricultural depression as responsible for a loss of upwards of £60,000 of income in 1893. Turning to the effects of the depression upon the emoluments of the Heads, Fellows, Scholars, and Exhibitioners, to which the College revenues are mainly devoted, it appears that these effects have been mitigated by the circumstances that the external receipts are not exclusively agricultural, and that the emoluments are also partly derived from internal receipts and from Trusts. Still the emoluments of the Heads have fallen from £22,811 to £20,905, and of the Fellows from £83,820 to £74,749. The emoluments of the Scholars and Exhibitioners have however increased from £44,776 to £48,378, and their number has grown by upwards of ninety; and if the increased contributions made by the Colleges to the University are taken into consideration, the fall in the total payments is only about 5 per cent. But there are Colleges, where diminutions have occurred of more than 25 per cent. in the emoluments of the Fellows, and the figures generally are altered considerably for the worse by eliminating a few prosperous Colleges.

CAMBRIDGE.—Mr. A. Hutchinson, Fellow of Pembroke College, has been appointed Demonstrator of Mineralogy and Assistant-Curator of the Museum, in place of Mr. Solly, who has retired.

The Downing Professor of Medicine (Dr. Bradbury) announces that the newly-organised Museum of Materia Medica and the Pharmacological Laboratory are now open daily to students of medicine, and that demonstrations will be given therein by Mr. Marshall, the assistant to the Professor.

Dr. Gaskell, F.R.S., has been appointed an additional member of the Board for Biology and Geology.

THE Royal Agricultural Society has now issued its revised regulations and syllabus for the society's senior examinations, framed in accordance with the important modifications recently decided upon. The council have resolved to place annually at the disposal of their education committee five life memberships of the society, to be awarded to the five candidates who stand highest on the list of winners of first-class certificates, and who obtain not less than two-thirds of the maximum number of marks. The gold medal of the society will be bestowed upon the candidate who stands highest on the list of winners of life memberships, provided that he has obtained not less than three-fourths of the maximum number of marks, and silver medals upon the other winners of life memberships, including the candidate at the head of the list, if he does not reach the standard required for a gold medal.

THE Association of Head Masters held its first meeting as an incorporated body on Thursday last. One of the items of the agenda was a paper in which Mr Stuart described the usual practice of teaching science, and said most of them were satisfied that such a system had no educational value at all. All experiments must be capable of being performed and the observations made by the students. The experiments must be chiefly quantitative and especially at first. Books and lecture demonstrations must be avoided. He thought that a good grounding in science might be given by doing practical work in an ordinary class-room, upon common tables, with home-made apparatus. The following resolutions were afterwards passed by the meeting:—

(*a*) "That the association is of opinion that examining bodies should encourage a more rational method of teaching science, by framing the syllabuses in such a manner that the practical work required may be strictly illustrative of the theoretical instruction given."

(*b*) "That it be referred to the general committee to appoint a small sub-committee, so that a report may be presented to the next summer general meeting containing detailed suggestions which it is proposed to make to examining bodies concerning examinations in science."

THE Research Scholarship given by her Majesty's Commissioners for the Exhibition of 1851, to Mr. Edward Taylor Jones, of the University College of North Wales, in 1892, has been renewed for a third year. Such renewal is only made in cases of exceptional merit, where valuable scientific results are likely to be obtained by a continuance of the scholar's research work. Mr. Jones has just completed, at the University of Berlin, an experimental investigation solving an important problem in magnetism. An account of the research has been communicated to her Majesty's Commissioners, and will shortly be published.

THE Professorship of Mathematics in the Government Training College, Ireland, vacant by the retirement of Principal Corbett, has been filled by the appointment of Mr. Dilworth, of Trinity College, Dublin.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, January 7.—M. Marey in the chair.—A list of the present members, foreign associates, and correspondents of the Academy is given.—M. A. Cornu was elected Vice-President for 1895.—Preparation, in the electric furnace, of *graphites foisonnants*, by M. Henri Moissan. For all varieties of graphite prepared by intense heat, the temperature of intumescence after soaking in nitric acid is about 165°–175° C. They resemble natural graphites in this and other respects, hence the probability that the latter have been produced at a very high temperature under moderate pressures in masses of iron which have since disappeared.—The vasomotor nerves of the veins, by M. L. Ranvier. From the results of experiments quoted, the author concludes that veins as well as arteries are supplied with vasomotor nerves.—On the first scientific voyages of the *Princess Alice*, by Prince Albert I. of Monaco.—An addition to Le Verrier's theory of the movement of Saturn and rectification of the Tables, by M. A. Gaillot.—On the approximate development of the perturbation function, by M. N. Coculesco.—On roots common to several equations, by M. Walther Dyck.—On the theory of a system of differential equations, by M. A. J. Stodolkievitz.—On the theory of exchangeable substitutions, by M. Demeczky.—On the absolute value of the magnetic elements on January 1, 1895, by M. Th. Moureaux. The values are given for (A) Parc Saint-Maur, Long. 0° 9′ 23″ E. and Lat. 48° 48′ 34″ N.; (B) Perpignan, Long. 0° 32′ 45″ E. and Lat. 42° 42′ 8″ N.

Elements.	Abs. values Jan. 1, 1895.		Secular variation in 1894.	
Declination	(A) 15° 12′·7	(B) 14° 3′·4	(A) −5′·3	(B) −5′·0
Inclination	65 4·9	60 9·9	−1·2	−0·8
Horizontal component	0·19641	0·22345	+0·00017	+0·00025
Vertical component	0·42277	0·38961	−0·00003	+0·00021
Total force	0·46617	0·44914	+0·00005	+0·00031

Use of the critical temperature of liquids for the recognition of their purity, by M. Raoul Pictet. A convenient method of determining the critical points of liquids is described. Any impurity causes a difference in the critical temperatures in the same sense as the difference produced in the boiling points, but in the former case the difference is of far greater magnitude than in the latter.—On the qualitative separation of nickel and cobalt, by M. A. Villiers. The author avails himself of the property of sodium tartrate in preventing the precipitation of nickel sulphide while allowing the complete precipitation of cobalt sulphide. Tartaric acid is added to the clear solution of the two metals, then soda (not potash) in large excess and hydrogen sulphide is passed. The nickel passes into the filtrate as a nearly black solution, mere traces give a brown tinge. The method is not quantitative.—Some points in the spermatogenesis of the Selacians, by M. Armand Sabatier.—On the genesis of intestinal epithelium, by M. Étienne de Rouville. Observations confirm the author's views that: (1) The conjunctive tissue continues more or less, during life, to be the matrix giving rise to the elements of other tissues; it is a post-embryonic blastoderm. (2) Epithelial tissues are only, in most cases, the forms limiting the free surfaces of conjunctive tissue.—Physiological researches on the Lamellibranchs (*Tapes decussata*, &c.), by M. Piéri.—On some lakes in the Alps and Pyrenees, by M. A. Delebecque. The depths and altitudes of most of the important mountain lakes are given.

BERLIN.

Physical Society, November 30, 1894.—Prof. von Bezold, President, in the chair.—Dr. Aschkinass described his experiments on the influence of electric waves on the galvanic resistance of metallic conductors. Gratings made of tinfoil when placed near a Hertz exciter showed a diminished resistance which was quite independent of the action of light due to the primary sparks, and was persistent after the cessation of the electric oscillations, but could then be restored to its original value by mere mechanical percussion. A series of experiments proved that it is really the electric waves which altered the resistance of the grating, and the results were extended to other metallic conductors. The speaker drew attention to analogous observations made by English and Swiss physicists who had found that filings of iron and other metals enclosed in glass tubes had their resistances altered by electric sparks discharged in their neighbourhood. In their case, also, the original resistance was restored by mechanical vibration.—Dr. Gross spoke on the electrolysis of a solution of mixed nitrate and sulphate of silver to which a little nitric acid had been added. Silver was deposited on the kathode, and a black substance on the anode; the latter he had not as yet obtained free from silver, but it did not contain any sulphur, although 60 per cent. of sulphuric acid had disappeared from the solution.

Physiological Society, December 7.—Prof. du Bois Reymond, President, in the chair.—Prof. L. Lewin gave an account of some experiments made with an alkaloid obtained from a North Mexican cactus called "Peyotl." It is well known that this plant has an intoxicating action, and in larger doses produces sleep and a state of nervous excitation accompanied by a so-called "power of prophesying," similarly attributed to the sulphurous exhalations of the temple at Delphi. Small doses of the alkaloid when given to frogs produced tetanic cramps and a greatly increased reflex irritability, analogous to strychnine; but with this difference, that by carefully apportioning the dose the effects were permanent for several days. Similar results were obtained with rabbits, and Prof. Lewin regarded the new alkaloid as specially adapted to further the study of the nature of tetanus. In rabbits it was noticed that during each paroxysm of cramps, the blood-vessels of the ears were widely distended. The speaker had also found alkaloids with powerful actions in many species of Cactus hitherto regarded as harmless by botanists, notably one closely resembling curare.—Dr. G. Joachim had investigated sphygmographically the effect of suspension by the head on the circulation, and in the case of a number of invalids, of whom some were suffering from heart-disease, had observed only a slightly increased frequency of pulse, which is probably merely attributable to psychic excitation.—Prof. Gad communicated the results of an investigation, made by a new method by Mr. Seeler, of Cleveland, on the terminations of motor nerves in muscles, which had shown that in addition to the motor fibre a non-medullated fibre leaves the sheath of Henle, and is distributed to the capillaries of the muscle-fibre, whereas the medullated motor-fibres spread out to the muscle itself.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Logic: Dr. C. Sigwart, translated by H. Dendy, 2 Vols., 2nd edition (Sonnenschein).—Les Abimes: E. A. Martel (Paris, Delagrave).—Essays on Rural Hygiene: Dr. G. V. Poore, 2nd edition (Longmans).—Annuaire de l'Académie Royale des Sciences, &c., de Belgique, 1895 (Bruxelles).—Astronomische Chronologie: Dr. W. F. Wislicenus (Leipzig, Teubner).—Handbuch der Theorie der Linearen Differentialgleichungen: Dr. L. Schlesinger, Erster Band (Leipzig, Teubner).—Laboratory Exercises in Botany: Prof. E. S. Bastin (Philadelphia, Saunders).—Smithsonian Report, 1893 (Washington).—Geological Survey, Alabama, Report on the Geology of the Coastal Plain of Alabama (Montgomery, Alabama).—Tables and Directions for the Qualitative Chemical Analysis of Moderately Complex Mixtures of Salts: M. M. P. Muir (Longmans).

PAMPHLETS.—Eighth Annual Report of the Liverpool Marine Biology Committee and their Biological Station at Port Erin: Prof. Herdman (Liverpool, Dobb).—On the Search for Coal in the South-East of England: W. J. Harrison (Birmingham).—Eine Discussion der Kräft der Chemischen Dynamik: Dr. L. Stettinheimer (Frankfurt a.M., Bechhold).—The Varieties of the Human Species: Prof. G. Sergi (Washington).—Royal Horticultural Society Report for 1894–5 (Victoria Street).—Ditto, Arrangements for 1895 (Victoria Street).

SERIALS.—Geographical Journal, January (Stanford).—American Journal of Science, January (New Haven).—Gazetta Chimica Italiana, Anno xxiv. 1894. Fasc. vi. (Roma).—Proceedings of the Physical Society of London, January (Taylor).—Journal of the Chemical Society. January (Gurney).—Ditto, Supplementary Number (Gurney).—Record of Technical and Secondary Education, January (Macmillan).—Beiträge zur Petrographie der Östlichen Centralalpen speciell des Gross-Venedigerstockes: Dr. E. Weinschenk, I. and II. (München).—Morphologisches Jahrbuch, 22 Band, 2 Heft (Leipzig, Engelmann).—Journal of the Franklin Institute, January (Pilhadelphia).—Journal of the Royal Horticultural Society, January (Victoria Street).—Engineering Magazine, January (Tucker).

THURSDAY, JANUARY 24, 1895.

A BAD METHOD IN TEXT-BOOKS.

Lehrbuch der Vergleichenden Anatomie. Von Arnold Lang, o. Professor der Zoologie und vergleich-Anatomie, Zurich. 4te Abtheilung: Echinodermen und Enteropneusten. (Jena: Fischer, 1894.)

PROF. ARNOLD LANG completes, by the publication of this fourth part, his treatise on the comparative anatomy of Invertebrata. As the successive parts of this work have appeared, the author has changed to a considerable degree the limits of space which he appears originally to have contemplated, and has consequently treated those groups reserved for later volumes at greater length than that which he permitted himself to occupy in the first part of the work. We note that he now proposes to rectify this inequality by the production of new editions of the earlier part of the treatise.

Prof. Lang remarks in an interesting "Nachwort," that "man hat es vielfach getadelt"—that is to say, "complaints have been very generally made"—that the names of authors are not cited in the discussions which constitute the text of his work. I confess that I am most emphatically in agreement with those who have "getadelt"; and I do not think that Prof. Arnold Lang's contention is either correct in itself or sufficient (if it were correct), when he asserts that the book would have been double the size it is, had he given an impartial account of the historical development of the knowledge of the facts which he describes, with reference to the names of the most important authors. There are, it seems to me, three good reasons for adopting the method to which Prof. Lang objects. Firstly, such a method (namely, a historical method not carried beyond the citation of the works of the chief contributors to surviving doctrine) is the most natural for the mind of the student to follow, and gives him the truest appreciation of the present condition of knowledge on any topic, and of its probable future development; secondly, such a citation of the names of really surviving authorities—that is to say, of authors whose work is at this moment admitted as being the original and approved source of observational record, or the theoretical conception still holding its ground—is, as a mere matter of bibliographical reference, of far more service to the student than an indiscriminate list of memoirs at the end of a chapter (such as Prof. Lang gives) without any indication of the contents of the memoirs named; thirdly, that such a citation is the bare justice to his predecessors and contemporaries which every teacher of zoology (or other advancing science) should feel bound to accord, and should, I venture to say, gladly and scrupulously take trouble to ensure for those whose original work he has appropriated and accepted.

I confess that I feel sensible of something ungenerous and even unfair when I read the long and careful statements as to the skeletal and other systems of the Echinoderms (300 pages), illustrated by admirable copies of other naturalists' drawings, made in the present volume by Prof. Lang, without citing in his text a single name of those to whom he and the world in general are indebted for all this knowledge. After all, it may well be questioned whether any man of science is justified in making statements, even in a text-book, as though he himself had investigated and was responsible for the accuracy of these statements in virtue of his own observations on the objects described, when all the time he is simply stating what this man and that man have seen, and he has not seen, though he omits to mention the name of any of those to whom he is indebted. When such a method is adopted, one is quite unable to distinguish the individual opinions of the author from the mass of second-hand information which he pours out. A very simple introduction of the phrases, "as was first shown by X," or "according to the observations of Y," or again, "an observation which I can confirm, as it has been called in question," would alter the whole significance of Prof. Lang's discourse, and make it not only much more valuable, but much more interesting. At the same time, let me hasten to say that every one will at once accept Prof. Lang's statement, that his object in ignoring the names of zoologists has been to secure brevity. My contention is that the end has not justified the means.

Take, for instance, the so-called "apical" nervous system of the Crinoids. The discovery of this remarkable and altogether improbable nervous system by that staunch and unwearied naturalist, Dr. W. B. Carpenter, in his old age, is one of the most delightful episodes in the history of comparative anatomy. He made the discovery after he was seventy years of age, and no one believed that his interpretation of his observations was correct when he first announced it. Old as he was, he lived to see his discovery confirmed and accepted on all sides. This extraordinary nervous system is described at some length, and explained by figures in Prof. Lang's book; yet the name of Dr. Carpenter is not once mentioned in connection with it, and the figures given (p. 966) are taken from and ascribed to Beyrich (!) and Carpenter's son Herbert, who merely worked out, long after his father's complete publication, some details of the old man's discovery. On the other hand, the mere accident that the cœca of the lantern-membrane, discovered by Prof. Charles Stewart in the Cidaridæ, have no special name, results in a recognition of his interesting discovery by the title of the "Stewartschen Organen."

The unsatisfactory character of Prof. Lang's method, if we regard his book as one for reference and assistance in tracing the more recent discoveries, is well exhibited in the section of little more than one page (pp. 1036, 1037) on the axial organ of Echinoderms (dorsal organ, heart, pseudo-heart, renal organ, plastidogenous gland, ovoid gland, lymph gland). Here the space assigned by the author seems to be singularly out of proportion to that given to other topics, and we get not only the very scantiest description of the axial organ in Asterids, Ophiurids, Echinoids, and Crinoids, but no indication or reference *whatever* to ampler sources of information. Since this is really one of the critical subjects of recent investigation in Echinoderm anatomy, it is to be regretted that Prof. Lang says so little about it.

Whatever faults one may find with Prof. Lang's book, there is no doubt that it also has merits, and will be found to contain a survey of Echinoderm morphology more extensive than that accorded to the morphology of other groups by the same author, as well as some useful original diagrams, such as that of Pentremites, on p. 968.

E. RAY LANKESTER.

THE STUDY OF ROCKS.

Lehrbuch der Petrographie. Von Dr. Ferdinand Zirkel, Ord. Professor der Mineralogie und Geognosie an der Universität Leipzig. Zweite gänzlich neu verfasste Auflage. Three vols. 8vo. Pp. 2619. (Leipzig: Engelmann, 1893-94.)

THE appearance of a second edition of Prof. Zirkel's admirable "Lehrbuch der Petrographie" is an event of no little importance in the history of geological science. The part played by the author of this work in developing the methods of microscopic analysis, as applied to rocks, is too well known to require recapitulation in this place, and the long series of petrographical memoirs with which he has enriched geological literature—dealing with the rocks of the North American as well as with those of the European continent—are familiar to all students. While a great number of works treating of the microscopic study of rocks (including the author's own "Die mikroscopische Beschaffenheit der Mineralien und Gesteine") have appeared during the twenty-eight years which have elapsed since the first edition of the "Petrographie" was published, there is not one among them that quite occupies the place of that excellent treatise—with its wealth of information on the history and development of petrographical nomenclature.

The rapidity of growth of this branch of geological science during the past thirty years, is brought out in a very striking manner by a comparison of the first and second editions of this standard work. The first edition consisted of two thin volumes with an aggregate of 1241 pages; the second edition forms three bulky volumes with 2619 pages. But this is not all: it is evident to any one who peruses these volumes, that, in spite of the employment of more than double the number of enlarged pages, with much small type introduced, the author has found it impossible to discuss in all their aspects the views of previous authors with the completeness and comprehensiveness that were so remarkable in the first edition of the book. The student may be satisfied that Prof. Zirkel has overlooked little or nothing of importance in the literature of his subject; but, not unfrequently, it will be noticed that in his attempt to deal as concisely as possible with this vast mass of literature, he has made statements with respect to the views of the authors quoted, which are scarcely borne out by a reference to the memoirs themselves. While, therefore, this new edition will be invaluable in supplying ample references to petrographical literature, it will not in any way obviate the necessity of consulting the original memoirs.

As indicating the fulness with which the subject is now treated, we may mention that the number of pages dealing with "General Petrography" has increased from 171 to 634. The account given of the optical properties of minerals and of the structure of rocks, as made out by the aid of the microscope, is naturally responsible for a large part of this increase; the description of the common rock-forming minerals, which was comprised in forty pages in the first edition, now requiring no less than 291 pages. The greatest defect in this part of the work will be found in the absence of illustrations. Of this the author is fully sensible, as will be seen from a reference to his preface; but, as he justly pleads, the addition of illustrations could not fail to add to the bulk and cost of a book that has already grown to encyclopædic dimensions.

Every student of geology will naturally examine the work with the desire to learn what are the present views of so great an authority as Prof. Zirkel on the vexed subject of rock-classification and nomenclature. In the first edition of the book, our author, following the plan of most German writers upon the subject, attempted to class rocks according to their structure and mineralogical constitution, quite irrespectively of their origin, into simple crystalline rocks (ice, rock-salt, quartz-rock, limestone, &c.), compound crystalline rocks of granular and schistose character respectively, and clastic, or fragmental, rocks. In the second edition, he departs from this method, and commences the descriptive portion of the book with an account of the "Massige eruptive Erstarrungsgesteine," which occupies no less than 1292 pages. This is followed by an account of the "Krystallinische Schiefer" (275 pp.), the "Krystallinische oder nicht-klastiche Sedimentgesteine" (230 pp.), and the "Klastichen Gesteine" (125 pp.). It will thus be seen that the primitive classification into crystalline (simple and compound) rocks and clastic rocks, has been abandoned for one in which account is taken of their mode of origin.

In dealing with the great class of igneous rocks, Prof. Zirkel has also introduced some modifications of his original method. In 1866, he grouped these rocks, according to the nature of the alumino-alkaline silicate present in them, into Orthoclase-rocks, Oligoclase-rocks, Nepheline- and Leucite-rocks, Labradorite-rocks, Anorthite-rocks, and rocks without felspathic constituents. The obvious objections to this classification were: (1) That many rocks contain several distinct species of felspar, notably in their porphyritic constituents, and in their groundmass respectively; and (2) that geologists possess no simple, infallible, and easily applied test for ascertaining the exact species of felspars present in rocks. In 1873 (in his "Mikroskopische Beschaffenheit der Mineralien und Gesteine"), Prof. Zirkel abandoned this classification for the simpler division of felspar-bearing rocks into Orthoclastic and Plagioclastic. This classification, which is facilitated by the general presence of twin striation as an easily recognised distinction of the plagioclases, has now been very generally adopted by petrographers. In the work before us, however, the author divides the felspar-bearing igneous rocks into two series, distinguished by the predominance of an "alkali felspar" or of a "soda-lime felspar" respectively. It does not appear to us that anything is gained by this new departure, which will compensate for the admitted difficulty of applying the test for the discrimination of the two classes. Another change in classification which will interest English readers is that, while the separation of volcanic rocks into two series, the pre-tertiary (palæo-volcanic) and post-tertiary (neo-volcanic) is maintained, the Plutonic rocks are admitted to be of all ages.

Geologists will, alas, look in vain in this work for any indication that they may hope for a speedy termination of the terrible confusion that has so long prevailed with respect to petrographical nomenclature. On the contrary, they will find that in addition to having to reckon with the schools of Paris and Heidelberg, as they have done in the past, they will now have to take account of a third—that of Leipzig! With some of Prof. Zirkel's criticisms of contemporary palæontological literature, English and American geologists will heartily sympathise. The employment of such terms as granitite, granophyre, &c., with significations different from those given to them by the authors of th names, cannot but fail to lead to almost endless confusion, and we are glad to see that the authority of Prof. Zirkel is thrown into the scale against such principles of nomenclature being adopted; but in other cases we cannot but think that his objections to the nomenclature of other authors are not likely to be sustained by future workers in this branch of science.

Whether the confusion that now exists can be removed by any friendly discussion between the representatives of rival schools—such as those of the international committee proposed at the late Geological Congress at Zurich—time alone can show. If this be impossible, and writers in France and Germany, respectively, continue to ignore the terminology employed in other countries than their own, then it appears to us that, if science is to maintain her cosmopolitan character, only one method of escape is possible. We must follow the example of the other natural-history sciences in adopting the test of *priority* as absolute and final in our terminology of rocks. That many inconveniences must result from such a course may be readily admitted; and it will not be easy to fix upon the Linnæus of our science—or to decide upon the date at which exact petrographical literature may be supposed to have commenced. But almost any trouble and difficulty of this kind is worth encountering, if we may hope that geologists in the future will, in speaking of rocks, attain that great desideratum of "one thing—one name."

In the meanwhile, we are not ungrateful to the author of the work before us for the enormous labour and pains he has taken in wading through the great mass of petrographical literature; in furnishing us with correct statements concerning the origin and history of terms; and in placing on record the decisions he has arrived at upon many of the difficult problems that confront us. The "Lehrbuch der Petrographie" has always been a standard work of reference; and, in its new form, it has become more indispensable than ever. J. W. J.

OUR BOOK SHELF.

Pithecanthropus Erectus, eine Menschenaehnliche Uebergangsform aus Java. By E. Dubois. 4to, pp. 40, illustrated. (Batavia, 1894.)

JAVA, from its geographical situation, being just one of those countries where the remains of a connecting form between man and the higher apes would be extremely likely to occur, zoologists have naturally been attracted by the title of the work before us, which proclaims in no uncertain tones that such a missing link has actually been discovered. A feeling of disappointment will, however, probably come over the student, when he finds how imperfect are the remains on the evidence of which this startling announcement is made; and when he has submitted them to a critical examination, he will probably have little difficulty in concluding that they do not belong to a wild animal at all. The specimens described are three in number, and were discovered in strata of presumed Pleistocene age near a spot called Trinil. The first of these is a last upper molar tooth, found during the drying-up of a river-bed in the autumn of 1891. A month later, the roof of a large cranium was discovered in the same bed, at a distance of only about a yard from the spot where the tooth laid. Finally, in August 1892, at a distance of some sixteen yards higher up the stream, a left femur was disinterred, which is stated to present much more human resemblances than either of the other two specimens. The bed from which this bone was derived is stated to have been the same as that from which the other two specimens were obtained. The author is confident that all are referable to a single animal; and we are content to accept this view.

Especial stress is laid on the femur as indicative of human affinities; and here again we are in agreement with the author, only we would go one step further, and say that it actually is human. As is pointed out in the text, this bone has a large exostosis below the lesser trochanter; and we believe that such slight differences as it shows from normal human femora, are due to this diseased condition. With regard to the skull, which shows a marked human facies, but an extremely small development of the brain-cavity, the absence of ridges on the calvarium clearly shows that it can belong to no wild anthropoid; and there appears every reason to regard it as that of a microcephalous idiot, of an unusually elongated type. The molar, so far as we can see from the figure, may likewise perfectly well be human.

Haeckel's "*Pithecanthropus*" may, therefore, be relegated to the position of an hypothetical unknown creature for which it was originally proposed; while the specific name "*erectus*" must become a synonym of the frequently misapplied "*sapieus.*" R. L.

The Planet Earth. An Astronomical Introduction to Geography. By R. A. Gregory, F.R.A.S. (London: Macmillan and Co., 1894.)

IT is, perhaps, one of the consequences of the antiquity of astronomy that it is not now usually presented to the youthful mind in a thoroughly scientific manner. The established truths of the science, in so far as they concern the earth's place as a planet, though once so astounding to mankind, are now so commonplace that the educational advantages of a study of the phenomena which brought them to light are frequently overlooked altogether. As in the case of geography, information rather than education appears to be the principal aim of astronomical teaching when it is not carried beyond the elementary stage which it reaches in schools; although, when properly handled, there is no subject better calculated to lead the mind into a scientific groove.

We therefore cordially welcome this attempt to indicate the lines which should be followed for a profitable study of that portion of astronomy which deals with the earth as a planet. The bald statements as to the earth's dimensions and movements, so frequently appearing in the text-books of geography, furnish the sole astronomical knowledge which many acquire; but they are, as Mr. Gregory remarks, quite inadequate. The design of the little book before us, is first to direct the students' attention to observations which they may generally make for themselves, and then to show how such phenomena can be accounted for. Thus, in the first chapter, a concise account is given of the means of naming and identifying stars, sufficient to make possible an intelligent observation of the diurnal motion of the celestial sphere; and in the next chapter, it is shown that the observations can be explained by regarding the earth as a spinning globe. The same method is followed throughout.

On the whole, the subject-matter has been judiciously selected, but a slight want of proportion is shown in introducing explanations of the phases of Mercury and Venus, while those of the moon are not referred to at all. The chapter on the determination of the size of the earth would have been a little more educational if the description of the methods employed had been accompanied by hints as to the amount of playground surveying which is possible by the use of a protractor and foot-rule.

The book forms an admirable introduction to astronomy, which stands a fair chance of fulfilling the author's hope "that this little book will help to revive the observational astronomy of pre-telescopic times." This branch of astronomical knowledge is certainly not without danger of being neglected in favour of the fascinating and rapidly-advancing study of the results obtained by the use of the camera and spectroscope. The explanations are models of clearness and accuracy, and the diagrams illustrating them are excellent. Many of them are new, and involve original ideas of the author; as, for instance, a diagram illustrating the sun's apparent path in winter and summer, and another showing the principle of Foucault's pendulum by a lecture experiment. Teachers of geography and physiography will do well to make themselves familiar with Mr. Gregory's methods.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Hodgkins Prizes.

THE time for the reception of treatises or essays offered in competition for the Hodgkins Fund Prizes of 10,000 dols., of 2000 dols., and of 1000 dols. respectively, closed on December 31, 1894, and all papers so offered are now in the hands of the Committee of Award.

In view of the very large number of competitors, of the delay which will be necessarily caused by the intended careful examination, and of the further time which may be required to consult a European Advisory Committee, if one be appointed, it is announced that authors are now at liberty to publish these treatises or essays without prejudice to their interest as competitors.

S. P. LANGLEY.

Washington, January 10.

The Artificial Spectrum Top.

As the spectrum top is exciting a good deal of interest at the present moment, perhaps I may be allowed to record some experiments which I have made with a view of arriving at a solution of the colour problem which it sets. I have observed the colours produced by the white light of the positive pole of the electric arc, and also by monochromatic light produced by means of my colour-patch apparatus. The top was rotated on a horizontal axis at any desired speed by means of an electromotor. The following colours were observed (No. 1, No. 2, No. 3, and No. 4 are the triple lines in order from the centre of rotation):

White light.

No. 1. Crimson.
No. 2. Olive green.
No. 3. Grey (slightly violet).
No. 4. Dark violet.

(When the yellow light of gas is used, the above results would be modified).

Red (C light).

No. 1. Red.
No. 2. Lighter red.
No. 3. Very light olive green.
No. 4. Darker olive green.

Green (Magnesium b).

No. 1. Bluish-green.
No. 2. Lighter bluish-green.
No. 3. Same as No. 2.
No. 4. Ruddy black.

Blue (near the blue lithium).

No. 1. Grass green.
No. 2. Lighter grass green.
No. 3. Same as No. 2.
No. 4. Ruddy black.

Violet (all the violet of the spectrum).

No. 1, 2, and 3. Light violet.
No. 4. Darker violet with a suspicion of red.

When a red a little below the red lithium line was employed, all the groups appeared dark red, and as in the 3 sensation theory this part and the violet are simple sensations, the results obtained in these last, were to be expected.

The next two series are interesting, observations being made in white light compounded by the mixture of two simple colours.

Mixture of red and green to make white.

No. 1. Indigo-blue.
No. 2. Reddish orange.
No. 3. Same as No. 2.
No. 4. Darker orange.

Mixture of yellow and blue to make white.

No. 1. Sky blue.
No. 2. Sage green.
No. 3. Same as No. 2.
No. 4. Bluish-black (perhaps black).

These results were confirmed by an independent observer. When the rotation was reversed the same order of colours was observed, but in the reversed order. These observations seem to confirm the original opinion I had formed regarding these phenomena.

Bearing in mind that none of the observed colours in the lines are pure colours, but mixed with a certain quantity of white, and are seen on a more or less dark ground, then if the order of persistency of the three colour sensations be violet (blue), green, red, the results would be as given above. Should this be so, the velocity of rotation must alter the position of the colours seen in white light, the violet being the last to be seen on No. 1 when rotated more rapidly, and this is the case. The effect of contrast also has to be taken into account.

I have made a good many more experiments under varying conditions of position and dimensions of lines and proportions of black to white; and it seems possible that this toy, when modified, may be adapted to give valuable information as regards certain problems in colour vision.

W. DE W. ABNEY.

WE have recently made a few experiments bearing on the phenomena exhibited by Mr. C. E. Benham's artificial spectrum top (see NATURE, November 29, 1894, p. 113), and the explanation of them suggested by Prof. Liveing (NATURE, December 13, 1894, p. 167), and have obtained results which we believe to be novel and of some scientific interest.

In the first place, if Prof. Liveing's explanation be correct, there seems to be no reason why the same effects should not be obtained with broad bands instead of lines, the bands being drawn in precisely the same manner as the lines upon the white half of the disc.

It appeared to us of some importance to determine if this were really the case, as we thought the effects obtained with Mr. Benham's top might possibly be due to irradiation being different in amount for the different colours, while the change in colour with reversion in direction of rotation was presumably due to the black lines succeeding, upon a given part of the retina, a previously white ground in the one case and a previously black one in the other.

If this were so, by using broad bands instead of lines, one would expect to get a coloured line at each border, while the central portion remained uncoloured. Prof. Liveing's theory would lead one to expect a uniformly coloured band.

Accordingly, we prepared a disc, one half of which was blackened and the other half left white, as in Mr. Benham's top, and on the white half were described three black circular bands about one centimetre broad, with radii of about 4·7 and 10 centimetres respectively, and each with an arc of 45°. The outer band was described in an opposite sense to the two inner bands, that is to say, in such a manner that if the disc was rotating so that the order of succession for the two inner bands was black field, bands, white field, for the outer band it was white, bands, black. The disc was rotated by attaching it to the spindle of an electromotor, the speed of which could be graduated by friction against the spindle.

On rotating the disc at a slow speed, in such a direction that the order of succession for the two inner bands was black, bands, white, the following results were obtained:—The two inner bands were each bounded on both inner and outer edges by a bright red line, fading off towards the centre in a dark, somewhat reddish, ground, which became less coloured and darker as it approached the centre. The outer band presented a marked contrast to these two; the whole extent of the band itself was black, entirely free from colour, but on the white ground on both borders of the band, and apparently outside it, there appeared a brilliant coloured band, varying in colour from blue to green. On reversing the direction of rotation, the appearances were exactly reversed; the inner bands now became black bordered by green, and the outer band reddish black lined by bright red.

We do not contend that this experiment proves that the effect is one of irradiation, for it might easily be supposed that the heightened effect at the border is one of contrast with the surrounding whiter coloured field. Our next experiment, on the effect of change in the speed of rotation, also tends to negative the idea that the colours are due to irradiation, as there is no reason to think that if irradiation were the cause, there would be a change in colour with a change in the speed of rotation, as was found to be the case.

To test the effect of change in the speed of rotation, a disc of one of Mr. Benham's tops was detached, fixed to the spindle of the electromotor, and rotated in such a direction as to cause the three central bands to appear red with a slow speed of rotation. On gradually increasing the speed, a remarkable series of changes in appearance presented itself. The bright blood-red of the three inner lines gradually grew darker and duller, and then passing rapidly through a transition, the shades of which we were unable to observe, gave place to a most vivid green, which in turn, with still increasing speed, passed through another transition stage into blue, deepening into a full violet at the greatest speed we could obtain. On causing the motor to slow down, the same changes in an inverse order from violet to red were observed. These changes in colour *with the same direction of rotation* are very remarkable, and seem to us to be in direct opposition to Mr. Benham's explanation supplied with the top; for if the colours are due to a certain percentage of the etherial vibrations being cut off, this percentage will remain the same for all speeds, and there is no reason apparent why there should be a change in colour with difference in speed. Neither are they easily explainable on Prof. Liveing's theory that red is the first colour to appear, and blue the last to disappear; also, the green we got at the intermediate rate was certainly not a neutral grey or green, but a pure vivid green. Probably other observers have not used a greater speed than that of the first transition stage from red to green, which has a kind of neutral green tint.

An experiment was next made with a disc constructed similarly to that of Mr. Benham, but having white lines drawn on the black semicircle instead of black lines on the white part. On rotating this disc so that *white* lines on *black* ground succeeded the black surface, with slow rotation the colour obtained was red, but a different kind of red to the deep blood-red given by Mr. Benham's top in the case of *black* lines on a *white* ground also following a black surface, viz. a very bright red, evidently not saturated. With higher speeds there followed a light green and light blue, both evidently containing white. The difference in hue of the two series of colours seems obviously that in the case of the white-lined disc the colours are mixed with white, and in that of the black-lined are mixed with black.

Throughout the series of experiments we have tried to eliminate psychical errors as much as possible, by experimenting on persons unacquainted with the expected results.

Belfast, January 15. J. M. FINNEGAN. B. MOORE.

The Kinetic Theory of Gases.

THE difficulty of reconciling line spectra with the kinetic theory of gases, has been referred to by Prof. Fitzgerald (NATURE, January 3, p. 221). The following considerations show that it is possible under certain suppositions to have a number of spectral rays with a very restricted number of degrees of freedom. Most of us, I believe, now accept a definite atomic charge of electricity, and if each charge is imagined to be capable of moving along the surface of an atom, it would represent two degrees of freedom. If a molecule is capable of sending out a homogeneous vibration, it means that there must be a definite position of equilibrium of the "electron." If there are several such positions, the vibrations may take place in several periods. Any one molecule may perform for a certain time a simple periodic oscillation about one position of equilibrium, and owing to some impact the electron may be knocked over into a new position. The vibrations under these circumstances would not be quite homogeneous, but if the electron oscillates about any one position sufficiently long to perform a few thousand oscillations, we should hardly notice the want of homogeneity. Each electron at a given time would only send out vibrations which in our instruments would appear as homogeneous. Each molecule could thus successively give rise to a number of spectral rays, and at any one time the electron in the different molecules would, by the laws of probability, be distributed over all possible positions of equilibrium, so that we should always see all the vibrations which any one molecule of the gas is capable of sending out. The probability of an electron oscillating about one of its positions of equilibrium need not be the same in all cases. Hence a line may be weak not because the vibration has a smaller amplitude, but because fewer molecules give rise to it. The fact that the vibrations of a gas are not quite homogeneous, is borne out by experiment. If impacts become more frequent by increased pressure, we should expect from the above views that the time during which an electron performs a certain oscillation is shortened; hence the line should widen, which is the case. I have spoken, for the sake of simplicity, as if an electron vibrating about one position of equilibrium could only do so in one period. If the forces called into play, by a displacement, depend on the direction of the displacement, there would be two possible frequencies. If the surface is nearly symmetrical, we should have double lines.

The only weight I attach to these speculations lies in the illustration it affords that a number of spectral lines does not necessarily mean an equal number of degrees of freedom. In the existence of the "electron" I firmly believe; and this necessarily implies a very restricted number of variables

ARTHUR SCHUSTER.

"Acquired Characters."

IT would appear that Prof. Lankester has not thought it worth while to read all the letters that have appeared in NATURE on the question raised by Sir Edward Fry, unless it is to be inferred from his remarks that he confines himself to the consideration of the arguments of those who have a place on the scientific Olympus of the Royal Society. In my letter, published December 6, I defended Lamarck's laws against the accusation that they were reciprocally destructive. Prof. Lankester reiterates his accusation without any further support. But this is not the whole question. In his last letter he suggests that acquired characters corresponding to Mr. Galton's definition should be taken, and an investigation made as to whether they are inherited or not in later generations. But in his former letter (November 29) he suggested very distinctly and deliberately that such an investigation was unnecessary, because the question was already settled. He has already condemned the heretic, and now consents to his trial. His words were—"Since the old character had not become fixed and congenital after many thousands of successive generations of individuals had developed it in response to environment, but gave place to a new character when new conditions operated on an individual, why should we suppose that the new character is likely to become fixed after a much shorter time of responsive existence?" To apply this once more to the case of pigment in relation to light. For thousands of generations no pigment has been developed, say, on the lower side of a flat fish, no light having fallen on it. The skin is experimentally exposed to light, and pigment appears: therefore the acquired character of absence of pigment, after thousands of generations, has produced no hereditary change, has not altered the potentialities of the tissue. The argument is fallacious, because the question of how much pigment is entirely ignored, and also the question how long the development of pigment experimentally takes. The force of the argument is entirely on the other side. Assume in this case, as Prof. Lankester does in his general argument, that the old character, the absence of pigment, is an acquired character. Then experiment has shown that this character is inherited: that is to say, the action of light obviously overcomes a resistance in producing pigment, and after years does not produce as much as on the upper side is present from the beginning. This resistance can be nothing else than heredity, the inheritance of a tendency to pigmentlessness. Therefore the acquired character is inherited. It is undeniable and indisputable that the argument propounded by Prof. Lankester proves the inheritance of acquired characters, if it is properly applied in accordance with the facts. This is on the assumption that the "old characters" are acquired. If they are not acquired, the argument has no force at all. The facts allow us to say that the tendency to pigmentlessness, or the resistance to the development of pigment on the lower side of a flounder, is certainly inherited, but whether or not it is due to the absence of light during many successive generations we do not know. As Sir Edward Fry says, if we by definition confine the term "acquired character" within the limits of an individual history, then of course an acquired character can never be inherited. The question is whether the conditions which produce a change in the individual can affect the offspring? The experimental investigation must take the following course. Suppose a given amount of stimulation X to act upon individuals in successive generations, producing in the first generation a result x. Then the question is if X remains the same, does x remain constant or not? If there is no inherited effect, then x must remain constant in all succeeding generations. If x increases by some amount, however small, and becomes $x+a$, then a is not acquired by the individual, but inherited, and it is clear that the result will go on increasing to $x+2a$, $x+3a$, and so on to $x+na$, where n represents the number of generations. In my own opinion, there is evidence that something of this kind does occur, though definite investigations are much to be desired.

Plymouth, January 11. J. T. CUNNINGHAM.

As one who has been reading the discussion in your pages on the meaning of the term "acquired characters," I may perhaps be permitted to direct attention to the history of the term. It was first used with reference not to species but to individuals. Every character of an individual is either derived from the fecundated ovum or acquired during life. This was obvious; and the question arose: Could acquired characters be transmitted? As long as the term is applied to an individual, it has that kind of precision which is desirable in all scientific terminology, namely, that it perfectly explains itself.

Glasgow, January 12. JOHN CLELAND.

Chinese Theories of the Origin of Amber.

IN my letter on "Some Oriental Beliefs about Bees and Wasps" (NATURE, vol. l. p. 30, May 10, 1894), I have traced the origin of the Chinese belief in the production of amber from bees into the presence in amber of hymenopterous remains. Apparently developed from this belief, there is another misconception recorded by Cháng Hwá (killed 300 A.D.), whose passage on the subject reads as follows: "In 'Shinsien-chuèn,' it is said, the resins of the pine and arbor-vitæ, after remaining underground for one thousand years, are turned into *Pachyma cocos* (Fuh-ling),[1] which is turned into amber.' Notwithstanding this statement, the Mount Tai produces Pachyma, but no amber; whereas Yung-chang . . . produces amber, but no Pachyma. Another theory is that amber is made by burning the honey-combs. Which is true of these two theories is not yet decided."[2]

Of all Chinese theories propounded to account for the origin of amber, the most veracious one is given in Li Shi-Chin's work,[3] thus: "Amber originates in the resin of pines; when the pines, with their branches and knots luxuriantly growing, were heated by the sun, the resin came out of the wood; it coagulated after days and sunk underground, and after undergoing subterraneous changes, left behind the lustrous substance [which is amber]. In this condition still it has in it the tenacity of resin, so that when it is rubbed and warmed between the palms, it can pick up particles of dust. Those insects in its enclosure had cohered with it before its sinking underground.'

Besides the resin of pines, the exudation from the "Fung" (*Liquidambar Maximowiczii*) is asserted by Kán Páu-Shing (lived in the tenth century A.D.) to be a nascent form of amber,[4] the opinion well coinciding with the Western idea that has given to styrax the name "Liquidambar."[5]

In "Shi-shwoh" (written in the fifth century A.D.) amber is said to be formed from the subterraneous metamorphosis of the gum of peach trees,[6] which reminds us of the simile, "Like gum from the cherry," used by Pliny in his exposition of the resinous origin of amber.[7]

Some other theories are full of absurdity. One of these holds that the dragon's blood buried underground turns to amber, and the demon's to agate.[8] Also, the etymological origin of "Hú-pèh," the Chinese name for amber, is involved in myth. In ancient times this word was written in two letters, together signifying "Tiger's Soul," which is explained in this way: "At night the tiger applies its one eye for illumination, and another for vision. When it is shot with arrow the light of the eye, which is the tiger's soul, sinks underground, and turns into a white stone. . . . Amber resembles this stone; hence the name."[9]

According to "Hwái-nán-tze" (written in the second century B.C.), "the dodder is the outgrowth of amber."[10] Almost inexplicable as this story may appear, I have found certain clues to its elucidation. Káu Yú (lived in the second century A.D.) gives "Nü-ló" (*i.e. Usnea longissima*)[11] as a synonym of "Tú-sze" (*i.e.* the dodder).[12] From this it is evident that the early Chinese have confounded Usnea with dodder—the confusion caused by the superficial resemblance and similar habitats of the two plants.[13] Now, there is a Chinese belief recorded about 240 B.C., that *Pachyma cocos* is the root of dodder,[14] which has doubtless grown out of the common occurrence upon and under the pines of the Usnea and Pachyma. And as this Pachyma had been held as an intermediary phase through which resins were to pass into amber (see above), it would seem that the story which affirms the dodder to be the outgrowth of amber, was not inconsistent with the understanding of the early Chinese theorisers. Rhynchodemus Terrestris in Germany.

IN NATURE of October 25, 1894 (p. 617), Mr. Scharff mentioned *Rhynchodemus terrestris*, as stated, in Germany, near Würzburg, by Semper. It would seem that the worm was exceedingly rare. But I found it repeatedly at several points of Saxony and Thuringia, in the mountains and in the plain, in leaved and fir wood, under moss or dead leaves. Sufficient attention would detect it without doubt in many regions. Recently Mr. Ehrmann found several specimens feeding on a dead *Arion empiricorum*. H. SIMROTH.

he precise significance of these words, as lately determined by he Council of the Society.

Two courses appeared to be open: either to submit proofs to the authors of the abstracts of their papers sent to the Society, if any substantial (*i.e.* more than typographical) alteration had been made; in which case, the authors themselves would naturally bear the responsibility of their statements; or to throw the whole responsibility on the Editors, leaving them to make any excisions or alterations they may choose in the abstracts sent to them; or indeed, if they so think fit, entirely to rewrite them. The Council, in order to secure rapid publication, have chosen the latter alternative; and it should be understood that the abstracts are now "official"—*i.e.* the responsibility for all statements put forth rests solely on the Editors of the *Proceedings*. WILLIAM RAMSAY.

University College, London, W.C., January 14.

Philosophy and Natural Science.

WHILST feeling obliged to your reviewer's appreciation of my essay (p. 220), I am bound to rectify some very glaring discrepancies.

(1) As plainly stated in my preface, my essay has *not* obtained the Philosophical Society's prize, but only an "honourable recognition," and two fifths of the prize sum.

(2) Eighth line from bottom (p. 220), for "physical," read "*psychical*," as said in my paper (p. 30).

(3) Your reviewer makes me say: "Physical development is not the cause, but the effect of psychical development"; whereas, I have expressedly *combated* this view of Wundt's (p. 32).

(4) Neither did I say: "The modifications in the brain and nervous system throughout the animal kingdom are intelligible as resulting from psychical causes . . ." but only (p. 32) that *in many cases* the beginnings of modifications are intelligible from the psychical side—*e.g.* the modifications of many organs—resulting from sexual selection.

(5) Lastly, far from saying that the high mental position of man, on the one hand, and of ants on the other, "is independent of the structure of the nervous system," my sentence (p. 34) is: "Here, where the organic substratum (*i.e.* the brain) in both types differs even in its principal morphological features, it is most evident how occult are the processes which constitute the proper material side of psychical phenomena."

Freiburg, Badenia, January 5. DAVID WETTERHAN.

---

(1) THE facts are that the Philosophical Society of Berlin offered a prize of 1000 marks for an essay on "The relation of philosophy to the empirical knowledge of nature."

The essay reviewed, only obtained 400 marks of this prize, and an honourable mention. In a hasty glance at the preface I overlooked the words "ein Antheil von vierhundert Mark," which occur in the next line to "der als Preis ausgesetzen Summe," which caught my eye.

(2) This is evidently a slip of the pen, which I regret was overlooked in proof.

(3) In my notes, jotted down as I read the pamphlet, I put Wundt's words in quotation marks, intending to point out Mr. Wetterhan's opposition thereto; but in writing the review, I unfortunately omitted the commas, and, I regret, entirely misrepresented the author's views. Perhaps I may quote from p. 32 of the pamphlet: "Man durfte Wundt's Satz, 'dass die physische Entwicklung nicht die Ursache, sondern vielmehr die Wirkung der psychischen Entwicklung ist,' zu weitgehend, und auch in seinen Konsequenz bedenklich finden." We are then referred to page 46, where we read: "Der Ausführung dagegen, welche Wundt (s.o. p. 32) jenem Prinzipe gegeben hat, vermag ich kaum eher beizustimmen, als der verwandten Ideen Schopenhauer's."

(4) It appears to me that the passage will bear the construction which I put upon it; though perhaps "throughout" the animal series is too inclusive as a rendering of "der Tierreihen."

(5) The author had been discussing the similarity of habits and instincts in ants and termites, and then remarks that there is a distinct agreement in the mental functions ("von geistigen, ja gemütlichen Funktionen") of bees with those of the higher animals. He refers to Darwin's opinion that the small brain of a bee is a more wonderful thing than the brain of a Man: and I think I was entitled to make the obviously true remark that this "mental development is independent of the structure of the nervous system." I was not quoting Mr. Wetterhan's words, but giving the general sense of the passage.

In conclusion, I must express my regret that the condensation of some of the author's remarks should have resulted in a confused expression of his views. THE REVIEWER.

SOME EARLY TERRESTRIAL MAGNETIC DISCOVERIES PERTAINING TO ENGLAND.

IT should be a source of considerable pride to British men of science that so many of the discoveries in terrestrial magnetism have been made in England. And yet, owing to the absence of a complete and carefully written history of the development of this science, probably few could enumerate all the achievements in this subject by Englishmen.

In February 1893 the writer had the good fortune to light upon a book,[1] by Will Whiston, containing matter pertaining to the terrestrial magnetism of England, which appears to have been entirely overlooked by prominent terrestrial magneticians. Owing to pressure of work, this interesting book, of which a copy was found in the Royal Library of Berlin, could not be subjected to a critical examination until the early part of 1894, when the writer called the attention of prominent Berlin investigators, such as Prof. Hellmann and Dr. Eschenhagen, to it.[2] In the meantime, Dr. W. Felgentraeger, Assistant at the Göttingen Magnetic Observatory, made an independent discovery of Whiston's book, and carefully worked up part of the material contained therein.[3] The writer has since found time to complete his examination of Whiston's contribution, and has embodied his results in a paper[4] presented by Prof. Cleveland Abbe before the Philosophical Society of Washington on November 10, 1894. In the following these results will be briefly sketched.

As will appear from the title of Whiston's work, the chief object was the exposition of a method for determining the longitude and latitude by means of the magnetic dip-needle, *i.e.* by means of the angle which a magnetic needle mounted on a horizontal axis, when placed in the vertical plane of passing through the magnetic meridian, makes with the plane of the horizon. It will be recalled that at that time great prizes had been offered by the English Parliament for an easy and trustworthy method of determining longitude at sea. From the very birth of terrestrial magnetism we find methods proposed for determining longitude by means of magnetic observations, and, like the problem of perpetual motion, these magnetic methods were revived every once in a while until the beginning of the nineteenth century. Owing to the irregular distribution of magnetism within the earth's surface, and on account of the many fluctuations terrestrial magnetism is subject to, these magnetic attempts to determine geographical position have been doomed to failure. They, nevertheless, have done much to promote the science of terrestrial magnetism. A striking instance of this is the book of Whiston's. The prime object of the book has failed of

[1] "The Longitude and Latitude found by the Inclinatory or Dipping Needle; wherein the Laws of Magnetism are also discover'd. To which is prefix'd an Historical Preface; and to which is subjoin'd Mr. Robert Norman's New Attractive, or Account of the first Invention of the Dipping Needle." By Will Whiston, M.A., sometime Professor of Mathematicks in the University of Cambridge. (London, 1721. 8vo, xxviii. 115, iv. and 43 pp. 2 charts and 3 cuts.)

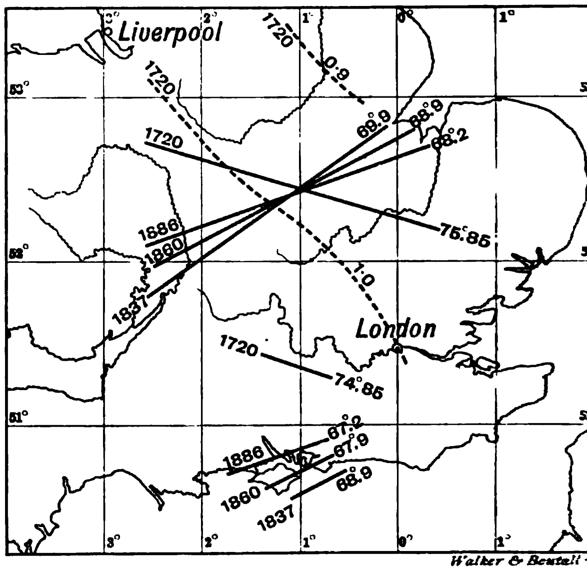
[4] Entitled "The Earliest Isoclinics and Observations of Magnetic Force." (*Bull. Phil. Soc., Wash.*, vol. xii. pp. 397-410.)

its purpose,[5] yet the incidental discoveries, the importance of which the author himself did not fully appreciate, may perpetuate the name of Whiston for ever. It is most remarkable that his contributions have been, apparently, entirely overlooked.

Whiston, who, as stated in the title of his book, was at one time Professor of Mathematics at Cambridge, being Sir Isaac Newton's successor, was banished not long after assuming the chair, on account of heresy—he was a Unitarian. He was led to pursue the longitude problem magnetically through Halley's famous Isogonic Chart of 1700,[6] which came under his notice. As is well known, this chart of Halley's, giving the lines of equal magnetic declination, *i.e.* these lines on the earth's surface connecting all the places at which a magnetic needle swung horizontally has the same bearing, is the earliest published chart of its kind. In consequence, these lines have likewise been termed the "Halleyan Lines." Since then Halley's method has been effectually applied to the representation of other terrestrial phenomena, *e.g.* distribution of temperature ("Humboldt's Isotherms," 1817). Wilcke is credited as first applying Halley's method to the representation of the distribution of the magnetic *inclination*, and Wilcke's isoclinics are therefore referred to occasionally as the "Wilckean Lines." Wilcke published his chart, covering the greater portion of the earth, in 1768.[7] It appears, however, that the credit of first drawing the isoclinics should be accorded to Whiston. Wilcke nowhere states in the article cited that he for the first time has drawn the lines of equal magnetic inclination, and it is, moreover, reasonable to suppose, by his reference to Whiston's book, that he was familiar with its contents.

Whiston was led to drawing the isoclinics upon finding that the "Halleyan Lines," through "the Quickness of the Mutation of those Lines and their different Position in the rest of the World," could not be satisfactorily used for the determination of longitude. He therefore began to consider the "lines of equal dip,"[8] thinking they would answer his purpose better. To this end he collected all observations of dip made up to his time, and with their assistance drew, as far as then possible, the "lines of equal dip" upon Mr. Molyneux's terrestrial globe. Furthermore, to practically test his method, he made dip observations himself in 1719 and 1720 in various portions of England, and with their aid drew and published the *first isoclinics*, to be sure for only a small portion of the earth, viz. for southern England and north-western France. These isoclinics were laid down on two small charts (11·4 × 18·2 cm.), and are given opposite p. xxviii. of his book. The first chart is the result of dip observations made in 1719 with a needle 12 inches long; the second[9] is based upon more numerous observations made in 1720 with a 47½-inch needle. The results with the two needles differ, on the average, by about 1½°, the long needle giving the larger value. To counteract the error due to flexure of the long needle, Whiston placed a small "Poise of brass circular Wire," which required shifting to and fro according to dip, on the north end of the needle. Whiston believed that the longer the needle, the better the result if the needle be poised as stated. It is needless to say that experience has not borne him out in this respect. Owing to the large discrepancy between the results of the two needles, it might appear, then, that but little value can be attached to these Whistonian isoclinics. The writer finds, however, in his paper that the mean of the two results can doubtless be accepted as being within 1° of the truth. Moreover, while the *absolute* value may be impaired to the extent mentioned, the *relative* value remains intact, as the effect of the constant instrumental error would be almost entirely eliminated when considering the *relative* distribution of the dip over England. It is this latter fact that may give a value to these early isoclinics. Thus in 1720, according to Whiston, the isoclinics over England ran approximately from west-north-west to east-south-east, while to-day they go roughly from west-south-west to east-north-east. In the accompanying sketch, the mean isoclinics are shown by full lines for the epochs 1720, 1837, 1860, and 1886, as drawn by Dr. Felgentraeger in the paper cited.[3] It will be seen that between 1720 to about 1837 they shifted from year to year, *anti-clockwise;* they are now moving *clockwise*. Sabine,[10] I believe, was the first to call attention to this reversal of motion. It is hoped that this matter will receive further investigation.



Walker & Boutall sc.

Whiston comes in, however, for a still greater share in the early terrestrial magnetic discoveries. He invents, namely, a new and indirect method of determining the dip—the vibration method. He swings a magnetic needle horizontally, and determines the time of one horizontal vibration. He then swings the *same* needle mounted as a dip-needle, and again determines the time of one vibration. From the two times of vibration it is a simple matter to compute the prevailing dip. Whiston proposes this method as an approximate check upon the direct method where the angle of dip is measured at once. For example, Whiston found at London the time of one horizontal vibration of his long needle 120° from the magnetic meridian to be 60¼ seconds, which reduced to the magnetic meridian gives 42·6 seconds. The time of one vibration of the same needle, mounted as dip-needle, was found to be 22 seconds. If F is the total magnetic force, we then have the following relation:

$$F : F \cos \text{Dip} = (42{\cdot}6)^2 : (22)^2, \text{ or Dip} = 74^\circ\ 32'.$$

Now, the mean of the results of the direct measurements with the 12-inch needle (73¾°), and of the 47½-inch

[5] When Graham discovered, a few years after the publication of Whiston's book, that terrestrial magnetism is subject to a daily variation, Whiston perceived the inutility of his method. See "Memoirs of the Life and Writings of Mr. William Whiston. Written by himself." (London, 1749, vol. I. p. 297.)

[6] Published in London in 1701, and reproduced photolithographically in Greenwich "Observations," 1869. To be soon republished in "Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus." Edited by Prof. Dr. G. Hellmann. (Berlin, A. Ascher and Co.)

[7] "Sv. Vetensk. Akad. Handl.," 1768, p. 193.

[8] Whiston even calls these lines also "Magnetick Parallels."

[9] Reproduced in facsimile in Dr. Felgentraeger's paper (see Ref. 3). Both charts are to be given, also, in facsimile, in Hellmann's "Neudrucke," No. 4 (see Ref. 6).

[10] *Proc. Roy. Soc.*, vol. xi. p. 144: "The angle of intersection of the meridian and isoclinics has been diminishing up to about 1840, when a reversal took place, and the angle is now increasing."

needle ($75\frac{1}{8}°$), is $74° 28'$. Hence the agreement is quite satisfactory. We can probably say that the magnetic dip in London in 1720·0 was $74·5° \pm 0·5°$.

The invention of this new method of determining dip, led to still more important results. In making the dip observations with the long needle in 1720, for the purpose of his second chart, he at the same time observed the time of one horizontal vibration of the same needle, with the express purpose of determining the distribution of the force. These vibration-times are tabulated on his second chart.[11] From them the distribution of relative intensity can be determined. *These observations of Whiston's are undoubtedly the earliest relative terrestrial magnetic force observations ever made.* It is usually believed that the earliest relative intensity observations are the defective ones of Mallet (1769), or the more successful ones, but lost in shipwreck, of Lamanon (1785–87). The absolute value of these Whistonian intensity observations can, of course, not be checked; however, the relative value admits of some control. Thus the writer in his paper has reduced the observations, taking the value of the horizontal force at London as unity, and, with the aid of the reduced values, has roughly sketched the isodynamics (the broken lines in the figure) as prevailing over southern England in 1720. It will be seen that these lines of equal magnetic horizontal force have the same general trend as the isoclinics, as, indeed, they roughly should. Again, taking two stations (London and Saltfleet), which are practically in the same meridian and are distant from each other 2° in latitude, through which, consequently, the same isodynamic would not be likely to pass, it is found that the difference of the vibration-times—$60\frac{1}{4}$ and 66 seconds respectively, is in the right sense, *i.e.*, since the force varies inversely as the squares of the vibration-times, *the more northerly station, Saltfleet, gives the smaller horizontal force*, as it should. To be sure these early intensity observations are affected with a large probable error; they may, however, not deserve to be assigned to utter oblivion.

Upon the presentation of the writer's paper before the Washington Philosophical Society, Prof. Abbe became interested in the matter, and kindly called the author's attention to a later book[12] of Whiston's, a copy of which was likewise found in the Royal Library of Berlin. Whiston, in this book, gives an account of dip-observations made in various portions of the earth, with the aid of most liberal means furnished by King George and others, for the purpose of testing his magnetic method of determining geographical position. He sent "four several Dipping-Needles to Sea," and "with proper Instructions to the Masters of the Vessels" to observe the dip with both methods (direct and indirect), "to discover the State of Magnetism in the several parts of the Globe." Thus Captain James Jolly set out in July, 1722, for Archangel with one of Whiston's dipping-needles. Owing to a defect of the instrument he could observe only horizontal vibrations. Whiston says (p. 84), "he made me twenty-eight very good Horizontal Observations from the Latitude of 65 quite to Archangel." . . . "In this Space the Needle altered its Velocity very greatly, as I expected it would: And 5 Vibrations which at first were perform'd in about 280", beyond the North Cape, came to 250"; till towards Archangel it gradually returned to about 177"." The first figure, 280", is probably a misprint, and should be 180". *These observations are the first to show the truth of the law that horizontal intensity decreases in approaching the magnetic pole.* Humboldt has credited Lamanon (1785–87) with the discovery of this law; it was not, however, firmly established until Humboldt's observations of 1798–1803. Furthermore, Captain Othniel Beal set out about the same time as Captain Jolly for Boston. From thence he sailed to Barbados, and thence to Charlestown, South Carolina. At all these places and at sea he made dip observations with both methods. A dip of $68° 22'$ is given for Boston, and of $44\frac{1}{2}°$ for Barbados, on p. 92. *These two dips precede by fifty-eight years any dip that has hitherto become known in the United States.* The vibration-times are unfortunately not given. A third dip instrument was sent with Captain Tempest to Antigua and St. Christopher's, a fourth sent with Captain Michel to Hamburg. The results with the last two instruments had not yet been all received at the writing of the book. Whiston does not give the actual observations, but says, on p. 90, "The original Journals are all in the Hands of my great Friend and patron, Samuel Molyneux, Esq., Secretary to his Royal Highness the Prince of Wales, and Fellow of the Royal Society: which Journals, when I have compleated the rest of the Observations I hope to procure, I intend to publish entire, for the more full Satisfaction of the curious." It seems that Whiston never published these records. It is hoped that the present article will induce some one to look them up. They may possibly be a valuable find.

In conclusion, let us sum up Whiston's achievements.

(1) Whiston drew the first isoclinics (1719–20).

(2) He invented the vibration method of determining the dip.

(3) He made the first relative terrestrial magnetic intensity observations (1720).

(4) The first intensity observations (1722), revealing the law of decrease of horizontal terrestrial magnetic force with approach towards magnetic pole, were made under his instructions.

L. A. BAUER.

[11] The only thing that Whiston says with respect to the method employed, is the following Passage on page 112, viz.: "The Difference of this *Strength* of the Magnetick Power, from its *Direction*, is most visible in my Second Map hereto prefix'd. Where I have all along set down the 'Seconds' wherein my Needle perform'd a single horizontal Vibration, at about 120 Degrees from the Magnetick Meridian, in most Places, whose Squares, when Allowance has been made for the different Obliquity of the several Directions as to our Horizon, will give us the different *Strength* of that Magnetick Power at those several Places; as does the angle of dip give us the different *Direction* of the same power there. Now, at first Sight, the former there appears to be irregular, and the latter regular; as is the Case also of our Terella." Why Whiston should have observed the vibration time 120° *from the magnetic meridian*, instead of across the magnetic meridian, the writer has not been able to ascertain. Whiston does not appear to have made any further use of his observations.

[12] "The Calculation of Solar Eclipses without Parallaxes . . . . with an Account of some late Observations made with Dipping-Needles, in order to discover the Longitude and Latitude at Sea." (London, 1724.)

THE TEACHING UNIVERSITY FOR LONDON.

DURING the last week very satisfactory progress has been made towards the reorganisation of the University of London as a teaching as well as an examining body. In the first place, King's College has been brought into line with the other teaching institutions of the metropolis by expressing a general assent to the recommendations of the Gresham Commission, coupled with the proviso that any Statutory Commission appointed to give effect to the Gresham Commissioners' recommendations should have power to make such modifications in the scheme as may seem to them expedient after consultation with the bodies affected—a proviso already insisted on by every teaching institution that has expressed its general approval of the scheme.

The adhesion of King's College to the views of the other teaching institutions mentioned in the Report of the Gresham Commission, was made known on the eve of the reception by Lord Rosebery of the deputation of delegates from the London colleges, and made it possible for these to present their case with the strength derived from complete accord.

On Tuesday last, Lord Rosebery received two deputations—one in the morning in favour of the Gresham scheme, in which representatives of the Senate, the

Annual Committee of Convocation, and the Committee of Graduates of the University of London; the Royal Colleges of Physicians and Surgeons; University College; King's College; Bedford College; the Medical Schools; the Theological Colleges; and the Association for Promoting a Professorial University for London took part, and a second in the afternoon, composed solely of members of Convocation opposed to the scheme.

Lord Rosebery's replies show that personally he is anxious to give effect to the Commissioners' recommendations. To the first deputation he said that the Government attach great importance to the Report of the Commission, and are fully sensible of the fact that the present time seems to offer a favourable opportunity, and one that ought not to be postponed, for the appointment of a Statutory Commission in the sense desired by those who had addressed him; while to the second, he made it clear that the opinions of the Government point in the direction of the appointment of a Statutory Commission, which would be able to receive full representations from any interests involved, and thereby be enabled to arrive at a scheme not unsatisfactory both to the present University and to the Empire at large.

Lastly, on Tuesday evening, Convocation of the University of London met, and for the first time came face to face with the question of approval or disapproval of the Commissioners' recommendations. As pointed out in a previous article (vol. l. p. 269), the power of veto possessed by Convocation under the Charter lent considerable importance to the decision arrived at, since an adverse vote might seriously retard the reorganisation of the existing University. In view of this contingency, it is highly satisfactory to record that Convocation, the last of the bodies to which the scheme has been submitted, by 157 votes to 133 resolved—"That Convocation, while desiring to express generally its approval of the proposals contained in the Report of the Royal Commission, is of opinion that power ought to be given to the Statutory Commission to vary the details of the scheme, and that it ought to be made an instruction to the Commissioners, before framing the statutes and regulations, to confer with duly accredited representatives of the Senate and of Convocation as to the modifications which may be desirable;" a previous resolution affirming that there should be one University in London, and not two, being carried by a slightly larger majority, namely, 206 votes to 175. These majorities may not be large, but they may be fairly taken to proportionately represent the opinion of the 3600 members of Convocation, since so far as any expression of opinion has been elicited by the various parties, 1165 members have expressed general approval of the Commissioners' recommendations, while 900 have indicated that in their view any teaching University for London ought to be constituted apart from the existing University. It may be earnestly hoped that with this vote the long controversy within the University has come to an end, and that all parties will now unite in the endeavour to make the new University worthy of the capital of the Empire. W. PALMER WYNNE.

NOTES.

WE are informed that Mr. G. F. Scott Elliot has arrived at Blantyre, in the Shiré Highlands, on his way home. His route from Ruwenzori has been by Karagwe and Urundi, to the extreme north of Tanganyika, which was traversed in Arab dhows to Abercorn. Thence he followed the usual route by the Stevenson Road to Lake Nyassa and the Upper Shiré.

PROF. E. WARBURG, Professor of Physics in Freiburg University, has been appointed Prof. Kundt's successor in Berlin University.

M. HAUTEFEUILLE, Professor of Mineralogy at the Sorbonne, has been elected a member of the Section de Minéralogie of the Paris Academy of Sciences.

DR. S. NAWASCHIN has been appointed Professor of Botany and Director of the Botanic Garden at Kiew, Russia.

THE death is recorded, at Berne, on December 13, of Dr. F. A. Flückiger, well known for his researches in pharmacologica botany, at the age of sixty-six.

DR. MURRAY THOMSON died on the 13th inst., in his sixty-first year. He was a Fellow of the Royal Society of Edinburgh and a Fellow of the University of Calcutta. For some years he was Professor of Experimental Science in the Government Engineering College, Roorkee, and chemical examiner for the Government in the North-Western Provinces of India. He was also the author of several medical and chemical treatises.

THE *Times* correspondent at Teheran reports that the town of Kuchan, which was destroyed by an earthquake fourteen months ago, and immediately rebuilt, was again destroyed on January 17. The extent of the damage and the loss of life are not yet known. Earthquake shocks were also felt at Meshed, but no damage was done.

WE learn that a general survey of the tides and currents on the Canadian coasts is now being commenced by the Canadian Department of Marine and Fisheries. It cannot fail to be of great use to navigation, and of especial interest to science, as the districts will include the phenomenal one of the Bay of Fundy with its 70 feet rise of tide, with which we have nothing to compare in magnitude in the British Isles.

THE Königliche Gesellschaft der Wissenschaften of Göttingen are organising a conference of delegates of scientific societies and academies, for the consideration of the relations between the variations in the intensity of gravity and the geological constitution of the earth's crust. It is intended that the congress shall take place at Innsbrück on September 5, where and when the International Geodetic Association will hold a meeting.

THE first number of the new series of *Science* has now reached us. To the editorial committee announced in our issue of December 20, should be added President T. C. Mendenhall of the Worcester Polytechnic Institute (Physics), Prof. R. H. Thurston of Cornell University (Engineering), Prof. Le Conte of the University of California (Geology), and Prof. H. F. Osborn of Columbia College (General Biology). The editorial committee, composed of the American men of science best known in England, and the contents of the first number, promise a journal that will adequately represent the progress of science in America. If in a multitude of counsellors there is wisdom, the journal should greatly advance scientific knowledge; not, however, by publishing memoirs and papers for specialists, but by promoting intercourse between students of all branches of nature.

ON Friday, the 11th inst., the Physical Society of London, in response to an invitation from Prof. Carey Foster, visited the new physical laboratories of University College. Before the commencement of the regular meeting in the lecture theatre (a report of which will be found in another column), the large number of members present went over the laboratories and practical class-rooms. There are three large rooms solidly built on the ground, and devoted to the use of the more advanced students, and of those engaged in original research. They are in a separate building apart from the main structure, and were specially built for physical work. Above one of them is the optical room, while within the main building there are two large basement rooms, one used chiefly for electrical and magnetic measurements, and one reserved for the practical classes. On the floor above are the lecture theatre and smaller classroom, apparatus room, chemical room, &c. The laboratories are lighted in the main with electric light, the direct current, supplied by the St. Pancras Vestry, being also used to charge a set of about fifty accumulators. A collection of apparatus was on view, more especially that designed for educational experiments, and used by students in the practical classes. Some of the pieces shown were of historical interest, among them being various instruments designed and used by Ritchie, who was formerly Professor of Natural Philosophy in the College.

ON Thursday last, January 17, the French Society of Aerial Navigation inaugurated the lectures to be delivered to the pupils of the newly-established school of aeronautics. During an address, Prof. Cornu, who was in the chair, said that he was glad that the Academy of Sciences had always exhibited an interest in aerial navigation. In 1782, a programme was drawn up of experiments to be conducted with the help of balloons. In 1794, there was established at Meudon the first aeronautical school, and the first captive balloons were made. In 1802, Gay-Lussac and Biot made the first scientific ascents, which remained almost unequalled until sixty years afterwards, when Glaisher took his aerial travels. The first dirigible balloon was constructed in 1870. Later, Paul Bert investigated the condition of human life at high altitudes. With these facts before them, the pupils of the French aeronautical school were reminded that their efforts would always be supported by the Academy. Aeronautics had been always popular in France, and had rendered good services to science and to the country.

SOME forgotten pages of photographic history were brought before the Brixton Camera Club, by Mr. W. H. Harrison, on January 15. It was pointed out that the many photographic researches of Foucault have been so completely overlooked that in scarcely any recent photographic history is mention to be found of more than his name, if so much as that. Foucault's early experiments in photographing the spectrum upon daguerreotype plates are interesting, and his results were not complicated by the presence of collodion, gelatine, or other colloids. In those early days photographers were so anxious to improve processes and to quicken them for purposes of portraiture, that perhaps these researches in the higher branches of photography interested them little, and soon afterwards were forgotten entirely, so that the name of Foucault as a pioneer of photography has practically passed out of the literature of the subject for nearly a generation. H. Bayard, the first to exhibit a selection of photographs to the general public, in July 1839, has also been much neglected in modern photographic literature. By means of his process, direct positives could be obtained without the intervention of a negative. Bayard's process seems likely to initiate useful modifications at the present time, in the easy production of reversed negatives. Sometimes it is now facetiously said that the best place for backings to prevent halation is on the front of the plate, meaning the use of a thick coating of emulsion: perhaps on Bayard's principle something of the kind may hereafter be done in a more literal sense. It should be remembered that there are two kinds of halation, and that one of them is due to reflection among the particles of silver haloid in the film itself. Perhaps something of especial benefit in astronomical photography may hereafter be evolved from Bayard's principle. Who knows but that it may hereafter lead to the production of a new class of dry plates which can be freely exposed to light, and, when required for use, sensitised by an alcoholic or other volatile liquid containing a haloid salt, to enable the re-drying to be effected quickly?

DR. A. MACDONALD, of the U.S. Bureau of Education, has sent us a number of statistics, showing the sensibility to pain, by pressure, in hands of individuals of different classes, sexes, and nationalities. So far as they go, the results indicate that the majority of people are more sensitive to pain in their left hand than in the right. Women appear to be more sensitive to pain than men, but of course it does not necessarily follow that women cannot endure more pain than men. American professional men are more sensitive to pain than American business men, and also than English or German professional men. The labouring classes are much less sensitive to pain than the non-labouring classes, and the women of the lower classes are much less sensitive to pain than those of the better classes. The general conclusion is that the more developed the nervous system, the more sensitive it is to pain. It is worth remark that, while the thickness of tissue on the hand has some influence, it has by no means so much as one might suppose, *à priori*; for many with thin hands require much pressure before experiencing any pain.

AN auriferous quartz-vein has been met with near Douglas in the Isle of Man. This seems to be the first recorded discovery of gold in that island, though, in view of its presence in the very similar districts of Merioneth and Wicklow, it is not in any way surprising.

Electrical Discovery is the title of a new fortnightly journal, in which it is intended to publish information on electrical patents filed in the British Patent Office. The *Official Journal* furnishes short abstracts of such inventions, but these do not appear until after the period for opposing the grants of the patents has expired. The new journal is designed to supply the need, by giving electricians early abstracts of all patent specifications and amendments relating to electricity. Digests and reports of patent cases of interest to electricians will also be included, and an index of articles on electrical subjects.

A FEW years ago it was practicable for persons of moderate income to subscribe to all the periodicals devoted to engineering and allied sciences, and to keep abreast with the contents. Now the number of such journals is so great, and so many are the memoirs and works bearing on engineering, that engineers, like the rest of us, are feeling the need of an index of their literature. Suggestions for the construction of such an index are given by Prof. G. D. Shephardson in the *Transactions* of the American Institute of Electrical Engineers for November 1894, and the following number contains a report of a long discussion on the subject. It is a satisfactory sign of the development of the scientific side of engineering, that electrical, mechanical, hydraulic, civil, and mining engineers want an index to their literature.

THE great Andalusian earthquake of December 25, 1884, as is now well known, produced slight disturbances of the magnetic curves at Lisbon, Parc St. Maur, Greenwich, and Wilhelmshaven. Two astronomical clocks were also stopped at the observatory of San Fernando, near Cadiz. From the times so recorded, the French Commission appointed to study the earthquake obtained values which seemed to show that the velocity of the earthquake wave diminished as it radiated outwards. In two recent papers (*R. Accad. dei Lincei, Rend.* iii. 1894, pp. 303–310, 317–325), Dr. G. Agamennone reconsiders the problem. He shows that the apparent diminution of velocity would disappear if the time at Cadiz were a minute too late. And an error of this kind, he remarks, is possible, for the times given for the magnetic observatories correspond to the beginning of the movement, whereas the clocks at Cadiz would be stopped during a later phase. Assuming the velocity uniform, he finds it to be 3·15 ± ·19 kilometres per second, a value which agrees very closely with some recent determinations.

THE light of the Blue Grotto of Capri, as well as that of the so-called red and green grottoes (*grotto rosso* and *grotto verte*) has been spectroscopically tested by Dr. H. W. Vogel, and is described in the current number of *Wiedemann's Annalen.* The most striking fact about the Blue Grotto was the occurrence of an absorption band between the Fraunhofer lines C and E of the solar spectrum, which does not occur in ordinary water. In addition to this, the red and the orange were extinguished as far as the D line. The same spectrum was exhibited by the water in front of the grotto. The "green grotto" is a rocky tunnel filled with bluish-green sea-water. The rocky walls show green reflections in the interior, produced by the impact of the bluish light from the water upon the yellow stones. But the absorption band noted in the Blue Grotto is here entirely absent. From the top of the cliffs, patches of azure-blue water could be seen surrounded by green. They all showed the absorption band, and retained their position permanently, so that they are probably due to some local cause. The "red grotto" does not show a trace of red light.

ATTENTION was recently drawn in our columns to an interesting observation made by Dr. Ostroumoff, of Sebastopol, on the power possessed by the Copepod *Pontellina mediterranea*, of jumping in the air upon the surface film of water. It appears from several further communications that this peculiar habit is also possessed by several other Copepods, viz. *Pontella atlantica* (M. Edw.), according to Dahl (*Verh. deutsch. Zool. Gesell.* 1894, p. 64), and *Pontella securifer* (Brady), according to an observation made by Captain Hendorff, who states that he several times saw this Copepod leap quite a foot high from the water in which it was contained. Herr Mrázek, in recording Captain Hendorff's observations (*Zool. Anz.* No. 415, p. 5), also mentions the additional case of a Schizopod having the same habits. This phenomenon, however, can be easily observed in the case of British Schizopods, and appears to be the result of abnormal conditions rather than a natural habit. Herr Mrázek does not support Dr. Ostroumoff in his view of the connection between this habit and the process of exuviation; he regards the movements in question as either purposeless and sportive, or for the sake of effecting escape from enemies. The latter view certainly receives support from the somewhat analogous case of the flying fish.

WE have received an elaborate paper read before the Congress of Scandinavian Naturalists at Copenhagen, by Dr. Ernst Abery, on the transmission of yellow fever. Much uncertainty and difference of opinion exist as to the means by which this disease is distributed, some authorities asserting that it has a purely local malarial origin, and cannot be imported into a place; whilst others are equally convinced that it can be imported, but is not transmissible directly from one individual to another. Dr. Abery, who has made a special study of the subject, has gathered together the principal facts about the dissemination of yellow fever, which are admitted by various authorities, and seeks to connect them together and explain them by a theory of his own. He accepts for this purpose the presence of a particular microbe specific to yellow fever, and regards it as capable of existing in different forms, such as spores and rodlets, and endowed with correspondingly different characters and degrees of virulence. By means of this theory, Dr. Abery explains many otherwise puzzling phenomena, and has produced an excellent working hypothesis. Unfortunately, however, it must remain only a hypothesis, for so far no microbe specific to yellow fever has been discovered and accepted; but possibly the author intends attacking this aspect of the question next.

THE new volume of *Memoirs* (Zapiski) of the Caucasian Geographical Society (vol. xvi.) is again one of exceptional interest. It contains, first, a series of botanical papers on the flora of Northern Caucasia, by I. Akinfieff, together with an account of a journey of the same author in Ossetia and Svanetia; three papers, by N. M. Alboff, on the vegetation of Western Transcaucasia, on new species found in Abkhasia, and on the Abkhasian ferns; and an abridged translation of several papers, by Dr. E. Dieck, on the flora of Western Transcaucasia; the series thus making a very valuable addition to our present knowledge of the flora of Caucasus. And next, the same volume contains a series of papers devoted to the still imperfectly known parts of the central section of the Main Caucasus ridge. M. N. Zhukoff contributes a paper on the glaciers of North-east Svanetia, with a new and very interesting map (1·3 miles to the inch) of a wide glacier region; A. V. Pastukhoff describes his ascensions of the Shah-dagh and the Ararat, as well as his visits to some of the high-level villages, of which Kurush, situated at a height of 8175 feet, is the highest in Caucasia—the paper being accompanied by small maps and photographs of the Kichen-dagh, the Nesen-dagh, and the Kurush village; M. and Mme. Rossikoff contribute two papers on the glaciers and Alpine lakes of the Central Caucasus main chain, giving exact measurements of the speed of motion of several glaciers; and another Alpinist, N. Dinnik, gives a description of Mount Oshten and the surrounding parts of the province of Kuban, which is full of very interesting geographical and botanical data. And, finally, two papers, by MM. Shalikoff and Andronikoff, are geographical and statistical descriptions of two districts of the government of Tiflis—Ksan and Uraveli. An index of all the papers contained in the hitherto published volumes of both the *Memoirs* (Zapiski) and the *Bulletin* (Izvestia) of the Caucasian Geographical Society, is also a most welcome feature of the present volume.

A SECOND edition of Dr. G. V. Poore's instructive "Essays on Rural Hygiene" has been published by Messrs. Longmans, Green, and Co. The new edition includes more than fifty additional pages.

THE Rose Polytechnic Institute, Terre Haute, Indiana, has published a bulletin on "Physical Units," by Prof. Thomas Gray. The bulletin comprises a concise and admirable collection of definitions of fundamental and derived units.

No. 2 of the *Botanisches Centralblatt* for 1895 contains an exhaustive bibliography of the colouring matters of plants, by Dr. Hermann Ritter Schrötter-Kristelli, together with some new observations on the occurrence of carotin.

A WORK entitled "Molecules and the Molecular Theory of Matter," by A. D. Risteen, will be published in February by Messrs. Ginn and Co. The work is intended to be a popular exposition of the molecular theory of matter as it is held by the leading physicists of to-day. The subject is treated from a physical standpoint.

WHEN a book twenty years of age blossoms into a second edition, it is hardly necessary to say that the original must have undergone a thorough revision. This is the case with Prof. Alfred Newton's little "Zoology," published in 1874, among a series of manuals of elementary science, by the Society for Promoting Christian Knowledge. The new edition takes in much of the zoological work done during the past two decades, thus rendering it one of the cheapest, handiest, and best broad introductions to the study of zoology

THE publication is announced of the first number of a *Phycotheca Boreali-americana*, by Messrs. F. S. Collins and Isaac Holden and Dr. W. A. Setchell. The work will include all families of Algæ, both freshwater and marine (except, for the present, Characeæ, Desmidieæ, and Diatomaceæ), from the Arctic Ocean to the Isthmus of Panama, including the West Indies. Each number will include fifty species, and the price will be five dollars. Subscriptions and offers of contributions are to be addressed to Mr. Frank S. Collins, 97 Dexter Street, Mass., U.S.A.

FROM a note in the *Botanical Gazette* we learn that the fox-tail grass or squirrel-tail grass, *Hordeum jubatum*, is a serious pest to stock in the Western States of America. The barbed awns break up into pieces, penetrate the gums, especially near the teeth, producing swelling, and ultimately suppuration, of the gums, and ulceration of the jaw-bones and teeth, the latter being so loosened as to drop out. If the animal continues to eat hay containing this grass, the disease progresses till the bony tissue of the jaws is disarranged, the ulcers extend to all parts of the jaw-bone, and it becomes distorted and enlarged. The marrow-filled interior is changed into great cavities filled with the broken awns. This condition may continue till the cavities extend entirely through the jaw, and the tightly-packed awns protrude till they may be pulled out with forceps or fingers.

THE completeness of the series of Eocene and Cretaceous strata exposed along the great central river system of Alabama, is well known to American geologists. A report on the geology of the coastal plain of Alabama, just issued by the Geological Survey of that State, shows that, on account of the fine exposures along the river banks, and the great number and perfection of the fossils, the region presents the most complete and varied series of Eocene and Cretaceous strata known in the United States. All that relates to Cretaceous, Tertiary, and Post-Tertiary formations in the vicinity of the Alabama and Tombigbee rivers, is described in the first part of the report. The second part contains all the data of practical value concerning the various phosphatic marls, greensands, &c., occurring in the region surveyed, and the third part includes a number of geological details referring to the different counties of the State. Prof. E. A. Smith, the State Geologist, and those who have assisted him, may be congratulated upon the publication of this important account of the stratigraphy of the Cretaceous and Tertiary formations of the Gulf region of Alabama.

AN inorganic mode of preparing hydrazine, N_2H_4, is described by Dr. Duden, of the Jena University Laboratory, in the latest issue of the *Berichte*. Hitherto the numerous methods of formation of this important hydride of nitrogen, described by its discoverer, Prof. Curtius, and his assistants, and by Thiele and von Pechmann, have all been based upon the decomposition of more or less unstable organic compounds of the diazo, nitrosamine, or nitramine types. Dr. Duden has succeeded in an inorganic synthesis by use of a singular compound, discovered by Davy and further investigated by Raschig and by Divers and Haga, which is produced by the action of sulphurous acid upon potassium nitrite. This compound, whose composition is represented by the formula $K_2SO_3 . N_2O_2$, is now found to yield hydrazine upon careful reduction in alkaline solution. Divers and Haga showed that the ordinary products of reduction of the compound with sodium amalgam in concentrated alkaline solution are mainly potassium hyponitrite KNO and hydrogen potassium sulphite $HKSO_3$, smaller quantities of hydroxylamine and ammonia being likewise produced. Dr. Duden finds that if the reduction with sodium amalgam, or zinc dust and ammonia or soda, is carried out at a low temperature, the solution produced possesses very strong reducing properties, and after acidification deposits the salt of hydrazine corresponding to the acid employed. The freshly prepared compound of potassium sulphite and nitric oxide is suspended in water cooled by ice, and sodium amalgam is gradually added with further extraneous cooling by means of a freezing mixture, until the liquid is found to strongly reduce Fehling's solution and yields, after acidification and warming to expel sulphur dioxide, a precipitate of benzalazine upon the addition of benzaldehyde. The benzalazine so obtained is found to exhibit all the properties of the compound as described by Prof. Curtius; it melts at 93° and yields numbers on analysis exactly agreeing with the formula $(C_6H_5CHN)_2$. With sulphuric acid it yields hydrazine sulphate $(N_2H_4)_2 . H_2SO_4$, identical in melting point (256°) and all other properties with that derived from the organic methods of preparation. The formation of hydrazine from the compound of nitric oxide and potassium sulphite would appear to occur in two stages, an intermediate reduction compound being first produced of analogous constitution to Davy's salt in accordance with the following equation:

$$\begin{matrix}KSO_3\\KO\end{matrix}\Big\rangle N . NO + 6H = \begin{matrix}KSO_3\\H\end{matrix}\Big\rangle N . NH_2 + H_2O + KOH.$$

A further reaction then occurs between the intermediate compound and the alkali, with production of potassium sulphate and hydrazine

$$\begin{matrix}KSO_3\\H\end{matrix}\Big\rangle N . NH_2 + KOH = K_2SO_4 + H_2N . NH_2.$$

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mr. H. Ralls; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Mr. Fred Bissmire; a Dusty Ichneumon (*Herpestes pulverulentus*), a White-throated Monitor (*Varanus albigularis*) from South Africa, presented by Mr. J. E. Matcham; a Derbian Wallaby (*Halmaturus derbianus*) from Australia, presented by Mr. Joseph Palmer; a Jackal Buzzard (*Buteo jacal*) from South Africa, presented by Mr. E. Wingate; a Yellow-headed Conure (*Conurus jendaya*) from South-east Brazil, a Brown-throated Conure (*Conurus æruginosus*) from South America, presented by Mrs. Hankey; three Eroded Cinixys (*Cinixys erosa*), two Home's Cinixys (*Cinixys homeana*) from West Africa, presented by Mr. J. Banks Elliot; a Lesueur's Water Lizard (*Physignathus lesueuri*) from Australia, deposited; a Rosy-billed Duck (*Metopiana peposaca*), a Garden's Night Heron (*Nycticorax gardeni*) from South America, purchased.

OUR ASTRONOMICAL COLUMN.

THE PERSEID METEORS.—This well-known shower of meteors should be of the greatest interest to the mathematician, as well as to the observer. At Pulkova, in 1893, the shower was observed from July 22 to September 12, and a discussion of the 563 paths recorded forms the subject of an interesting paper by Dr. Bredichin (*Bull. Imp. Acad. Sc.*, St. Petersburg, September 1894). It has long been known that the Perseids are not as other regularly recurring meteor showers, and Dr. Bredichin explains their peculiarities by supposing that they are not produced by a swarm of meteorites, in the true sense of the word, but by particles circulating in different orbits. These orbits have widely differing inclinations, and the other elements also show striking departures from each other. One gets a good idea of the system which is suggested, by imagining a bundle of materialised orbits crossing the earth's orbit at the points which the earth occupies during August, and for some days before and after. The particles with long periods correspond to the meteors at the beginning of the showers, and to the primitive position of the comet from which the meteors are supposed to be derived, which, having a moderate period, has left these meteors behind. The position of the node of the comet is not symmetrical with reference to the nodes of the meteors, but appears to be nearer the beginning than the end of the showers. This continuity of the phenomena for so long a time seems to confirm the idea of a variety of periods for the particles, and indicate also the repeated omission of the meteors from the body of the comet. If the forces of disruption were only those which have ordinarily been considered, the meteors would be dispersed in a long thin stream along the length of the orbit, as in the case of the November meteors; but since the orbits of the meteors are variously inclined to that of the comet, another force, acting transversely to the plane of the orbit, must be admitted as an important factor. The anomalous phenomena of the tails of some comets—a subject with which Dr. Bredichin is already closely associated—and the energetic emissions which have been noted in several comets, including that which is connected with the Perseids, serve to demonstrate the possibility of such an action as that which he supposes to have taken place in the case of this swarm.

COMET 1894 I (DENNING) AND BRORSEN'S COMET.—Dr. Hind contributes to the current number of the *Astronomische Nachrichten* (No. 3271) a very interesting note as to the identity of Denning's comet with that discovered by Brorsen. To investigate the question, he has found, with M. Schulhof's elements for Denning's comet and Dr. Lamp's elements for Brorsen's comet, that the distance of the orbits would be 0·0367 in Longitude 285° (1894·0), and that in April 1881 the comets approached one another within a distance of 0.138. On this account, he says, during the comet's recession from perihelion, might not Brorsen's comet have met with a catastrophe, causing disintegration and the return of a portion of it to perihelion, in a somewhat different orbit, in Denning's comet of last year?

Dr. E. Lamp has also considered this question of identity, and, in referring to Dr. Hind's note, writes that the similarity of the two orbits is very striking, and that, in the beginning of 1881, the two bodies must have been very close to one another near the point of intersection of the two orbits. With the same elements as used by Dr. Hind, he finds the point of intersection of the orbits in Longitude 284° 47′ and South Latitude 1° 57′. The places of the two bodies are then as follows:—

	Denning.	Brorsen.
	° ′	° ′
True anomaly	154 22	169 7
Ecc. anomaly	123 22	147 25
Radius vector	5·240	5·218

The point of nearest approach in the orbit of Denning's comet occurs in a position 5′ behind, and in the Brorsen's orbit 4′ before, the actual place, the distance between these points being 0·022 radii of the earth's orbit. Dr. Lamp suggests that, by decreasing Schulhof's value of the mean daily motion by about 28″, the comets would thus be brought together. The question, however, is in a very undecided state, but astronomers will await with interest the results of Dr. Lamp's investigation as to whether the comets furnish an instance of a mere approach or of a real physical connection.

STARS HAVING PECULIAR SPECTRA.—Prof. E. C. Pickering states in the *Astronomische Nachrichten*, No. 3269, that an examination of photographs of stellar spectra, taken at the Arequipa Station of the Harvard College Observatory, has led to the discovery of four new variable stars in Centaurus, Lupus, Pavo, and Microscopium, and ten other objects with spectroscopic peculiarities. Of these, the spectra of five are classified as Type IV.; two appear to belong to Type V.; one (R.A. 18h. 38·4m. Decl. −27° 55′) is a nebula; one has H^{β} bright; and the photographic spectrum of the remaining object contains no blue light. To show how difficult it is to draw any sharp distinction between nebulæ and bright line stars, we quote the concluding paragraph of Prof. Pickering's communication. "The photographic spectra of faint gaseous nebulæ and stars of the fifth type closely resemble each other, and can only be distinguished by the wave-length of the principal bright line. In gaseous nebulæ this line (5007) is of greater wave-length than $H\beta$, while in stars of the fifth type, the line 4688 is of shorter wave-length. A superposition of a chart and spectrum plate of the star whose approximate position for 1900 is R.A. = 15h. 10m. Decl. −45° 17′, which has been announced as a star of the fifth type (*Astronomische Nachrichten*, vol. 135, p. 195), shows that this object is in reality a gaseous nebula."

NITROGEN FIXATION IN ALGÆ.

IN NATURE of March 29, 1894, Prof. Marshall Ward gave a clear and excellent *résumé* of certain aspects of the question of nitrogen fixation in plants. Since the publication of that article, fresh and most important additions have been made to the subject.

Last May, P. Kossowitsch published an account of his experiments on Algæ in respect to their nitrogen-fixing powers (*Bot. Zeitung*, May 16, 1894), and a short account of this contribution should form an appropriate supplement to Prof. Ward's paper.

In 1888, Prof. Frank, of Berlin, had stated his opinion that Algæ possessed the power of free nitrogen fixation.

In 1892, Messrs. Schloesing and Laurent published an account of their classical researches dealing with many plants, among which Algæ also found a place. Their experiments with these forms range in two series. In the first they found that if they kept soil, covered with Algæ and containing bacteria of certain kinds, under observation for some time, an increase in nitrogen was perceptible. On the other hand, if they prevented the formation of Algæ, although the same bacteria remained, there was no noticeable addition to the nitrogen of the system. In the second set of experiments, in which different Algæ were employed, no nitrogen fixation could be perceived. It was evident from this that either particular kinds of Algæ only have "fixing" powers, or that suitable bacteria were not simultaneously present in the second case, and that Algæ can only fix with the additional aid of these micro-organisms.

In the following year, Koch and Kossowitsch devoted their attention to the subject, and went over much the same ground as Laurent and Schloesing, confirming their results, and adding new facts, the value of which, however, was somewhat enhanced by the algal cultures never consisting of any single species alone, but of several intermingled. Accordingly when, in 1894, Kossowitsch set himself the task of determining whether Algæ in themselves possess the power of assimilating free atmospheric nitrogen or not, the first obstacle he had to overcome was the difficulty of finding a method by which he could obtain a single algal species in absolute purity. This was ultimately effected by growing the Algæ on gelatinous silicic acid permeated with a nutritive solution, and subsequently on sterilised sand also containing food solution. The steps by which the isolation was effected were slow and beset with difficulties, which sprang up in the most unexpected manner, and the pages of Kossowitsch's memoir which deal with this subject possess a separate and great interest of their own; space, however, will not permit that the matter be detailed here. Having obtained the Algæ in a state of purity, the next step was to transfer them to the apparatus in which their nitrogen-fixing powers were to be tested.

This consisted of a central air-tight vessel connected with a series of U-tubes, which were blown into bulbs at certain intervals. These bulbs contained strong sulphuric acid. The whole apparatus was sterilised, and the Algæ under consideration sown upon a sterilised nutritive substratum in the central vessel. Air freed from all traces of nitrogen compounds was blown into the vessel through the U-tubes, the sulphuric acid in which killed any organisms which might be contained in this air.

The Alga which was first experimented on was Cystococcus (or an extremely similar form). Every precaution was taken in introducing this into the apparatus.

Using a nutritive solution perfectly free from all nitrates, it was seen that the Algæ refused to show any signs of growth; it was clear, therefore, that at least to start development a trace of nitrate must be added to the sand. The addition of other nitrogen compounds was found to be useless, and accordingly a small and accurately measured quantity of a nitrate was mixed with the food solution in the central vessel. The whole apparatus thus fixed up was placed in the light, and left for some weeks. At first rapid increase in the Algæ was noticeable, but after the lapse of about three weeks things evidently came to a standstill.

The addition of more nitrate-free nutritive solution gave no result; but if only the merest trace of a nitrate were added, there was an immediate resumption of activity.

These facts in themselves are very good proof of the inability of Cystococcus to fix atmospheric nitrogen; but to make matters doubly sure, a careful chemical analysis was made. This showed that there was no increase in nitrogen during all the weeks the Algæ had been flourishing, and that accordingly no iota of the stream of free nitrogen which had been constantly passing through the apparatus had been "fixed." So far, then, the first Alga which had been put to the test of experiment showed itself incapable of utilising atmospheric nitrogen.

Kossowitch now turned to fresh experiments, choosing algal cultures of sometimes one, sometimes several species taken together; to all of these he added simultaneously soil-bacteria of mixed sorts. The apparatus employed was very nearly the same as that above described. In these experiments he desired to test the supposition of Berthelot and Winogradsky, who considered the presence of certain organic substances to be favourable to the fixation of nitrogen; he accordingly arranged his experiments in five pairs, both members of each couple having identical conditions, except that in the one a small quantity of sugar (dextrose) was added to the nutritive solution, whilst in the other no organic compound was present. One set was arranged with Cystococcus and soil-bacteria, and the results obtained showed that in the absence of organic materials a small but yet noticeable increase in the nitrogen of the system had taken place (from 2·6 mg. to 3·1 mg.) Where sugar had been previously added, however, there were three times as much nitrogen after the experiment as before. In a second pair of cultures the Alga Stichococcus and certain bacteria were used, but here in no case, either with or without sugar, was there any increase in nitrogen. This shows that Stichococcus has in itself no power of nitrogen fixation.

Another couple contained a mixture of several Algæ, Nostoc, Cylindrospermum, &c., and certain soil-bacteria. In this instance a very large fixation of nitrogen took place, both where sugar was present and where not; in fact, in the former case the nitrogen was increased more than nine-fold.

All these observations shed much light upon the question of the relations existing between Algæ, micro-organisms, and atmospheric nitrogen. They show:—

(1) That at least two Algæ—Cystococcus and Stichococcus—possess no "fixing" powers in themselves.

(2) That many Algæ, taken together with certain micro-organisms of the soil, do possess the power of assimilating atmospheric nitrogen.

(3) That this power is much increased by the addition of such organic substances as sugar.

It should be noticed that among the ten cultures used in the second set of experiments, only two contained definitely isolated algal species, viz. the cases of the two cultures of Cystococcus and soil-bacteria.

It was just in this instance, moreover, that it had been shown that the Alga itself had no capacity for fixing atmospheric nitrogen. Accordingly, there could be little doubt that it was through the agency of the micro-organisms that the "fixation" had taken place in these latter cultures.

The experiments of Laurent and Schloesing had shown that if in a culture of Algæ and bacteria endowed with "fixing" powers, the Algæ were destroyed, the bacteria lost partly, if not entirely, this capacity, which the mixture had possessed. This pointed clearly to the fact that there was some close relationship existing between the Algæ and micro-organisms.

There are many facts which seem to indicate the nature of this relationship.

Berthelot found that the nitrification of the soil only took place as long as organic compounds were present; if these were exhausted, the nitrifying process ceased. Gautier and Drouin also showed the importance which organic compounds have with respect to nitrification. Kossowitsch's own experiments, in which the advantage of adding sugar to the culture was shown, also point in the same direction.

From such observations as these, Kossowitsch concludes that the relationship which the Algæ bear to the micro-organisms is one connected with the organic food supply of these latter; he thinks that the Algæ, furnished with nitrogen by the bacteria, assimilate carbohydrate material, part of which goes to their own maintenance, but part also to that of the micro-organisms. It is, therefore, in his belief, an instance of symbiosis in which each supplies the wants of the other. There are many facts, partly the result of his own observations, partly the result of those of others, which uphold this view. If the mixed culture be placed in the light, there is a far more noticeable nitrogen increase than when in darkness. Again, if a rich supply of carbon dioxide gas be provided, this is marked by a decided rise in nitrogen-fixing powers. Both these conditions are such as are known to influence carbohydrate assimilation in chlorophyll-containing organisms; but all experience is antagonistic to the view that light should be beneficial to the vital activity of the bacteria, and there are only one or two exceptional instances (Nitromonas, &c.) in which carbon dioxide can be directly assimilated by these micro-organisms.

Moreover, in the cases where the bacteria are brought into immediate contact with the Alga, as in those species of Algæ which are enveloped in a gelatinous covering wherein the micro-organisms become embedded, nitrogen fixation appears to be greatly aided, and the addition of sugar to the culture has no such marked effect as in the instances where non-gelatinous Algæ are employed. The explanation of this seems to be that the bacteria embedded in the gelatinous sheath are amply provided with carbohydrate food without the addition of sugar, which, therefore, comes more or less as a superfluity.

All this seems to justify Kossowitsch's view of the part played by the Algæ in the fixation of nitrogen; it appears to show that they have an indirect, but none the less important, influence upon the process.

This is roughly the extent of Kossowitsch's article; it has been impossible to give here its details, the bare outlines of his researches could alone be mentioned, but it is hoped that sufficient has been said to show the importance of his work, perhaps even to indicate the interest which every page of his memoir possesses, dealing as it does with one of the most fascinating branches of vegetable physiology.

RUDOLF BEER.

THE COMMERCIAL SYNTHESIS OF ILLUMINATING HYDROCARBONS.[1]

THE direct combination of carbon and hydrogen in the electric arc is a true case of synthesis, and if we could form acetylene in this way in sufficiently large quantities, it would be perfectly easy to build up from the acetylene the whole of the other hydrocarbons which can be used for illuminating purposes. For instance, if acetylene be passed through a tube heated to just visible redness, it is rapidly and readily converted into benzol; at a higher temperature naphthalene is produced, whilst by the action of nascent hydrogen on acetylene, ethylene and ethane can be built up. From the benzol we readily derive aniline, and the whole of that magnificent series of colouring matters which have gladdened the heart of the fair portion of the community during the past five-and-twenty years, whilst the ethylene produced from acetylene can be readily converted into ethyl alcohol, by consecutively treating it with sulphuric acid and water, and from the alcohol, again, an enormous number of other organic substances can be produced, so that acetylene can, without exaggeration, be looked upon as one of the great keystones of the organic edifice, and, given a cheap and easy method of preparing it, it is hardly possible to foresee the results which will be ultimately produced.

In 1836, it was found that when making potassium, by distillation from potassic carbonate and carbon, small quantities of a bye-product, consisting of a compound of potassium and carbon, was produced, and that this was decomposed by water with liberation of acetylene; whilst Wöhler, by fusing an alloy of zinc and calcium with carbon, made calcic carbide, and used it as a source from which to obtain acetylene by the action of water.

Nothing more was done until 1892, when Macquenne prepared barium carbide by heating at a high temperature a mixture of barium carbonate, powdered magnesium, and charcoal, the resulting mass evolving acetylene, when treated with water; whilst, still later, Travers made calcic carbide by heating together calcic chloride, carbon, and sodium. None of these processes, however, gave any commercial promise, as the costly nature of the potassium, sodium, magnesium, or calcium-zinc alloy which had to be used, made the acetylene produced from the carbide too expensive.

Whilst working with an electric furnace, and endeavouring by its aid to form an alloy of calcium from some of its compounds, Mr. T. L. Willson noticed that a mixture containing lime and powdered anthracite, under the influence of the tem-

1 Abstract of a paper by Prof. Vivian B. Lewes, read before the Society of Arts, Wednesday, January 16.

perature of the arc, fused down to a heavy semi-metallic mass, which having been examined, and found not to be the substance sought, was thrown into a bucket containing water, with the result that violent effervescence of the water marked the rapid evolution of a gas, the overwhelming odour of which enforced attention to its presence, and which, on the application of a light, burnt with a smoky, but luminous flame.

Investigation into the cause of this phenomenon soon showed that in a properly constructed electric furnace, finely ground up chalk or lime, mixed with powdered carbon in any form, whether it were charcoal, anthracite, coke, coal, or graphite, can be fused with the formation of a compound known as calcic carbide, containing 40 parts by weight of the element calcium, the basis of lime, and 24 parts by weight of carbon, and that, on the addition to this of water, a double decomposition takes place, the oxygen of the water combining with the calcium of the calcic carbide to form calcic oxide or lime, whilst the hydrogen unites with the carbon of the calcic carbide to form acetylene, the cost of the gas so produced bringing it not only within the range of commercial possibilities for use *per se*, but also the building up from it of a host of other compounds, whilst the production of the calcic carbide from chalk and from any form of carbon, renders us practically independent of coal and oil, and places in our hands the prime factor by which nature in all probability produces those great underground storehouses of liquid fuel upon which the world is so largely drawing to-day.

Calcic carbide is a dark grey substance, having a specific gravity of 2·262, and, when pure, a pound of it will yield on decomposition 5·3 cubic feet of acetylene. Unless, however, it is quite fresh, or means have been taken to carefully protect it from air, the outer surface gets slightly acted upon by atmospheric moisture, so that in practice the yield would not exceed five cubic feet. The density and hardness of the mass, however, protects it to a great extent from atmospheric action, so that in lumps it does not deteriorate as fast as would be expected, but in the powdered condition it is rapidly acted upon.

The acetylene made from it, when analysed by absorption with bromine, the analysis being also checked by determining the amount present by precipitation of silver acetylide, gives 98 per cent. of acetylene and 2 per cent. of air, and traces of sulphuretted hydrogen, the presence of this impurity being due to traces of sulphate of lime—gypsum—in the chalk used for making it, and to pyrites in the coal employed.

Acetylene is a clear, colourless gas with an intensely penetrating odour which somewhat resembles garlic, its strong smell being a very great safeguard in its use, as the smallest leakage would be at once detected; indeed, so pungent is this odour, that it would be practically impossible to go into a room which contained any dangerous quantity of the gas.

This is an important point to remember, as the researches of Bistrow and Liebreich show that the gas is poisonous, combining with the hæmoglobin of the blood to form a compound similar to that produced by carbon monoxide; whilst the great danger of the latter gas is that having no smell, its presence is not detected until symptoms of poisoning begin to show themselves, so that no fear need be apprehended of danger from this source with acetylene.

Acetylene is soluble in water and most other liquids, and at ordinary temperature and pressure—60° F. and 30 inches of mercury—10 volumes of water will absorb 11 volumes of the gas; but as soon as the gas is dissolved, the water being saturated takes up no more. Water already saturated with coal-gas does not take up acetylene quite so readily, whilst the gas is practically insoluble in saturated brine—100 volumes of a saturated salt solution only dissolving 5 volumes of the gas. The gas is far more soluble in alcohol, which at normal temperature and pressure takes up six times its own volume of the acetylene, whilst 10 volumes of paraffin under the same conditions will absorb 26 volumes of the gas. It is a heavy gas, having a specific gravity of 0·91.

When a light is applied to acetylene, it burns with a luminous and intensely smoky flame, and when a mixture of one volume of acetylene with one volume of air is ignited in a cylinder, a dull red flame runs down the cylinder, leaving behind a mass of soot, and throwing out a dense black smoke. When acetylene is mixed with 1·25 times its own volume of air, the mixture begins to be slightly explosive, the explosive violence increasing until it reaches a maximum with about twelve times its volume of air, and gradually decreases in violence until, with a mixture of one volume of acetylene to twenty of air, it ceases to be explosive.

The gas can be condensed to a liquid by pressure, Andsell finding that it liquefied at a pressure of 21·5 atmospheres, at a temperature of 0° C., whilst Cailletet found that at 1° C. it required a pressure of 48 atmospheres, the first-named pressure being probably about the correct one. The liquid so produced is mobile, and highly refractive, and when sprayed into air, the conversion of the liquid into the gaseous condition absorbs so much heat that some of the escaping liquid is converted into a snow-like solid, which catches fire on applying a light to it, and burns until the solid is all converted into gas and is consumed.

In my researches upon the luminosity of flame, I have shown that all the hydrocarbons present in coal-gas and other luminous flames are converted by the baking action taking place in the inner non-luminous zone of the flame into acetylene before any luminosity is produced, and that it is the acetylene which by its rapid decomposition at 1200° C. provides the luminous flame with these carbon particles, which, being heated to incandescence by various causes, endow the flame with the power of emitting light. The acetylene, being in this way proved to be the cause of luminosity, one would expect that in this gas we have the most powerful of the gaseous hydrocarbon illuminants; and experiment at once shows that this is the case.

Owing to its intense richness, it can only be consumed in small flat-flame burners, but under these conditions emits a light greater than that given by any other known gas, its illuminating value calculated to a consumption of 5 cubic feet an hour being no less than 240 candles.

Illuminating Power of Hydrocarbons for a Consumption of 5 cubic feet of Gas.

	Candles.
Methane	5·2
Ethane	35·7
Propane	56·7
Ethylene	70·0
Butylene	123·0
Acetylene	240·0

It is stated that the carbide can be made at about £4 a ton; and if this be so, it should have a great future, as a ton will yield 11,000 cubic feet of the gas. The lime left as a bye-product would be worth 10*s*. a ton, and the gas would cost at this rate 6*s*. 4½*d*. per 1000 cubic feet, and in illuminating value would be equal to London coal gas at 6*d*. a thousand. Its easy production would make it available for illuminating purposes in country houses, whilst its high illuminating value should make it useful for enriching poor coal gas.

CHEMICAL CHANGES BETWEEN SEA-WATER AND OCEANIC DEPOSITS.[1]

THE numerous analyses of sea-water by Forchhammer previous to 1865, and the later analyses by Dittmar, from samples collected during the *Challenger* Expedition, show that while the *salinity*—*i.e.* the amount of dissolved salts contained in 100 parts of sea-water—varies greatly in different regions of the ocean, still the composition of these dissolved salts—*i.e.* the ratio of the constituents of sea-salts—remains practically the same in all the superficial waters of the ocean. Consequently, it is only necessary to determine the chlorine in a definite weight of water to ascertain at once the respective quantities of the other salts present in the sample. Dittmar's examination of the *Challenger* waters has, however, shown that lime is slightly, although distinctly, more abundant in samples of sea-water collected in greater depths than in those samples collected nearer the surface of the ocean, and Dittmar's tables showing the difference between the chlorine calculated from the specific gravity and the chlorine found by analysis[2] point to differences in the composition of the sea-salts; but the observations are

[1] Abstract of a Paper read before the Royal Society of Edinburgh on March 7, 1892, by Dr. John Murray and Robert Irvine, and published in *Trans.*, vol. xxxvii. part 2, No. 23.

[2] Dittmar, "*Challenger* Report on the Composition of Ocean Water," "Phys. Chem. *Chall.* Exp.," part 1, p. 43.

relatively so few, these differences so slight, so mixed up with observational errors, and so irregular in their geographical and bathymetrical distribution, that they cannot be said to indicate any general law other than a greater quantity of lime in deep water.

But there is abundant evidence that great changes in chemical composition take place in the substances deposited on the floor of the ocean, and, with the view of throwing some light on the manner in which these changes are brought about, it occurred to us to examine the composition of the sea-water associated or mixed up with marine deposits on the floor of the ocean, and especially with that variety of marine deposits known as Blue Mud.

The depth at which a fine blue mud may form in the sea, depends entirely on the depth of water and the extent of the basin; or, in other words, on the height and length of the waves.[1] In harbours it may be deposited not deeper than 1 or 2 fathoms, while along the western coasts of Scotland and Ireland, which are exposed to the waves of the wide and deep Atlantic, the true mud-line may be situated at a depth of about 150 or 200 fathoms.

In this paper we state the results of our investigation into the composition of the sea-salts in samples of water enclosed in the blue muds from Granton Harbour and Quarry, near Edinburgh, at Queensferry, N.B., and other places. The water was obtained by filling a canvas bag with the mud and collecting the water which filtered through, the first portions being rejected.

The Specific Gravity of the filtrate was about normal for in-shore water, ranging from 1024 to 1026.

Chemical Composition of the Sea-water Salts in Mud-water.—On comparison with normal sea-water salts, the sulphates were greatly reduced, while the alkalinity (combined carbonic acid) was correspondingly increased, sometimes rising to ten times above the normal.

When a portion of the clear water filtered from the harbour muds was boiled, a precipitate was thrown down in a crystalline form, consisting of carbonates of lime and magnesia in the following proportions:—

$CaCO_3$	73·30
$MgCO_3$	26·70
	100·00

Before boiling, the water had an alkalinity of 0·7760 grms. per litre, while after boiling it showed an alkalinity of only 0·2200 grms., thus proving that the alkalinity was mainly due to the formation and presence of these carbonates rendered soluble by free carbonic acid.

Saline and albumenoid ammonia ranged from 4 to 80 parts, and 1 to 5 parts per million, respectively. Lime was much less, and magnesia slightly less than the normal. The chlorine and the total bases were higher than normal water of equal density. Bicarbonate of manganese was present in the water up to 1 part in 16,000. Normal sea-water contains no manganese.

The following table gives a comparison of the composition of normal and mud-waters:—

	Average sea-water.[2]	Mud-water.
Sodium chloride, NaCl	77·758	79·019
Magnesium ,, $MgCl_2$	10·878	11·222
Magnesium bromide, $MgBr_2$ ...	0·217	0·220
Magnesium sulphate, $MgSO_4$ ...	4·737	3·232
Potassium ,, K_2SO_4 ...	2·465	2·506
Ammonium ,, $(NH_4)_2SO_4$	...	0·206
Magnesium carbonate, $MgCO_3$ ...	...	0·729
Calcium ,, $CaCO_3$ ...	0·345	2·686
Calcium sulphate, $CaSO_4$ ...	3·600	...
Manganous carbonate, $MnCO_3$ ...	...	0·180
	100·000	100·000

[1] See Murray and Renard, "*Challenger* Report on Deep-Sea Deposits," p. 185. (London, 1891.)

[2] See Dittmar, *op. cit.* pp. 137-138 and 203.

It will be seen that the total salts of the mud-water are low in proportion to the chlorine, consequently the D value—that is, the density minus 1000 divided by the chlorine—will be lower than normal water. In normal water the D value is 1·457, in mud water 1·430.

The reactions that take place in Blue Muds seem to be the following, and may be distinctly proved from the analyses of mud-water, as well as from a consideration of the whole subject. During the process of decomposition it appears that the greater part of the oxygen for the oxidation of the carbon and hydrogen of the organic substances in the blue muds is derived from the sulphur salts of the alkaline and earthy alkaline metals in sea-water, which, in the first instance, are reduced to the form of sulphides. These sulphides, owing to their instability, especially in the presence of free or loosely-combined carbonic acid, are decomposed as formed. The sulphur thus reduced from the sulphates may in part, on passing as hydrosulphuric acid into the water immediately above the mud, become oxidised back again into sulphuric acid, which in turn, decomposing the carbonate of lime always present in the water (or in the deposit), would re-form sulphates.

This oxidation is effected but slowly, as the following laboratory experiments show:—

Exp. I.—A solution of hydrosulphuric acid (H_2S) in pure water, which at first gave no precipitate with barium chloride, after standing a month, gave a distinct precipitate of barium sulphate, showing that the hydrosulphuric acid had been oxidised into sulphuric acid (SO_3).

Exp. II.—A solution of hydrosulphuric acid in sea-water was exposed to the air till complete oxidation had taken place. On titration the sea-water had lost its alkalinity, the sulphuric acid being proportionately increased.

Exp. III.—Hydrosulphuric acid was passed into water holding carbonates of calcium and magnesium in suspension, and resulted in a yellowish solution of the sulphides of calcium and magnesium, carbonic acid being expelled. The sulphides so formed were in turn decomposed by excess of carbonic acid, with evolution of hydrosulphuric acid, bicarbonates being formed, the reaction apparently depending on which acid is in excess.[1]

A certain part of the sulphides, or it may be of hydrosulphuric acid, derived from the soluble sulphides by the action of the free carbonic acid present in the mud, reduces the ferric oxides of the deposit, forming sulphide of iron, which so long as it is not exposed to the action of oxygen, remains stable, being in this respect unlike sulphide of manganese.[2] The sulphide of iron gives the characteristic blue-black colour to the great majority of the blue muds, especially where there is abundance of organic matter. It is by this process that sulphur is continually being abstracted from sea-water and locked up in marine deposits, which may finally be converted into blue-coloured shales, schists, and marls.[3] In these rocks the crystalline pyrites (FeS_2) has evidently its origin in the processes of death and decay going on at the time of their deposition at the sea-bottom, the sulphur of the sulphide of iron being derived from the sulphates of the sea-water, and not from the sulphur of the organisms, as generally supposed. This decomposition seems to be due to the action of bacteria in causing putrefactive changes in dead organic matter. We have found that if sea-water containing putrescible organic matter be sterilised by boiling, and thereafter care be taken to prevent the ingress of bacteria to this cooled liquid, the changes above indicated do not take place. Apparently the organic matter must be broken down by bacteria into its component elements, which in the nascent condition are capable of reducing the sulphates to a lower form of combination. The bisulphide of iron in the coal measures has without doubt a similar origin.

[1] See also *Comptes rendus*, tom. lxxxiii. pp. 58 and 345 (1876). Note by Naudin and Montholon; also Sainte Claire Deville, *Leçons sur la Dissociation*, 1864.

[2] Irvine and Gibson, *Proc. Roy. Soc. Edin.* p. 37, 1891.

[3] The black or dark blue colour of many shales and schists is due principally to the presence of iron, either combined with silica as silicate, or more rarely in the condition of carbonate or oxide. These shales, schists, &c., contain organic matter in a state of decomposition. In the older rocks its condition nearly approaches that of graphitic carbon; in a dark schist from Argyllshire only 0·91 per cent. of *graphitic* organic matter was found. In the more recent formations the organic matter, if in sufficient quantity, may give rise to the formation of petroleum. See paper by Dr. J. J. Jahn, *Jahrbuch der K.K. Geolog. Reichsanstalt*, 1892, Bd. 42, Heft 2.

The principal reactions which occur in mud-waters may be explained by the following formulæ:—

$$(1)\ RSO_4 + 2C = 2CO_2 + RS,$$

where R is an earthy alkaline metal.

$$(2)\ RS + 2CO_2 + H_2O = H_2S + RCO_3CO_2.$$
$$(3)\ RS + RCO_3CO_2 + H_2O = 2RCO_3 + H_2S.$$

On the hydrosulphuric acid meeting with ferric oxide (Fe_2O_3) present in the surface layer of these blue muds the following reaction occurs:—

$$(4)\ Fe_2O_3 + 3H_2S = 2FeS + S + 3H_2O.$$

Part of the sulphur is thus fixed in the mud, and part, if there be not sufficient iron in the mud, may escape into the water above, where, meeting oxygen, it will be converted into sulphuric acid (H_2SO_4), and return into RSO_4. The products RCO_3CO_2 in (2), and RCO_3 in (3), or the bicarbonate and carbonate of the metal are found in the water strained from the mud.

The increase of alkaline ammoniacal salts points, however, to a further reaction, by which carbonate of lime is increased in a slight degree, for as ammonium carbonate [$(NH_4)_2CO_3$] is formed by the decomposition of the albuminoids present, the sulphates in the sea-water by this means are decomposed, sulphate of ammonia [$(NH_4)_2SO_4$] and earthy carbonates being the result.

In the red muds and clays, either from the abundance of oxygen in the superincumbent waters, from the ochreous matter present in the mud or clay, or from the organic matter being small in quantity, the sulphide of iron is either not formed, or is after formation soon oxidised into ferric hydrate, which then gives its characteristic red colour to these deposits.

It may be accepted as the rule that muds containing a large amount of organic matter relatively to the iron present invariably partake of the characteristic blue-black colour, whilst if organic matter be low in amount, or altogether absent, the black sulphide is either not formed at all, or is oxidised into peroxide of iron.

Our attention has been recently drawn to a most interesting paper, read before the British Association, Edinburgh (1892) meeting, by N. Andrussow, on the "Russian Exploration of the Black Sea."[1]

The condition of the water in the Black Sea below the 100-fathom line, in which hydrosulphuric acid and sulphides exist in great abundance, is due to the same action as that now being carried on so widely in the formation of the blue muds on the ocean floor, viz. the deoxidation of the sulphates in the water by organic matter, and not, as stated in Andrussow's paper, as simply the decomposition-products after death of a great number of organisms. But a compound or double reaction appears in this instance to be taking place, viz.—

Firstly, on those portions of the bottom within a moderate distance from the shore, ordinary blue mud containing sulphide of iron (in large amount) is being deposited.

Secondly, in the deep water, especially far from the shore, below a depth of 100 fathoms where the oxygen has been used up, the hydrosulphuric acid, not having enough iron present in the floating mud to combine with, or to fix it as sulphide of iron (FeS), is found in the free condition. At the same time there must be a large quantity of free or loosely-combined carbonic acid in the water, the result of the deoxidation of the sulphates by organic matter, which naturally would decompose the sulphides at their inception (or as these are formed). That this is probably the case appears from the fact that in the greater depths of the Black Sea, far from land, there exists a large deposit of mud consisting principally of carbonate of lime, precipitated from its waters, which hold in solution lime and other salts as well as hydrosulphuric and carbonic acids. In the laboratory experiments noted above we have the rationale of these conditions. The deep water in the Black Sea may be thus in a state of continual change, the alkalinity in this case being due either to sulphides or carbonates in so far as carbonic acid or hydrosulphuric acid predominates, and not wholly to carbonic acid as in the open ocean, where sulphides cannot remain permanent owing to the constant excess of oxygen present; but it is evident that, since the light grey mud consists principally of carbonate of lime, the carbonic acid must, it may be on account of the pressure or temperature, have had the advantage over the hydrosulphuric acid.

[1] "On Deep-Sea Research in the Black Sea," giving the results of an expedition (under the superintendence of Colonel J. B. Spindler) sent out by the Russian Government in 1890 and 1891. These results have already been partly published in the preliminary transactions of the Russian Geographical Society (in Russian), the physical results in German by Prof. Woicjkoff in *Petermann's Mitteilungen*. An abstract of Andrussow's paper has been published in the Royal Geographical Society's *Journal*, January 1893, giving a very fair epitome of the various points dealt with.

METEOROLOGICAL WORK IN AUSTRALIA.[1]

THE object of the present paper is to place before the Association a brief and succinct account of meteorological work in Australia. Mr. Russell has already told us, in his interesting paper on astronomical and meteorological workers, read before the Association at its first meeting in Sydney in 1888, what had been done in the early days of the mother colony, and brings the history up to the year 1860, or immediately following the commencement of the active work of the new observatory completed in 1858, an establishment with which he has been associated during the past thirty-four years, and over which he has presided since his appointment as astronomer in 1870, on the death of Mr. Smalley in July of that year.

It is unnecessary that I should travel over the same ground. My intention is to carry on the history of which Mr. Russell has already given us the opening chapter. Indeed, as regards meteorology but little had been done before the advent of Mr. Scott, the first Director of the Sydney Observatory, in 1858, who, Mr. Russell tells me, established twelve meteorological stations, two of which, Brisbane and Rockhampton, were in Queensland, then forming part of New South Wales. Each station was equipped with a standard barometer, dry and wet bulb thermometers, maximum and minimum thermometers, and a rain gauge.

Meteorological stations had previously—in 1840—been established at South Head, Port Macquarie, and Port Phillip, Victoria being then under the Government of New South Wales. The observations at South Head were kept up, but, I fear, not in a very satisfactory or systematic manner, for fifteen years, or until 1855. At Port Phillip and Port Macquarie they are said to have been discontinued after six years. During Mr. Smalley's tenure of office several stations started by his predecessor, for some reason or other, probably owing to his bad health, were closed or allowed to fall into disuse. These were, however, speedily re-established by Mr. Russell: and I may here mention, as showing the active manner in which that gentleman has prosecuted the work commenced by Mr. Scott, that he has now, in addition to the Sydney Observatory, thirty-five meteorological stations, having barometers, dry and wet bulb thermometers, maximum and minimum thermometers, and rain gauges; 139 stations furnished with thermometers and rain gauges; and 1063 stations having rain gauges.

The Sydney Observatory is equipped with continuous self-recording barograph and thermograph, pluviometer and anemograph, made after Mr. Russell's own designs, besides underground thermometers at depths of 10 feet, 5 feet, 2 feet 6 inches, and 1 inch; an evaporation tank, or atmometer, &c.; a record, combined with the valuable astronomical work being done, worthy of the oldest colony of the group, which had already gained distinction in its promotion of science by the Dawes Point Observatory, erected in 1788, and the celebrated Paramatta Observatory, established in 1821 by Sir Thomas Brisbane.

In Mr. Tebbutt, Mr. Russell has found a most valuable coadjutor. That gentleman has not only carried out an extensive series of astronomical observations entirely at his own cost, but also furnished his observatory with a complete meteorological outfit.

In Victoria there were only broken records of rainfall, temperature, and weather, made chiefly by New South Wales officials in Melbourne, from 1840 to about 1849, and of rainfall up to 1851. In 1854 observations of barometer and temperature for astronomical purposes only, and of rainfall, were made at the Williamstown Observatory, then in charge of Mr. R. L. J. Ellery. Meteorological observations were also made at Melbourne by Mr. Brough Smyth, of the Crown Lands De-

[1] Abstract of a Paper read before the Australasian Association for the Advancement of Science, by Sir C. Todd, K.C.M.G., F.R.S.;

partment, from 1856 to the end of February 1858, when Prof. Neumayer, now Director of the Nautical Observatory at Hamburg, commenced systematic observations at the new Magnetic and Meteorological Observatory, at Flagstaff Hill, Melbourne. Dr. Neumayer also established several observing stations at the lighthouses on the coast, and at a few places inland.

On the retirement of Dr. Neumayer in 1863, the Magnetic and Meteorological Department was transferred to the present Astronomical Observatory, then just erected, and placed under the direction of the astronomer, Mr. Ellery, in whose hands the institution soon became what it is to-day—not only a credit to the colony which founded it, but second to none in the southern hemisphere. He threw all his energy and skill as a physicist into his work, and early introduced photographic and other systems, by which we obtain continuous records of all variations of terrestrial magnetism, barometric pressure, and changes of temperature, electrical states of the atmosphere, and the direction and force or velocity of the wind, besides thermometers sunk at various depths (3 feet, 6 feet, and 8 feet) to determine the temperature of the ground; while, as regards astronomy, we have only to visit the observatory to see that it possesses some of the finest instruments in the world.

Besides the Melbourne Observatory, he has established meteorological stations of the second order at Portland, Cape Otway, Wilson's Promontory, Gabo Island, Ballarat (Mount Pleasant), Bendigo, Echuca, Sale (at the School of Mines), and twenty-three stations of the third order, besides 515 rainfall stations judiciously distributed throughout the colony.

In South Australia, thanks to the late Sir George Kingston, father of the present Premier, we have a continuous record of the rainfall in Adelaide from 1839, which that gentleman maintained until 1878.

Meteorological observations, more or less complete, were made at the Survey Office for a number of years, or until I took up the work in November 1856, when the observatory records commenced under my direction as Government Astronomer.

Since May 1860, all the observations have been made at the West Terrace observatory. For several years I had no assistant, and having a growing telegraph department to look after and control, the area of my work was necessarily restricted, and I laboured under many disadvantages; but I early established meteorological stations at Clare, Kapunda, Strathalbyn, Goolwa, Robe, and Mount Gambier, and placed rain gauges at the different telegraph offices. I also introduced the system of publishing daily reports of the weather and rainfall from all stations at the head telegraph office in Adelaide.

We have now meteorological stations, having standard or Board of Trade barometers, dry and wet bulb thermometers, maximum and minimum thermometers, and rain gauges, at Port Darwin, Daly Waters, Alice Springs, Charlotte Waters, Strangways Springs, Farina, Port Augusta, Yongala, Clare, Kapunda, the Agricultural College at Roseworthy, Mount Barker, Strathalbyn, Eucla, Fowler's Bay, Streaky Bay, Port Lincoln, Cape Borda, Robe, Mount Gambier, and Cape Northumberland, and 370 rain gauges; at the lighthouses at Cape Borda and Cape Northumberland, and at the telegraph offices at Port Darwin and Alice Springs, the observations are taken every three hours, night and day; at other stations at 9h. a.m., 3h. p.m., 9h. p.m.; whilst at Alice Springs there is a large evaporation tank similar to the one at the observatory, which it may be convenient here to describe.

It consists, first, of a brick tank, lined with cement; internal measurement, 4ft. 6in. square and 3ft. 2in. deep. Inside this tank is another, made of slate, 3ft. square and 3ft. deep, leaving an intervening space between it and the larger tank of 7in. Both tanks are filled to the same level, or to within 3in. or 4in. of the top, fresh water being added as required. The evaporation is measured by a graduated vertical rod, which is carried by a float placed in a vertical cylinder of copper 4in. in diameter (perforated at the bottom) standing in the inner tank. The rod is graduated to $\frac{1}{10}$ of an inch, and is read off by means of a fixed vernier to $\frac{1}{100}$ of an inch. A rain guage is placed by the side of the tank, and both the evaporation and the rainfall are read at 9 a.m. and 9 p.m.

In Tasmania, the Imperial Government established a magnetic and meteorological observatory at Hobart, as part of an international scheme, in charge of Captain Kay, and systematic meteorological observations were conducted from 1841 to 1854, hourly readings being taken until the end of 1848. The results were published, together with the magnetic observations, in four large quarto volumes with a short but interesting and instructive article by the late Prof. Dove, then director of the meteorological stations in Prussia. Similar observatories were established at Greenwich, St. Helena, Cape of Good Hope, and Toronto, besides places in Europe, and by Russia in Asia.

From the beginning of 1855, the Imperial Observatory being closed, meteorological observations at Hobart were carried on by the late Mr. Francis Abbott until about the year 1880, when the Government took up the work, which was entrusted to the late Captain Shortt, R.N., who died in 1893. Captain Shortt proved a valuable coadjutor, and established eight other observing stations, besides a number of rain gauges in various parts of the island, of which there are now about fifty-nine.

In Western Australia, a meterological observatory was established by the Government in connection with the Surveyor-General's office, the work being entrusted to Mr. M. A. C. Fraser, in 1876, since which continuous records have been published. Prior to the date mentioned we have rain and temperature records at Perth from 1860 to 1869, taken by Mr. H. Knight. At present Mr. Fraser has fifteen meteorological stations, exclusive of Perth, and ninety-one rain gauges. At Perth there is a self-recording barometer, selected by me when in England in 1886. The observations in this colony are very valuable, extending, as they do, from the south coast well into the tropics at Wyndham, Cambridge Gulf.

In Queensland, as has already been stated, meteorological stations were started at Brisbane and Rockhampton by Mr. Scott, the first Government Astronomer of New South Wales. I do not know the exact date, but Mr. Scott arrived in the colony in 1858, and retired in 1862. The instruments were transferred to Queensland on its separation from the parent colony, and for some years the duties of meteorologist devolved on Mr. Edmund MacDonnell, who established several observing stations and a number of rain gauges.

In 1887, Mr. Wragge was appointed, who—with the great ability and energy which characterise him, and which had brought him so much renown in starting, I believe at his own expense, the high level observatory at Ben Nevis, where he conducted the work under difficulties which would have deterred most men—soon effected a complete revolution. Beginning his work on January 1, 1887, he speedily equipped stations of the several orders all over the colony, along the coast round to the Gulf of Carpentaria, and inland to the very western boundary of the colony. He classified his stations under five orders, according to the completeness of their equipment.

Following the example of Mr. Ellery, Mr. Russell, and myself, Mr. Wragge commenced the system of publishing daily reports of weather and rainfall, and a synoptic map similar to the map we had for some time been issuing in Adelaide. He also co-operated with us in publishing forecasts of the probable weather during each ensuing twenty-four hours, with this addition, that he issued forecasts not only for Queensland, but also for the other Australian colonies; and, as these latter were made without regard to those published at an earlier hour by the several local authorities, it has occasionally happened that the two forecasts for the same colony differed from each other. I will not venture an opinion as to the desirableness of this independent action, beyond remarking that supposing the judgment and qualifications of the other meteorologists to be equally good, their local experience, and the possession of more detailed information in regard especially to prognostics, clouds, &c., gives them an advantage, and their forecasts should be of equal value, and be more frequently justified. I regret that Mr. Wragge's collected observations have not yet been published—from causes, it may be presumed, beyond his control—in such detail as he himself would wish, and which, in the interests of science, we all desire. This is to be regretted, as his stations are so distributed as to represent the climate of all parts of that large colony.

Besides the stations in Queensland, Mr. Wragge tells me he has supplied instruments for two stations of the first order in New Guinea, for one in New Caledonia, one in Fiji, and one in Norfolk Island, and two others of the second order in New Guinea.

In New Zealand, I learn from Sir James Hector, that from 1853 meteorological reports were included in the yearly volume of statistics issued by the Registrar-General, but the observations were of irregular character, and possessed little value until 1859, when the work was taken up in a more systematic manner. Observers were appointed at Wanganui, Auckland, Napier, New Plymouth, Wellington, Nelson, Christchurch, and Dunedin, each being supplied with a set of standard instruments. The service appears to have been placed, in the first instance, under the supervision of Dr. Knight, the Auditor-General, but in 1867 it was transferred to Dr. (now Sir James) Hector, under whose skilful management great improvements were introduced. The principal stations are supplied with mercurial Fortin barometers, dry and wet bulb and self-registering maximum and minimum thermometers, solar and terrestrial radiation thermometers, Robinson's anemometers, and rain gauges. The height of every barometer above sea-level has been ascertained, and every reading, as in the other colonies, is reduced to sea-level and 32° F.

At present there are eight stations, viz. Te Aroha, Taranaki, Russell, The Bluff, Wellington, Lincoln, Hokitiki, and Dunedin, equipped as above, except Te Aroha, which has an aneroid; and seventy-nine rain stations.

To facilitate the transmission of daily weather reports, Sir James Hector has prepared a series of isobaric maps, which fairly represents all the different types of weather. These maps are numbered in consecutive order, and stereotyped copies are supplied to each station, so that all that is necessary is for the head office to telegraph to each office the number of the map to be posted up for the information of the public. In the same manner typical maps of the pressure in Australia have been prepared, with the assistance of Mr. Russell, of Sydney. The reports from a few selected stations, a brief description of the weather, and the number of the map, are daily exchanged between Wellington and Sydney (representing Australia); the New Zealand reports being transmitted by telegraph to the head office in each of the other colonies.

Spread throughout the colonies we have 357 meteorological stations, more or less completely equipped, and 2575 rain gauges.

It will be seen that, excepting the magnetic and meteorological observatory at Hobart, established in 1841, which was an Imperial institution, systematic observations under the auspices of the Colonial Governments date, speaking approximately, from about 1858, a date which closely coincides with that given by Prof. Waldo (1860) as marking a definite epoch in the development of the modern science of meteorology. The investigation of the law of storms by Buys Ballot, Dove, and others, and the researches of Ferrel, then just commenced, on the theory of atmospheric motions, cleared the way to further advances; and, later on, the utilisation of the electric telegraph, which is to the meteorologist what the telescope is to the astronomer, in extending his field of view over large areas of the earth's surface, enabled the observer to mark and watch the birthplace of storms, track their course and rate of translation. The same means informed him of the general distribution of pressure, and, knowing the laws governing the circulation of air currents round regions of high and low barometers, he soon felt himself justified in issuing warnings of coming gales and the probable state of the weather some hours in advance. He was no longer confined to his own particular locality, laboriously compiling statistics and studying local prognostics; he could look far around him, see storms a thousand or more miles distant, and tell people with a considerable amount of confidence when they might be expected and what would be their force. This is the great function of modern meteorology. But, like everything else, it took time. It required money from the State, which was not always readily forthcoming; it required, moreover, a complete and extensive organisation of skilled observers, all working on the same lines and with the same objects in view. It had also to win the confidence of a sceptical public, which still placed confidence in quack weather prophets, who could tell them what the weather would be all the year through, according to the phases of the moon. Confidence, we are told, is a plant of slow growth. So it is, and so it should be if progress is to be made on a sound, solid, lasting basis.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The University Lecturer in Geography (Mr. Yule Oldham) will during the present term give a course of lectures on the History of Geographical Discovery, in the Lecture-theatre of the Chemical Laboratory on Thursdays at noon, beginning on Thursday, January 24.

The Council of the Royal Geographical Society offer in the present academical year a Studentship of £100, to be used in the geographical investigation (physical or historical) of some district approved by the Council. Candidates must be members of the University of not more than eight years' standing from matriculation, who have attended the courses of lectures given in Cambridge by the University Lecturer in Geography. Applications should be addressed to the Vice-Chancellor not later than the last day of the full Lent term, March 15, 1895.

Prof. Ewing, F.R.S., has been appointed Chairman of the Examiners for the Mechanical Sciences Tripos.

The Gamble Prize for 1894 has been awarded to Miss Isabel Maddison, for her essay on "Singular solutions of differential equations of the first order."

THE first annual meeting of the Association of Technical Institutions was held on Friday last. In the course of an address, Mr. W. Mather, M.P., the President for the ensuing year, remarked that, so far as the pecuniary facilities conferred by the Technical Instruction Acts were concerned, local authorities had the means of annually bestowing on technical education in England and Wales (1) from grants under the Local Taxation Act, about £780,000; (2) from a penny rate levied on the total rateable value of the whole country, £664,500; (3) grants from the Department of Science and Art, about £355,000. The total amount available is thus, in round numbers, £1,800,000 per annum. To this must be added the voluntary aid given to technical schools and institutions. Among the resolutions adopted by the meeting was one for the appointment of a sub-committee to consider the best methods by which reform could be effected in the present system of examination in practical chemistry adopted by the Department of Science and Art, and to confer with other committees appointed with a similar object; and another to the effect that the result of examinations should not form the sole basis for the calculation of the grant in aid of science classes, but that there should also be a variable grant dependent on the report of the inspector on the equipment and arrangement for efficient instruction.

SOCIETIES AND ACADEMIES.

LONDON.

Mathematical Society, January 10.—Major Macmahon, R.A., F.R.S., President, in the chair. The Chairman gave a short obituary sketch of Mr. A. Cowper Ranyard, in the course of which he pointed out that that gentleman had only been a *pro tem.* secretary with the late Mr. G. C. De Morgan.—The secretaries elected at the first meeting of the Society, January 16, 1865, were Messrs. H. Cozens Hardy and H. M. Bompas. Mr. Hardy resigned at the second meeting (February 20), and Mr. W. Jardine was elected in his room.—The following communications were made:—Note on the expansion of functions, by Mr. Edward T. Dixon. The author had long thought that so fundamental a theorem as the expansion of a function in Taylor's series ought to be demonstrable from first principles in a simple maner which should be applicable to complex as well as to real quantities. The main feature in the proof he proposed was that the series was regarded not as the expansion in terms of powers of the increment of the variable, but rather as the expansion in terms of the values of the successive differential coefficients of the function for the given initial value of the variable. If two functions were equal for a given value of the variable, they would remain equal while the variable varied in any specified manner, so long as their rates of change remained equal and finite. The two sides of the equation known as Taylor's theorem were such functions; and the author explained how the limitations to the application of Taylor's theorem followed directly from his way of regarding the expansion. He also showed how the same line of argument applied to the case of complex variables, and how in that case also the limitations could easily be deduced.—Electrical distribution on two intersecting spheres, by Mr. H. M. Macdonald. In Maxwell's "Electricity and Magnetism," vol. i. §§ 165, 166, the problem of the distribution of electricity induced by an electrified point placed between them on two planes cutting at an angle which is a submultiple of two right angles, and the inverse problem of the conductor formed by two spherical surfaces cutting at such an angle (the angle referring to the dielectric) is solved by the method of point images. This method is inapplicable when the (dielectric) angle is not a submultiple of two right angles, as has been shown by W. D. Niven, *L.M.S.* vol. xii. p. 27. The only other case which has been hitherto solved is, the author thinks, that of the spherical bowl (Lord Kelvin, "Papers on Electrostatics and Magnetism," p. 178). In the paper by W. D. Niven, mentioned above, an attempt is made to deduce the capacity of such a conductor from the solution of a functional equation for a particular value of one of the variables, but the result obtained does not seem in the case of the spherical bowl to agree with Lord Kelvin's. The results obtained by the author also differ from those given by Niven. The object of the paper is to obtain the solution in the general case. To effect this, the functional image of a point placed between two planes intersecting at any angle is obtained in the form of a definite integral. In the next few paragraphs the reduction of this integral to known forms is effected in certain cases, and it is shown that the integration can be performed when the angle of intersection is any submultiple of four right angles; the case in which it is reducible to elliptic functions is also discussed. In § 5, the functional image of a line of uniform density parallel to the intersection of the planes is deduced. In § 7, the potential due to a freely-charged conductor bounded by two spherical surfaces cutting at any angle is obtained and some particular cases discussed. The capacity of such a conductor is obtained in § 8, in finite terms, and some particular cases are discussed in § 9; one of the most interesting of these is the capacity of a hemisphere, which is found to be nearly one and a quarter times that of the complete sphere, showing that the sharp edge acts somewhat like a condenser. Some cases are mentioned in the last paragraph which could be deduced from the results of the preceding ones.—The Dynamics of a Top, by Prof. A. G. Greenhill, F.R.S. To construct a model of the articulated deformable hyperboloid described by M. Darboux in Note xix. to Despeyrous' "Cours de Mécanique," t. ii., which shall realise the motion of the axis of a Top, the ratio of the axes of the focal ellipse must be taken equal to the modulus k of the associated elliptic functions. The parameters a and b of the two elliptic integrals of the third kind corresponding respectively to the lowest and highest vertical positions of the Top, which give the azimuth ψ, will be of the form

$$a = pK'i \text{ and } b = qK'i + K,$$

where p and q are real proper fractions. Then two points P and Q must be taken on the focal ellipse whose excentric angles, measured from the minor axis, are given by

$$\operatorname{am}\{(1 - p + q)K', k'\} \text{ and } \operatorname{am}\{(1 - p - q)K', k'\};$$

and if the tangents HI and HJ are drawn at Q and P, intersecting in H, these tangents make angles

$$\operatorname{am}\{(p + q)K', k'\} \text{ and } \operatorname{am}\{(p - q)K', k'\}$$

with the minor axis. The parallel tangents OC and OG being drawn, intersecting in O, the design of the model is completed, in Henrici's manner, by drawing any other two pairs of tangents to the focal ellipse; the tangents OG and OC being replaced by a pair of rods, representing the generators through O, HI and HJ representing the parallel generators through H, the other pairs of tangents representing the connecting generators, all freely jointed at the points of crossing. If OG is held fixed in a vertical position, the point H opposite to O is constrained to move in a fixed horizontal plane; and now if H is moved along a herpolhode of parameter $a + b$, the generator OC will imitate the motion of the axis of a Top. Starting with the hyperboloid flattened in the plane of its focal ellipse, and H at a maximum distance from OG, the axis OC is in its lowest position; and as H moves along the herpolhode to its minimum distance from OG, the axis rises to its highest position, when the hyperboloid becomes flattened in the plane of its focal hyperbola. If the herpolhode has points of inflexion, the path of a point C in the axis OC will be looped; since the motion in azimuth of OC vanishes as H passes through a point of inflexion. If $p - q = 1$, the point Q lies at the end of the minor axis of the focal ellipse; the path of C now has cusps. In the spherical pendulum the points H and O lie on the pedal of the focal ellipse with respect to the centre; this gives a geometrical interpretation of the equation

$$\wp' a = \pm \wp' b_1$$

discussed in Halphen's "Fonctions elliptiques," i. p. 110. The vector OH represents the resultant angular momentum of the Top; and the tangent to the path of H is thus perpendicular to the vertical plane GOC. When the momental ellipsoid at O of the Top is a sphere, then OH represents also the resultant angular velocity. But in the general case, when the momental ellipsoid at O is a spheroid, with axis OC, the resultant angular velocity is represented by the vector OI to a point I fixed in the generator HQ; also H and I describe equal curves with respect to OC in parallel planes perpendicular to OC, which are herpolhodes of parameter $a - b$. Since I can be joined to a fixed point in the opposite generator OG by a rod of fixed length, we have Darboux's theorem that the motion of the Top can be realised by rolling a herpolhode of parameter $a - b$, on a fixed sphere. The connection of the motion of a Top with herpolhodes has also been discussed by Dr. Routh, *Q.J.M.* xxiii. p. 34. As an application, consider Halphen's algebraical herpolhode

$$(\xi^2 + b^2)(\eta^2 + b^2) = a^4$$

or

$$\tfrac{1}{4}r^4 \sin^2 2\theta + b^2 r^2 + b^4 - a^4 = 0,$$

produced by rolling the hyperboloid of two sheets

$$\frac{x^2}{-a^2} + \frac{y^2}{-b^2} + \frac{z^2}{a^2} = 1$$

on a fixed plane at a distance b from the centre.

In the associated motion of the Top, $p + q = \frac{1}{2}$; the focal ellipse of the articulated hyperboloid is given by

$$\frac{x^2}{0} + \frac{y^2}{\frac{1}{4}b^2\left(\frac{a^2}{b^2} - 1\right)^2} + \frac{z^2}{\frac{1}{4}b^2\left(\frac{a^2}{b^2} + 1\right)^2} = 1;$$

the coordinates of H and O in its plane are given by

$$y^2 = \frac{a^2}{8}\left(\frac{a^2}{b^2} - 1\right), \quad z^2 = \frac{a^2}{8}\left(\frac{a^2}{b^2} + 1\right);$$

at P $y^2 = \frac{b^4}{8a^2}\left(\frac{a^2}{b^2} - 1\right)^3, \quad z^2 = \frac{b^4}{8a^2}\left(\frac{a^2}{b^2} + 1\right)^3$; at Q

$$y^2 = \frac{b^8}{8a^6}\left(\frac{a^2}{b^2} - 1\right)^3\left(\frac{a^2}{b^2} + 2\right)^2, \quad z^2 = \frac{b^8}{8a^6}\left(\frac{a^2}{b^2} + 1\right)^3\left(\frac{a^2}{b^2} - 2\right)^2.$$

The motion of the axis of the Top is given by

$$\sin^2\theta \cos 2\psi = 4\sqrt{2}\,\frac{ab^2}{(a^4 + 8b^4)^{\frac{1}{4}}}\sqrt{\left\{\frac{a^4 + 2b^4}{a^2\sqrt{(a^4 + 8b^4)}} - \cos\theta\right\}}.$$

$$\sin^2\theta \sin 2\psi = \left\{\frac{a^2}{\sqrt{(a^4 + 8b^4)}} - \cos\theta\right\}$$

$$\sqrt{\left\{\frac{a^2 + 4b^2}{\sqrt{(a^4 + 8b^4)}} + \cos\theta \cdot \frac{a^2 + 4b^2}{\sqrt{(a^4 + 8b^4)}} + \cos\theta\right\}}.$$

Thus for instance, if $a^2 = 2b^2$, $k = \frac{1}{3}$; the point Q is at an end of the minor axis of the focal ellipse, and the curve described by C has cusps. If $a^2 = 3b^2$, $k = \frac{1}{2}$; Halphen's herpolhode has points of inflexion where $r^2 = \frac{16}{3}b^2$, and r^2 varies between $4b^2$ and $8b^2$; the equation of the focal ellipse is

$$\frac{x^2}{0} + \frac{y^2}{b^2} + \frac{z^2}{4b^2} = 1,$$

and the coordinates of H and O are $\pm\frac{1}{2}\sqrt{3}\,b$, $\pm\frac{1}{2}\sqrt{6}\,b$.—Some properties of generalised Brocard circles, by Mr. J. Griffiths. —On fundamental systems for algebraic functions, by Mr. H. F. Baker.

Physical Society, January 11.—Extra meeting, in the physical laboratories of University College (by invitation of Prof. Carey Foster).—Prof. Rücker, President, in the chair.—Prof. Ramsay read a paper, by himself and Miss Dorothy Marshall, on the measurement of latent heats of vaporisation of various organic liquids. The liquid to be examined is placed in a small flask with a narrow neck, and within this is a platinum wire which has its two ends fused through the bottom, so as to be capable of conveying an electric current. The flask is completely enclosed in a jacket, which is filled with the vapour of liquid of the same kind. Before the current is turned on, the vapour jacket is kept going for some time, so that the liquid in the flask is raised just to its boiling point, but no appreciable evaporation takes place. As soon as the current is turned on, boiling commences, and all the heat developed in the wire is expended in producing evaporation. By weighing the flask before and after, the mass of liquid vaporised is determined. So far the authors have only used the method for comparative determinations. Two arrangements of the kind described are placed side by side, and the same current is sent through their two wires, which are joined in series and have approximately equal resistances. The ratio of amounts of heat expended on the two liquids divided by the ratio of the masses vaporised, is equal to the ratio of their latent heats. The determinations made by this method agree well with those of other observers; but the authors' object is to obtain values correct within about ½ per cent. for a large number of liquids, rather than a highly accurate value for any one substance. In reply to Mr. Griffiths, the authors stated that the platinum wire was found to rise about 20° above the temperature of the liquid, and Mr. Griffiths said that his experience had been similar. He did not see why a very high degree of accuracy should not be obtainable by the method. Prof. Rücker expressed his admiration for the work, and thought it justified by the fact that the results accorded more nearly with theory than those of other observers. —Mr. Eumorfopoulos read a paper on the determination of thermal conductivity and emissivity. In the first series of experiments described, two bars of the same material and polish, and each of uniform circular section, are heated, each at one end, until the distribution of temperature has become steady. By means of two thermo-joints (one on each rod) a series of isothermal points are then found. According to the ordinary theory, if the two bars agree in temperature at a given pair of points, they will also agree in temperature at distances x_1 and x_2 measured respectively from these points, where x_1 and x_2 are connected by the relation $x_1/x_2 = \sqrt{(r_1/r_2)}$, r_1 and r_2 being the radii of the rods. This relation was not found to hold good for the rods examined. In all cases x_1/x_2 was further removed from unity than the ordinary theory would require. One conclusion was that the formula usually adopted in such cases could not be used for the comparison of conductivities, unless the radii of the rods compared are equal, and their surfaces in the same condition. To settle the question, three brass rods were chosen, and their absolute conductivities compared by Ångström's method. The emissivity was found to vary considerably with the radius, being greater the thinner the rod; moreover, the value of the emissivity deduced from the first sine term of the Fourier's series was in each case found to be about 1·2 times as great as that deduced from the constant term. —Mr. A. W. Porter then read a paper on the influence of the dimensions of a body on the thermal emission from its surface. The ordinary assumption is that whether a body is *in vacuo* or surrounded by air, the "emissivity" (*i.e.* the amount of heat passing outwards from unit area per second per degree excess of temperature) is independent of the size of the body. Results obtained experimentally by Péclet for cylinders and spheres of different sizes, show that the emissivity depends materially upon the size of the body. Péclet's formulæ for cylinders and spheres surrounded by air show that for each of these forms the rate of emission per unit surface, exclusive of the radiation effect, may be represented by a constant *plus* a term inversely proportional to the radius. The author examines the results of supposing the loss to follow only in part the law of radiation, the remainder being assumed to follow the law of conduction. He thus arrives at a formula

$$e = h + \frac{c}{a\,(\log R - \log a)};$$

where e is the emissivity, a the radius of the rod, R the radius of a hollow cylinder which surrounds the bar, and above which the excesses of temperature are reckoned; while h and c are constants. This formula has been compared with experimental results of Ayrton and Kilgour, of MacFarlane, of Bottomley, and of Péclet, and has also been directly checked by experiments on a brass rod when surrounded by water-jackets of different radii, as well as on the same bar unjacketed. The author finds the agreement to be much closer than is the case on the theory of constant emissivity, or with empirically deduced formula of Ayrton and Kilgour, and he concludes that the enclosing boundary is as important a factor in determining emissivity as the size of the body itself. Prof. Carey Foster thought that in demonstrating the influence of the enclosure Mr. Porter had established an important point. Prof. Ayrton agreed as to the importance of the influence of the enclosure. He urged that in such experiments as those of Mr. Porter and Mr. Eumorfopoulos, the conductivity and emissivity, which were functions of the temperature, should not be assumed constant along the bar. Mr. Trotter objected to the use of the term emissivity as including loss of heat by contact with the air in addition to the loss by radiation. Mr. Griffiths said that in some of his experiments, where a wire conveying an electric current was immersed in a liquid in order to heat the latter, the rise of the temperature of the wire above that of the liquid was found to be nearly independent of the diameter of the wire. Mr. Eumorfopoulos said that in each case his comparison had been between portions of bars in which the range of temperature was the same. Moreover, the variation of emissivity and conductivity with temperature, as found by other observers, would be quite insufficient to account for his results. Mr. Porter said that the term emissivity had come to be accepted as referring to all heat lost at the surface of a body, whether by radiation or by conduction and convection. In that sense he had used the term. Prof. Rücker thought that emissivity, in this sense, was not a good term, but to change now would probably only make greater confusion.—Mr. G. U. Yule then gave a brief outline of his paper, on the passage of an oscillator wave-train through a plate of conducting dielectric. By a conducting dielectric the author means a substance whose conductivity and dielectric capacity are both of importance in the case under discussion; and the paper is mainly an investigation of the following problem: a train of plane electromagnetic waves falls at normal incidence on an infinite parallel sided plate of conducting dielectric, whose thickness is finite, and at the first face of the plate, the amplitude of the vibration vector in the incident train is zero up to a certain instant, and then becomes equal to an harmonic function of the time, multiplied by an exponential function with negative index: to find what proportion of the energy of the whole incident train is reflected back, what proportion is transmitted through the plate, and what proportion absorbed. At successive incidences of reflected and re-reflected wave-trains upon the two bounding faces of the plate, the amplitudes and phase-changes of reflected and transmitted portions have to be taken into account, and the resulting infinite series of terms have to be summed. The analysis is very long, but the results obtained are exact. Curves are given, showing (for special numerical values of the constants of the problem) the quasi-periodic variation of the amounts of energy transmitted and reflected, as the thickness of the plate is increased from zero up to a high value. Other curves are given showing the effect of varying the dielectric constant and the conductivity of the plate, and the difference between a "damped" and an "undamped" wave-train in regard to intensity of reflected and transmitted portions. The author compares his calculated results with measurements obtained in the case of oscillator waves travelling along a double-wire circuit about 100 metres in length; the wires at the middle of the circuit being run through a jar containing distilled water, alcohol, or a very dilute electrolyte.—The necessary corrections, however, are difficult and uncertain, and the author has not found it possible to deal with them in a satisfactory way.—A letter from Dr. E. H. Barton was read, emphasising the necessity for taking into account the damping in the oscillator-train, and at the same time pointing out why, in his opinion, the corrections applied by Mr. Yule were inadequate and failed to yield intelligible results. Prof. Rücker congratulated Mr. Yule on his work, and on the importance of the results he had obtained. In returning the thanks of the Society to Prof. Carey Foster for the invitation to meet in University College, he expressed the pleasure he had felt in observing the extent and completeness of the laboratories. Hitherto London had been behind the provinces in this matter, and it was gratifying to find that students in London had now such opportunities for practical instruction in physics. The papers which had been read at that meeting were a proof that good use was being made of the laboratories for the purposes of research. The educational experiments they had seen in the laboratories were excellently devised, and he hoped that many of them would become a part of the regular course of instruction in the country. Prof. Foster briefly replied.

Chemical Society, Dec. 20, 1894.—Dr. H. E. Armstrong, President, in the chair.—The following papers were read:—An improved form of barometer, by J. N. Collie. The author has devised a portable barometer presenting several new features.—The constituents of *Piper ovatum*, by W. R. Dunstan and H. Garnett. *Piper ovatum* is a West Indian medicinal plant; the authors have separated from it a toxic alkaloidal substance, which they term piperovatine, $C_{16}H_{21}NO_2$; it seems likely to be of service in therapeutics.—Note on the active constituent of the Pellitory of medicine, by W. R. Dunstan and H. Garnett. The Pellitory of medicine (*Anacyclus pyrethrum*) contains an active substance, which they name pellitorine; it closely resembles piperovatine, and is possibly identical with it.—The determination of some high temperature freezing-points by means of platinum-resistance pyrometers, by C. T. Heycock and F. H. Neville. The authors give the results of freezing-point determinations of a number of metals and salts.—The preparation of adipic acid and some of its derivatives, by W. H. Ince. Contrary to the statements of Arppe and Malaguti, adipic acid is not produced in the action of nitric acid on sebacic acid or beef suet. The author has prepared α-monobromadipic acid in a state of purity, and has obtained α-hydroxyadipic acid.—The action of hydrogen chloride on the oxides of calcium, barium, and magnesium, by V. H. Veley. Dry hydrogen chloride does not act on quick-lime or magnesia at ordinary temperatures; at higher temperatures action occurs. Baryta is acted on at all temperatures by the dry gas.—Latent heat of fusion, by H. Crompton.—Metallic tartrasenites, by G. G. Henderson and A. R. Ewing. Arsenious oxide dissolves in hot solutions of acid tartrates, giving tartrasenites; the sodium salt, $C_4H_4O_6AsONa, 2\frac{1}{2}H_2O$, is stable and crystalline.—Note on the interaction of hydrogen sulphide and bismuth haloid compounds, by M. M. P. Muir and E. M. Eagles.

Zoological Society, January 15.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. P. Chalmers Mitchell exhibited and gave an account of a tibia and other bones of an extinct bird of the genus *Æpyornis* from Central Madagascar, which had been lent to him for exhibition by Mr. Joseph H. Fenn. With these bones was associated a skull of a species of *Hippopotamus*.—Prof. G. B. Howes exhibited and made remarks on the photograph of an embryo of *Ornithorhynchus*.—The Secretary exhibited, on behalf of Mr. R. Lydekker, a life-sized drawing of *Idiurus zenkeri*, a new and remarkably small form of flying squirrel from West Africa, recently described at Berlin.—Lord Lilford sent, for exhibition, the skin of a duck, believed to be a hybrid between the Mallard (*Anas boschas*) and the Teal (*Querquedula crecca*), that had been caught in a decoy in Northamptonshire.—The Rev. T. R. R. Stebbing exhibited a specimen of a species of *Peripatus* from Antigua.—Mr. Frederick Chapman gave an account of some Foraminifera obtained by the Royal Indian Marine Survey's s.s. *Investigator* from the Arabian Sea near the Laccadive Islands. The author described the forms found in the samples sent him. As many as 277 species and varieties were enumerated, some of which were new to science. Several of the species, which were here recorded for the first time from recent soundings, had been previously known from the Pliocene deposits of Kar Nicobar. One of the forms found in these recent deposits, viz., *Amphistegina radiata* (F. and M.), was described by the author as showing the presence of interseptal canals, a structure which had hitherto appeared to be restricted to Nummulites and allied forms. Examples of embryonic forms of the same species were also noted as being present in the peripheral chambers of the adult shell.—A communication was read from Mr. P. R. Uhler containing an enumeration of the Hemiptera-Homoptera of the Island of St. Vincent, West Indies. This paper had been based on specimens submitted to Mr. Uhler by the joint Committee of the Royal Society and British Association for the exploration of the Lesser Antilles.—A communication from Mr. T. D. A. Cockerell contained a description of a new species of the family *Coccidæ* belonging to *Lichtensia*, a genus new to the fauna of the Nearctic region. The species was named *L. lycii*.—Mr. Sclater read some notes on the recent occurrence of the Barbary Sheep in Egypt. A flock of these sheep had visited the eastern bank of the Nile above Wady Halfa in the summer of 1890.—A second paper by Mr. Sclater contained some notes on the recent breeding of the Surinam Water-Toad (*Pipa americana*) in the Society's reptile-house.

Entomological Society, January 16.—The sixty-second annual meeting; Mr. Henry John Elwes, President, in the chair.—An abstract of the treasurer's accounts, showing a good balance in the Society's favour, having been read by Mr. W. F. H. Blandford, one of the auditors, the secretary, Mr. H. Goss, read the report of the Council. It was then announced that the following gentlemen had been elected as officers and Council for 1895:—President, Prof. Raphael Meldola, F.R.S.; treasurer, Mr. Robert McLachlan, F.R.S.; secretaries, Mr. Herbert Goss and the Rev. Canon Fowler; librarian, Mr. George C. Champion; and as other members of the Council, Mr. George T. Bethune-Baker, Mr. Walter F. H. Blandford, Dr Frederick A. Dixey, Mr. Henry J. Elwes, Mr. Charles J. Gahan, Prof. Edward B. Poulton, F.R.S., Dr. David Sharp, F.R.S., and the Right Hon. Lord Walsingham, F.R.S. It was also announced that Prof. Meldola, the new President, would appoint Lord Walsingham, Mr. Henry J. Elwes, and Prof. Edward B. Poulton, Vice-Presidents for the session 1895–96. The outgoing President then delivered an interesting address on the geographical distribution of Lepidoptera. He remarked that though a great deal had been written of late years on the geographical distribution of plants, mammals, birds, fishes, and reptiles, comparatively little had yet been done by entomologists to show how far the natural divisions of the earth's surface which have been established for other classes were applicable to insects. Perhaps the proportion of known as compared with unknown insects was still too small, and the classification of the known species still too uncertain, to allow anything like the same methods to be applied to insects that had been used for mammals by Dr. Wallace, F.R.S., for birds by Dr. Sclater, F.R.S., and Dr. Bowdler Sharpe, and for plants by Sir J. Hooker, F.R.S., Mr. Thiselton Dyer, F.R.S., and Mr. W. B. Hemsley. The President enumerated the genera of the Rhopalocera, and pointed which of them were characteristic of the various regions and sub-regions into which the world had been divided by the zoologists and botanists above mentioned. He also exhibited specimens typical of these regions and sub-regions. The President then alluded to the prosperous condition of the Society, and to the increase in its numbers and income. Reference was also made to various Fellows of the Society and other entomologists who had died during the year, special mention being made of Herr H. T. Christoph, Mr. J. Jenner-Weir, Dr. F. Buchanan White, M. Lucien F. Lethierry, Pastor Wallengren, Dr. Jacob Spånberg, Major-General Carden, Dr. Hearder, and Mr. Wellman.—A vote of thanks to the President and other officers of the Society having been passed, Mr. Elwes, Mr. McLachlan, Mr. H. Goss, and Canon Fowler replied, and the proceedings terminated.

Royal Meteorological Society, January 16.—Mr. R. Inwards, President, in the chair.—The Council, in their report, reviewed the work done by the Society during the past year, and also stated that additional accommodation had been provided to meet the growing needs of the library. Forty-five new Fellows had been elected during the year. Mr. Inwards, in his presidential address, dealt with the subject of "weather fallacies," which he treated under the head of saints'-day fallacies, sun and moon fallacies, and those concerning animals and plants. He also referred to the almanac makers, weather prophets and impostors, who have from time to time furnished the world with fit materials for its credence or its ridicule.—Mr. C. Harding read a paper on the gale of December 21–22, 1894, over the British Isles. This storm was one of exceptional severity, especially over the northern portions of England and Ireland and in the south of Scotland. It developed energy very quickly, and travelled with great rapidity. The self-recording anemometers show that the greatest violence of the wind occurred at Fleetwood, where the velocity was 107 miles in the hour between 8.30 and 9.30 a.m. on the 22nd; and for four consecutive hours the velocity exceeded 100 miles. This is the greatest force of wind ever recorded in the British Isles, and is 10 miles an hour in excess of the highest wind velocity in the great storm of November 16–20, 1893. At Holyhead the wind in squalls attained the hourly velocity of 150 miles between 10 a.m and noon on the 22nd. The strongest force was mostly from the north-westward. Much destruction was wrought both on sea and land, and there was a heavy loss of life.

PARIS.

Academy of Sciences, January 14.—On a method of verification, applicable to the calculation of series in astronomical problems, by M. Poincaré.—On autumn cultivations for green manures, by M. P. P. Dehérain. The author insists on the importance of autumn cultivations for subsequent digging in, for two main reasons: (1) nitrates are retained by the roots of growing plants, which would otherwise be lost in the drainage waters; (2) if buried at the proper time, the decomposition of the vegetable matter affords a considerable amount of useful fertilisation.—Experimental researches on the critical point of liquids holding solid substances in solution, by M. Raoul Pictet. From the results obtained, it appears that either solid bodies become gaseous and mix with other gases at temperatures below their points of fusion and under considerable partial pressures of their own vapours, or the solid bodies present are dissolved in droplets momentarily formed in many places in the mass of gas above the critical temperature of the solvent. In the latter case, a solid deposit should be formed on superheating the vapours. This point has to be investigated.—The treatment of vines, infested by phylloxera, with peat-moss impregnated with a mineral oil, by M. F. de Mély. Details are given of a process which appears to effectually clear off the pest without injuring vegetation.—On a method of drawing a right line by the aid of jointed links, by M. Raoul Bricard.—M. J. Janssen called the attention of the Academy to the contents and scope of the *Annuaire du Bureau des Longitudes.*.—A letter from the *Königliche Gesellschaft der Wissenschaften* of Göttingen was read inviting the Academy to send delegates to Innsbrück, to take part in a meeting for the consideration of the problem of investigating the variation of the intensity of gravity with the geological character of the crust of the earth.—On the application to differential equations of methods analogous to those of Galois, by M. Jules Drach.—On the determination of the equations of continuous finite groups, by M. E. Vissiot.—On the law of transmission of energy between the source and the conductor, in the case of a permanent current, by M. Vaschy.—On the production of cathode rays, by M. Joseph de Kowalski. (1) The production of the so-called cathode rays does not depend on the discharge from metallic electrodes across a rarefied gas. (2) They are produced chiefly where the primary illumination attains a considerable intensity; that is, where the density of the current lines is very considerable. (3) Their direction of propagation is that of the current lines at the place where the rays are produced, from the negative to the positive poles.—On the *entraînement* of luminous waves by matter in motion, by M. G. Foussereau.—On some properties of silver sulphide, by M. A. Ditte. The double sulphides, $4Ag_2S.K_2S.2H_2O$ and $3Ag_2S.Na_2S.2H_2O$, are described, and a method for their preparation given.—On the preparation of amorphous silicon, by M. Vigouroux. The preparation is carried out by heating to about 540° a perfectly dry mixture of silica, magnesium, and magnesia. The silicon, by the usual treatment with acids, is obtained as a pulverulent, maroon-coloured substance.—On the protomorphic state: sulphides of zinc and manganese, by M. A. Villiers.—On some sensitive reactions of amido-benzoic acids, by M. Oechsner de Coninck.—On a class of nitriles, by M. Albert Colson.—On the constitution of hexamethylenetetramine, by MM. R. Cambier and A. Brochet.—On ethylenic methylal, by M. Louis Henry.—New researches on pectase and on the pectic fermentation, by MM. G. Bertrand and A. Mallèvre. Pectase exists in solution in the cellular sap of acid fruits, just as in carrot roots. There is no insoluble pectase. In acid fruits, its action is only apparent after neutralisation.—On the influence exercised by the nervous system and the internal pancreatic secretion on histolysis. Facts illustrating the mechanism of normal glycæmia and sugar diabetes. A note by M. M. Kaufmann.—The Pleistocene of the valley of Chambéry, by MM. J. Révil and J. Vivien.—Remains of striped hyænas from the quatenary of Bagnères-de-Bigorre (Hautes-Pyrénées), by M. Édouard Harlé.—On the quatenary phosphorites from the region of Uzès, by M. Charles Depéret.—An anemometer with multiple-electrical indications and automatic orientation, by M. Jules Richard.

BERLIN.

Physiological Society, December 21, 1894.—Prof. du Bois Reymond, President, in the chair.—Prof. Waldeyer gave a lengthy account of the most recent researches on the formative structures of the nervous system, laying special stress on the following statements. The entire nervous system consists of single elements which may most conveniently be called "neurons," each of which is composed of a nerve-cell and its processes. These processes are, on the one hand, protoplasmic "dendrites" which rapidly become branched, and, on the other hand "neurites" or "axons," which give off collateral branches, soon become medullated, and end in fine branchings, as also do the collaterals. Each nerve-cell has only one "axon." The dendrites convey impulses to the cell, the neurites or axons convey impulses from the cell. All nerve-fibres, both dendrites and neurites, end freely in fine branchings. Every physiological path of conduction, whether from the periphery to the central nervous system, or *vice versâ*, consists of two or more neurons, never of one. Conduction in the neurons is always longitudinal. Impulses are transmitted from one neuron to the other only by means of the free endings of the terminal branches. The lecture was illustrated by a series of schematic diagrams and some preparations.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—L'Industrie des Araneina: W. Wagner (St. Pétersbourg).—Summer Studies of Birds and Books: W. Warde Fowler (Macmillan).—Over de Bevruchting der Bloemen: J. MacLeod (Gent, Vuylsteke).—Lens-Work for Amateurs. H. Orford (Whittaker).—Steel Works Analysis: Prof. J. O. Arnold (Whittaker).—Handbook for Hertfordshire, Bedfordshire, and Huntingdonshire (Murray).—Calcareous Cements: G. R. Redgrave (Griffin).—An Elementary Text-Book of Metallurgy: Prof. A. H. Sexton (Griffin).—Electrical Engineering: W. Slingo and A. Brooker, new edition (Longmans).—A Popular Treatise on the Physiology of Plants: Dr P. Sorauer, translated by Prof. Weiss (Longmans).—Whence Comes Man, from "Nature" or from "God"?: A. J. Bell, new edition (Isbister).—Why does Man Exist?: A. J. Bell, new edition (Isbister).—A Collection of Appliances and Apparatus for the Prevention of Accidents in Factories, 2nd edition (Dulau).—Elektrophysiologie: Prof. W. Biedermann, Erste Abthg. (Jena, Fischer).—Allgemeine Physiologie: Dr. Max Verworn (Jena, Fischer).—Manuals of Elementary Science: *Zoology*: Prof. A. Newton, new edition (S.P.C.K.).—Manuals of Health: Air, Water, and Disinfectants: Dr. C. M. Aikman (S.P.C.K.).

PAMPHLETS.—Elementary Practical Chemistry: J. T. Hewitt and F. G. Pope (Whittaker).—Latent Heat of Steam and Absolute Zero: W. Donaldson (Waterlow).

SERIALS.—L'Anthropologie, tome v. No. 6 (Paris).—Quarterly Review, January (Murray).—Archives of Surgery, January (West).—Journal of Anatomy and Physiology, January (Griffin).—Botanische Jahrbücher, Neunzehnter Band, 4 Heft (Leipzig).—Royal Natural History, Part 15 (Warne).—Rendiconto dell'Accademia delle Scienze Fisiche e Matematische, serie 2ª, Vol. viii, Fasc. 11°, e 12° (Napoli)—Bulletins de la Société D'Anthropologie de Paris, Nos. 5–7 (Paris).—Bulletins of the Rose Polytechnic Institute. No. 1: Physical Units: Prof. T. Gray (Terre Haute, Ind.).

THURSDAY, JANUARY 31, 1895.

GEO-MORPHOLOGY.

Lithogenesis der Gegenwart. Beobachtungen über die Bildung der Gesteine an der heutigen Erdoberfläche. Dritter Theil einer Einleitung in die Geologie als historische Wissenschaft. By Johannes Walther. 8vo. pp. viii. + 535–1055. (Jena: G. Fischer, 1894.)

Geotektonische Probleme. By A. Rothpletz. 8vo. pp. 175. 107 figures, and 10 plates of sections. (Stuttgart: E. Schweizerbart, 1894.)

Morphologie der Erdoberfläche. By Dr. Albert Penck. Ratzel's "Bibliothek Geographischer Handbücher." 8vo. 2 vols. Vol. I. pp. xiv. + 171. 29 figures. Vol. II. pp. x. + 696. 38 figures. (Stuttgart: J. Engelmann, 1894.)

RECENT discussions in England as to the relations between geology and geography have only served to show that these sciences are so intimately associated that no satisfactory line of demarcation can be drawn between the two. These three works illustrate the extent to which this view has been accepted in the schools of Germany and Austria, and the valuable results to both sciences that follow from a due recognition of the fact. The three works agree in this, though they are very different in their aims and subject-matter. The first is a manual on rock-formation; the second, a monograph on one type of earth-movements; and the third, a systematic text-book of structural geography. One is a restatement of the principles of correlation, another a protest against speculation, and the other a compilation of the classifications of, and theories respecting, the different geographical forms. They have, however, so much in common in their methods, that they may be conveniently noticed together.

Prof. Walther's work goes even further. It shows not only the inseparability of geology and geography, but the need of a knowledge of biology for the correct application of the evidence of palæontology to stratigraphy. Since the days of William Smith, the evidence of fossils has been regarded as final in both historical and stratigraphical geology. It is therefore rather startling to find a geologist stating that the history of the earth could have been written from the structure of the rocks alone, without the assistance of the organic remains within them. It has been the rule, in the determination of the age of any particular bed, to accept only the evidence of the fossils as valid. So long as the method of correlation by the proportions of species and genera common to two horizons, was confined to comparatively simple areas, it gave fairly trustworthy results. But when extended beyond Britain and the North European plain, it was the cause of serious confusion. The classification of the very variable Cainozoic deposits of the Mediterranean basin were involved by it in chaos; it caused beds in Australia to be assigned to the highest instead of the lowest division of the Cainozoic, and led to limestones in the West Indies, probably formed in part within the historic period, being referred by high authorities to the Miocene. Even in such a simple sequence as that of England, the method led to errors, as, *e.g.*, in the exaggeration of the gaps in the geological record, such as that between the Chalk and the Lower London Tertiaries. Occasionally a warning against the neglect of lithology would be uttered, as by Godwin Austen and Sorby, or an effort made to use it. But the former were ignored; and the latter were not at first judicious, as in the case of the famous generalisation, that we are still living in the age of the Chalk, a suggestion about as useful as that we are still living in the Silurian, because sandbanks were formed then and are forming now.

For the recognition of the necessity for the limitation of palæontology, we have in the main to thank biology. Taxonomy—the study of distribution—has shown that age is only one of many conditions that govern the character of a fauna; the depth, the composition of the sea-floor, the distribution of the ocean currents, the proximity of different bathymetrical zones, all exercise an influence. Thus a fauna is often more allied to an extinct one, than to those which are living simultaneously in adjoining areas. Taxonomy has exercised its influence in two ways. In the first place, it has insisted on the proper recognition of the self-evident fact that deposits change in space as well as time; that a sandstone, *e.g.*, may change into a clay laterally as well as vertically. Thus it is now recognised that the dividing line between the Gault and the Upper Greensand is a varying lithological one, and that the latter formation in one area was formed at the same time as Gault was being laid down in another. In the second place, it has led to the adoption of more detailed, zonal stratigraphy, and the demonstration thereby, that adjacent beds of different composition, and containing different faunas, have often been deposited simultaneously in stratigraphical continuity.

These views have gradually worked their way into general recognition by geologists, but Walther's is probably the first text-book in which they have been adequately expressed. The inconvenience in map-making, and still more in map-reading, which they involve, has led, perhaps, to an unconscious bias against them. Hence, even when theoretically admitted, their guidance has not been accepted practically. Walther's "Geologie als historische Wissenschaft" is, however, saturated with the results of biological teaching, the influence of which we may trace in nearly every page of the "Lithogenesis." Though well skilled in palæontology, he does not attach an exaggerated importance to the evidence of this science, but seems even to tend to the other extreme: if he does not underrate its value, he at least protests that it is less indispensable than has been thought. In his ardour for lithology, he goes so far as to say (p. 538) that "if we had an exact phenomenology of rocks, we could, without fossils, from the rocks alone, read the history of the earth." Walther's work is an effort toward such a "phenomenology," by an exposition of the lines along which it may be attained. He defines (p. 537) the objects of lithogeny "as the elucidation of the development of the fossil rocks by the investigation of rock-forming processes now in operation." He urges that rocks should be studied from the same point of view as animals and plants. He thinks that in comparative lithology, ontogeny should hold the same place as it does in comparative morphology. This lithology he divides into three sections, equivalent to those adopted in biology. Thus, he says that the study of rock structure answers to comparative anatomy, the development of rocks now in process of formation to embryology, and petrography and stratigraphy to palæontology. Throughout the book he introduces biological terms and phylogenetic trees to emphasise his views. For example, he classifies rocks as homologous and analogous; as the former, he includes all those which are formed in the same "Facies-bezirke," and as the latter, those which are formed under different geographical climates. And climate, in the sense of this later-day lithology, is "the sum of all the meteorological and oceanographic conditions, including organic and inorganic processes," which affect the formation of a rock. The use, however, of these terms often appears of doubtful value; thus, when he states that the lavas of an oceanic island are only homologous with those of a continent, we doubt whether we are in any way better for the information.

The work is divided into three parts, entitled, respectively, "General Lithogeny," "the existing Facies-bezirke," and "the bases of Comparative Lithology." The first of these occupies fourteen chapters: it begins with an account of the destruction, deposition, and alteration of rocks. The destructive processes he divides into four classes: weathering, chemical, physical, and organic; ablation, both of ice and rock surfaces; transport; and corrasion. The last he restricts to the comparatively insignificant polishing action of loose material carried about by the wind, rivers, ice, or sea. According to Walther's scheme, denudation results from ablation, transport, and corrasion; he attributes it to four agencies, viz. the wind acting by "deflation," running water by "erosion," glacier ice by "exaration," and the sea by "abrasion." The second part of the book is the longest; each chapter is devoted to the description of a group of deposits, which he says are "homologous," as they are formed in the same "facies-bezirke" or geographical zone. Thus, on the continents there is the zone of the Polar Regions, with moraines, humus, ochre, &c.; the temperate zone, with its black earth, loess, &c.; the desert girdle, with its sand and salt deserts, and dried-up lake-basins; and the tropical zone, with its laterite and cotton soil, &c. Other groups of homologous rocks are the products of continental volcanoes, shore deposits and those of open seas, of oceanic abysses; coral reefs, and volcanic islands. Very obvious objections to this classification could be easily raised, and it certainly could not be recommended for the purposes of ordinary teaching; but as long as it is used only to illustrate the association of deposits, formed under any particular set of geographical conditions, it is extremely useful. The different subjects treated in the work are, moreover, brought well up to date. Thus, *e.g.*, in the account of the supposed iron-secreting organism *Gallionella*, the latest botanical researches of Molisch are summarised, and its character left more doubtful than ever. The chapter on coral-reefs is especially well done. The sketch of the life of a reef (pp. 915–927), which he calls the "richest of bionomic assemblages," is the best we know. The definition (p. 909) of a coral reef as being essentially formed of branching corals, with calcareous sediment filling the interspaces, expresses a truth which is often overlooked. Even this is enlarged on another page, where it is stated that geologically a reef must be regarded as including not only the calcareous sediment on the surface, but that which is formed around it, to the depth of as much as 3000 metres. He illustrates the slopes around coral islands by the numerical method, due to Dietrich, which brings out clearly the differences between such atolls as those of the Bahamas and Keeling Island. The mean figures which he gives do not, however, teach much. It is interesting, therefore, considering that the coral island question is handled with full knowledge of all the latest information, and that the author's own investigations took place upon a region to which Darwin's theory was never intended to apply, to notice that he accepts that theory as substantially correct. It is surprising, considering the accuracy of the rest of the chapter, that a recent photograph of a *Pectinia quadrata* is again quoted (p. 899) as a *Manicina areolata*.

The third section of the work is that which enunciates the general conclusions. It contains short chapters on the correlation of facies, the equivalence of rocks, the changes in the facies of deposits, and the lithological significance of organisms. This part of the book is, however, the least satisfactory; perhaps because most useful originality had been expected in it. Variations from the ordinary method of treatment and overstrained analogies had been passed in the hope that they would be turned to some account. This part of the book is, however, so general in its treatment, that the conclusions are rather indefinite. Nevertheless, the work is throughout so novel in treatment, so up to date in its information, that this cannot seriously impair its value.

Rothpletz's "Geotektonische Probleme" is a very different work from either of the others. Its title is a little misleading; one might expect from it an account of earth-movements in general, and a discussion of the theories of earth-structure by which these may be explained. One is, therefore, a little startled at finding that it commences with a protest against theories, and a warning against the danger of ideas creeping into general acceptance, under cover of a convenient term. He points out, for example, that Suess's term of "horst" for a mountain mass formed of one block of material, is so useful in descriptive geology, that it has been widely adopted. Rothpletz fears, therefore, that Suess's theory of the origin of "horsts," and its corollary that horizontal beds are never uplifted, may be unconsciously accepted. Similarly he foresees that, by the adoption of other convenient terms, the whole heresy of "Suessism" may gradually work its way into a position of influence it would never attain by its merits. The perils to geological progress threatened by this insidious "hypothesis building phantasy," as Rothpletz calls it, he thinks can only be averted by the critic, whose duty it is to bring all hypotheses to the test of facts. And the author sets himself to perform this task. His volume is devoted to the class of earth-movements known as "overthrusts." When cases of the inversion and repetition of strata were first noticed, they were regarded as due to the folding of the beds. During recent years, many of these have been shown to be due to the thrusting of one set of beds on to another, either horizontally or at a low angle. Rothpletz shows that these overthrusts are even wider in their distribution than is now generally admitted. He describes the most important cases, summarises the literature and various theories regarding them, and states the explanation which seems to him to agree best with the facts. Most of the examples quoted, the author has personally examined.

The first case taken is that of the classical Linth in the Glarus. This, as interpreted by Escher and Heim, has exercised a great influence on geological thought. The valley has previously been regarded as due to a great double fold. Rothpletz, however, maintains that it is a "graben" or rift-valley, formed by the subsidence of the block of material which once filled it up. One difficulty that hitherto told against this explanation, was the fact that the marginal faults had never been discovered. Rothpletz, however, maintains that they are there; he describes them at one point, in a section which, he declares (p. 10), "must silence the most utterly sceptical." The denial of Heim's famous double fold necessitates a new interpretation of other features in the geology of the country. Thus the rocks in the Schild—the mountain to the west of the town of Glarus—have been explained by Heim as the crushed-out beds of the middle limb of the fold. Rothpletz, however, maintains—and his evidence seems conclusive—that they are due to an overthrust. He adds a further difficulty to Heim's theory, by showing that if true it is inadequate as it stands. The country is more complex than a double fold can explain; a treble and a quadruple fold at least must be assumed, for the beds repeat themselves more than thrice. This Rothpletz explains by the assumption of three overthrusts, which he names after Schild, Kapf, and Plattenalp.

The next case considered is that of the mountain mass of Sentis, to the north of the Glarus area. This was described by Escher von der Linth in 1857. It was then said to be remarkable in having a great series of faults crossing the axes of the folds, but none parallel to them. This was confirmed by the maps and memoirs of Escher's pupils, and Suess, therefore, in 1885, made the Sentis the type of a class of mountain structure named "Blätter." Some discrepancies between the descriptions and the maps led Rothpletz to re-examine the country. The result is that he finds numerous faults parallel to the ridges, as well as across them, and also a series of overthrusts which occurred later than the folding, and earlier than the transverse faults.

From the Sentis it is natural to turn to the Juras. This range has long been famous owing to the ingenious devices designed to enable the fold theory to account for the rock sequences that occur there. But the "vanishing trick" diagrams, by which the absence of certain beds has been explained, have always been viewed with suspicion; they seemed too much like the schemes by which Ptolemaic astronomy was reconciled with facts. Müller in 1860 demonstrated their insufficiency, but they still survive. Rothpletz discusses this fold theory in its three most plausible modifications, viz. the faulting of over-folds; the folding of an area after the rocks in the centre have been raised by a double fault; lateral contraction forcing one side of a valley of erosion over on to the other. Rothpletz dismisses these, and accepts the theory of overthrusts along slightly inclined thrust-planes.

The fifth case is that of the highlands of the north-west of Scotland. This is so well known, that the author adds nothing new, except a doubt as to the relation of the minor and major thrusts. He notes with relish the abandonment of the view at first announced that the thrust-planes started as a result of the inversion of overfolds.

A simple example of overthrusting in a much later geological period is afforded by the granite of Lausitz in Saxony, which occurs above the Turonian limestones. This superposition was explained at first by the chalk having been deposited under an overhanging cliff, and then by the granite having been dropped as an erratic. Both these theories were ridiculously inadequate. The most popular explanation assigned an eruptive origin to the granite; the absence of contact-alterations and of apophyses from the granite is fatal to this. Overthrusting is the only theory left, and this Rothpletz accepts as satisfactory. The earth-movements in the coal-fields of Westphalia, Belgium, and northern France are next considered; these have long been known to be extremely complex. The explanation now accepted, is summarised with great lucidity, and illustrated by over thirty figures and three plates of sections. It attributes the present structure of the country to the inthrusts of slices of complex composition between other deposits. The last case considered is that of the area of the coast of Provence and the French Alps. The author has not personally examined the ground, and so would have preferred not to discuss it. Haug, however, has suggested that the assumed "pli-failles" (or fold-faults) are often only inverse faults, and that the latter are capable of explaining the phenomena without the hypothetical folds. Rothpletz, therefore, thinks it advisable to discontinue the use of the word "pli-faille," and suggests the substitution of "faille de recouvrement," or some other term which does not beg the question.

In the concluding chapter, Rothpletz summarises the general characters of overthrusts. He remarks that their importance is being more widely recognised, and that they are accepted now in explanation of many phenomena for which the agency of folding was formerly invoked. He thinks that they probably always occur in mountain formation. He discusses their relations to the earth-movements with which they are associated, as far as our present knowledge enables these to be generalised. Thus, the thrust-planes occur approximately parallel to the folds, but the inclination of the planes is usually in the opposite direction to that of the mountains: this might have been expected, as it is in harmony with some of Daubree's experiments. Divergences between the strike of folds and overthrusts, however, occur, and are explicable by the later origin of the latter. The inclination of thrust-planes is almost always different from that of the beds or folds; the former, however, both above and below the thrust-plane, occur in their normal sequence. Friction breccias, mylonites, &c., occur along the thrust-plane, while "schleppung," or terminal curvature of the beds toward the plane, is generally developed. A single thrust-plane may occur; but, as a rule, there are many parallel to one another, and this results in the type named by Suess the "Schuppen-structure." The chapter concludes by a consideration of the classification of earth-movements, and its difficulties; that advanced by Suess, he recognises as the most important, but he does not admit it as at all satisfactory.

This shyness of classifications is in striking contrast to the attitude of the last work, in which all the types of "earth-forms" are classified in a detail, and with a terminology, which seems at first needlessly elaborate. The work is a systematic account of the orography or structural geography of the earth, and is quite unlike any existing text-book. It has taken more than ten years to prepare. The delay has been partly due to the enormous amount of literature that has had to be considered, but also to the fact that during this period two works have appeared which have completely changed the whole aspect of geographical science. These are Richthofen's "Führer fur Förschungsreisende," and Suess' "Antlitz der Erde." The former introduced a more scientific classification of "earth-forms" or geographic types, while the latter has revolutionised our ideas as to how those earth-forms have been developed. One of the great advantages of Prof. Penck's work is that it is a re-description of the earth's surface in the terminology and in accordance with the views of these two leaders of geographical thought. It is a book which it is impossible to summarise. It is a compilation showing on every page the most detailed care and accuracy. No one acquainted with Prof. Penck's previous writings will be surprised at his extensive knowledge of the literature of both geography and physical geology. The numerous historical summaries that occur in it, show how thoroughly the author has ransacked literature, and how well the book has been brought up to date. Works published so late in 1894 as that containing Heim's description of the Pleistocene earth-movements in the Alps ("Die Enstehung der Alpinen Randseen"), and Günther's memoir on the influence of atmospheric pressure on isostacy, are included. It is only natural that English literature is not so thoroughly done as the German, but important omissions are surprisingly few. The two most important are probably the absence of reference to Whymper's work on aneroids, from the chapter on altitude determinations, and to C. Reid's explanation of the formation of the chalk coombes, from the discussion of the origin of dry valleys.

The work is divided into three parts, dealing respectively with general morphology, the surface of the earth, and the sea. Its plan is based on the conception of the earth's surface as composed of a series of "earth-forms" which range between the extremes of mountains and valleys. The description and classification of these, and the study of their origin and development, form the subject-matter of geographical morphology. This science, therefore, depends on the literature of geodesy, geology, and geography. The book commences with an outline of general morphology, which depends in the main on the first of these. The chapters on mathematical geography, and on morphography and morphometry, are probably the most valuable of the five devoted to this part of the subject. In these he states the latest conclusions upon various debated problems. He points out (p. 9) that the amount to which the form of the earth deviates from an ellipsoid of revolution is between ± 200 and ± 250 m. He discusses the relative value of the various geoids, and expresses a preference for Northern Europe, for Bessel's instead of Clarke's, which is used in England. The principles of earth-measurement are briefly considered; the standard levels used in different countries are tabulated, and their relations to each other shown. The value and method of construction of hysographic, klinographic, hypsoklinographic, and bathygraphic curves are shown. The difficulties in the determination of altitudes caused by the uncertainties of refraction are pointed out. The inevitable inaccuracy of map lines is illustrated by a list of the lengths assigned to a portion of the Istrian coast in a series of standard maps; the figures range from 105 km. to 223·81 km. The calculation of the volumes of continents is considered, and finally elaborate tables given of geographical statistics. The ratio of land to water is taken as 2·54 (p. 97); the principal previous estimates are given from the time of Riccioli, who in 1661 estimated that the land was in excess in the proportion of 8 to 5. An interesting sketch of the literature on "geographical homologies" shows how early attention was drawn to the remarkable parallels and contrasts in the distribution of land and water. This part of the work concludes with the consideration of the question of the permanence of oceans and continents. Penck quotes Cayeux as if this author's investigations proved the terrigenous origin of all the chalk, and though he notices Blanford's arguments, he does not seem to appreciate their full significance. His sketch of the literature of the subject shows that, though with some striking exceptions, the difference on this question has been one between geologists on one side, and geographers on the other. In this connection it is interesting to note that Penck accepts (p. 167) the view that the ocean floors have a higher specific gravity than the continents, and places the difference, according to Helmert's work, at ·001 of the specific gravity.

The second part of the book describes the surface of the earth, or the "Landoberflache." The first section of this deals with the composition of the earth's crust, and the forces that act upon it. The figures given to illustrate Suess' terms are very clear and instructive; the table of geological systems is, however, out of date; the Ordovician is not accepted, and the Tertiary and Quaternary are each regarded as equal to such divisions as the Trias and Permian. The account of the agents of denudation is very detailed and thorough. The hydraulics of river action (pp. 259–385) is treated with especial care, and the references to the literature of the subject include a much wider range than is usual. The controversy as to Baer's law of the influence of the earth's rotation on the direction of rivers is clearly summarised, and the truth of the law upheld; great stress is laid upon the deepening of the Rhine on its left bank in the regulated portions of its course. The author attributes to glaciers considerable erosive power; he maintains that the characteristic feature in erosion by ice, is that the excavations vary in depth with the strength of the rocks, so that true rock basins are formed (p. 409). He still accepts the glacial origin of cirques, and even approves of Ramsey's views of the origin of some of the Alpine lakes. The description of the existing "earth-forms," or geographic types, occupies the first 460 pages of the second volume. These "earth-forms" are divided into eight types—plains, heaped-up mounds, such as moraines and dunes, valleys and the highlands through which they run, basins, mountains, areas of subsidence, and finally fissures and caves. The characters, classification, method of formation and terminology, including both local and scientific names, are stated in detail. A sketch of the literature of each type is also given. The chapters on "Wannen" or basins, and on mountains, are probably the best. The book closes with an account of the oceans, and the deposits on their floors.

The one serious drawback to this book is its complete neglect of the evidence of zoological distribution. Thus, for example, the questions of the origin of the Caspian Sea and the lakes of Nicaragua, are fully considered, but no reference is made to their faunas. No theory, however, could be accepted which failed to account for the anomalous characters of these. But it would be too much to expect Prof. Penck to show the same mastery of the literature of biology as he does of geography and geology. In this respect, Walther's book is superior to that of Penck. But it is idle to estimate their respective merits, for the three works are so different. One cannot compare Walther's statements of the principles of correlation with Rothpletz's detailed mapping, and either with Penck's digest of literature. Penck's, however, will probably prove the most generally useful of the three. An English translation would be of great service, by calling attention to a branch of geography that has been unaccountably neglected in this country. Thus, in the Geographical Society's "Hints to Travellers," instead of the details of Richthofen's "Führer," the subject is not even mentioned. A translation would, moreover, necessitate greater precision in the definition of geographical terms, and the introduction of many new ones, for which there are now no equivalents in English, and which are essential to the scientific treatment of geography.

J. W. GREGORY.

ORGANIC CHEMISTRY.

The Rise and Development of Organic Chemistry. By Carl Schorlemmer, LL.D., F.R.S. Revised edition, edited by Arthur Smithells, B.Sc., Professor of Chemistry in the Yorkshire College, Leeds. (London: Macmillan and Co., 1894)

FOR some time this excellent historical survey of the development of organic chemistry has been out of print, and students of chemistry will heartily welcome the appearance of a second edition, which has been extended, in order to include a review of the more important results of the original investigation of the last ten to fifteen years.

Facing the title-page is an exceedingly good likeness of Schorlemmer, admirably reproduced from a photograph; then follows a short biographical notice, giving a brief sketch of the author's career, in which his brilliant researches are described. This is a very welcome addition to the book, because, as the editor points out, Schorlemmer, with characteristic modesty, mentions these researches only on two occasions in the book (pp. 141 and 197), and then but very briefly.

Chapters i. to v. are very much the same as in the first edition, only a few slight alterations having been made. Chapter vi. deals with the perfection of the methods of organic analysis by Liebig, and these important researches, which affected in such a marked manner the subsequent development of organic chemistry, are perhaps scarcely discussed at sufficient length; a more detailed account of the history of organic analysis is to be found in Roscoe and Schorlemmer's "Treatise of Chemistry" (vol. iii. p. 40). This chapter vi. also contains a short sketch of the work which led to the discovery by Raoult of his well-known method of determining the molecular weight known as the cryoscopic method.

Chapters vii. and viii. have not been much altered, but chapter ix., which deals with the constitution of benzene, tautomerism, and the asymmetric carbon atom, has, as was to be expected, been largely added to, and made to embrace most of the important results of recent work.

The constitution of benzene is dealt with in a very interesting manner. Baeyer's researches, on succinosuccinic ester, which led to the rejection of Ladenburg's prism formula, are discussed, as well as those of Bamberger, on the reduction of naphthalene derivatives, the results of which may be said to have completely confirmed Baeyer's views.

After a short description of Laar's tautomeric hypothesis, the remainder of the chapter is taken up with Le Bel and van't Hoff's theory of the asymmetric carbon atom, and with Wislicenus' development of this theory. In a future edition, more emphasis might, perhaps, with advantage be laid on the general applicability of these theories, so that the student may not receive the impression that they have only been found valuable in the explanation of isolated cases, as, for example, the isomerism of the malic and tartaric acids, and of fumaric and maleïc acids.

The first part of chapter x. is devoted, principally, to the history of organic synthesis, and contains an account of Frankland and Duppa's work on aceto-acetic ester, and of Conrad's researches on malonic ester, showing the value of these ethereal salts in synthetical work. The synthesis of malic, tartaric, and citric acid is also mentioned.

A very valuable historical sketch of the chemistry of the sugars, including a clear exposition of the more important results of E. Fischer's classical researches, followed by an account of Ladenburg's synthesis of coniine, and of the synthesis of uric acid, by Horbaczewski, concludes this excellent chapter.

The remainder of the book does not differ materially from the first edition, except that a very good index of authors' names and subjects has been added.

Students of organic chemistry must always be interested in the development of the science, and to them this work will be cordially welcome. It is a thoroughly readable book, written throughout in an attractive manner, and comprising in one small volume all the facts necessary for understanding the growth of organic chemistry.

Schorlemmer wrote, whenever possible, in German, and never had any real facility in writing English. The editor is, therefore, to be congratulated on the very satisfactory manner in which he has performed the difficult task of preparing this book for the press. Great care has evidently been taken in reading the proof-sheets, as we have only noticed one or two unimportant misprints.

OUR BOOK SHELF.

British Birds: being Coloured Illustrations of all the Species of Passerine Birds resident in the British Isles, with some Notes in reference to their Plumage. By Claude W. Wyatt. 4to. Pp. iv. 25. (London: William Wesley and Son, 1894.)

THE author is a well-known ornithologist, who has made two expeditions, of which the results have been published—one to the Peninsula of Sinai, and the other to the Magdalena Valley in Colombia—and these proved that he was not only a good collector, but also a keen field-naturalist. He then travelled extensively, and visited many parts of the globe, observing the habits of birds, and making sketches of every kind of scenery. The latter became a great feature in the plates of the "Monograph of the Swallows (Hirundinidæ)," which he brought out in conjunction with Dr. Bowdler Sharpe, who contributed the letterpress of the work, while Mr. Wyatt drew all the plates.

The present volume is the first of two which the author proposes to publish, the one before us dealing merely with the resident Passeres of the British Islands, while the second is to contain figures of all the migratory Passeres, the Picarian birds, the birds of prey, and the pigeons; but the game birds, waders, and swimming birds will be, presumably, treated of at a future period. Fifty species are illustrated by Mr. Wyatt in his first volume, and occupy twenty-five plates. As with his pictures of the swallows, the author makes a great feature of his accessories, and some of the landscapes are very pretty, and are evidently drawn from nature. The attitudes of the birds are life-like, and some of them are exceptionally good, the crows alone striking us as failing in massiveness of bill. The letterpress is of the simplest, and would have been all the better for more complete references to standard works, as many of those given are incorrectly quoted. It is, however, more as an artist than as a writer that Mr. Wyatt shines, and he is to be congratulated on having produced a very handsome volume, with beautifully coloured pictures of some of our most familiar favourites. As regards quality of paper, printing, colouring, and binding, there is nothing left to be desired.

Standard Methods in Physics and Electricity Criticised, and a Test for Electric Meters Proposed. By H. A. Naber. (Published by the Author, 1894.)

FROM the title and table of contents of this work, one would expect to find a treatise on experimental physics. This expectation is, however, rudely dispelled when one commences to examine the letterpress. After a very brief description of the form of gas voltameter which the author has devised (see NATURE, July 12, 1894), more than a hundred pages are devoted to what presumably the author considers an exhaustive examination of the different uses to which this voltameter may be put. The fact that his *voltameter* has a considerable resistance, causes the author considerable trouble, but he consoles himself with the reflection that a Cardew or other *voltmeter* generally has a resistance of from 100 to 900 ohms. The difficulties encountered in measuring a quantity of electricity by copper or silver deposition are dwelt upon, and a new objection is raised, namely, that since the deposits have to be weighed, variations in gravity will affect the results! At another part of the book the ordinary balance is considered devoid of sufficient accuracy, since the arms have generally different lengths, and Nicholson's hydrometer is recommended as a substitute when great accuracy is desired. In a chapter on sound, the author strongly recommends bicycle-wheels as a motive power. Apparently the cycle-wheels are to set themselves in motion, since the idea of driving any piece of machinery "by hand" is derided, and the great waste which takes place when water and other motors are used, is dwelt upon as a reason for their abandonment. One has met with the library steps which can be converted into half a dozen other articles of furniture; but these old friends sink into complete insignificance when compared with this gas voltameter and the numerous uses claimed for it, such as blowing soap-bubbles full of oxygen and hydrogen, which on being exploded can be used as fog-horns; supplying oxygen to aëronauts, or to explorers in coal-pits after an explosion; and preparing chlorine. It can also, we are told, be used as a barometer, pyknometer, ice calorimeter, dylatometer, thermostat, hygrometer, anemometer, level, or for exhausting incandescent lamp bulbs. The above are a few of the uses claimed, and are extracted from what the author describes as not an "exhaustive list"! W. W.

Electrical Engineering, for Electric Light Artisans and Students. By W. Slingo and A. Brooker. Pp. 740. New and revised edition. (London: Longmans, Green, and Co., 1895.)

AN admirable work, covering the whole field of electric lighting. Though designed to include those branches of the subject prescribed in the syllabus issued by the City and Guilds Technical Institute, its scope is such as "to make it embrace the requirements, not only of those actually employed in the electric lighting industry, but also of those who, while having little or no electrical knowledge, have under their supervision various kinds of electrical machinery." The book is not merely a descriptive catalogue of electrical machinery, like some that we know, but a clearly-written, and amply-illustrated, volume which has proved of great service to engineers during the past five years, and, in its revised form, is sure to hold its own in the future.

Lens-Work for Amateurs. By Henry Orford. Pp. 231. (London: Whittaker and Co., 1895.)

A LENS is defined in this volume as "a portion of a refracting medium . . . bounded by two spherical surfaces which have a common axis." In the following paragraph, lenses with one of their surfaces plane, are described; wherefore we would ask Mr. Orford, why he did not include these in his definition? This, however, is but a detail. As a whole, the book is a trustworthy guide to the manufacture of lenses, suitable alike for the amateur and the young workman. It is profusely, though rather coarsely, illustrated by diagrams, and the instructions are simple and practical.

Manual of Practical Morbid Anatomy. By H. D. Rolleston, M.A., M.D., F.R.C.P., and A. A. Kanthack, M.D., F.R.C.P. Pp. 240. (Cambridge: University Press, 1894.)

A PRACTICAL handbook for the post-mortem room, showing how to carry out a systematic examination of a body, and indicating what morbid changes should be looked for.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A New Step in Statistical Science.

CONTRIBUTIONS of an abstract kind to statistical science are so little read by the bulk of statisticians, that the scope of the remarkable memoir by Prof. Karl Pearson may be unappreciated by them unless attention is pointedly directed to it.[1]

Statisticians are conversant with the use of curves to epitomise masses of data. The forms of the majority of these curves are skewed or humped, and have hitherto been nondescript, except as Prof. K. Pearson's previous memoir showed, some of them may be dissected into two or more normal curves, having different constants. It is only a few curves that are symmetrical and conform closely to the normal law of facility of error. These few have been much studied, the numerous and valuable properties of the normal curve being extremely helpful in dealing with them. When the conformity between the observations and the normal law ceases to be close, the latter must be applied warily. When the discrepancy is serious, it becomes unsafe to trust the theory at all. Not a few statisticians have chafed under these limitations, and felt that the normal law is too limited in its grasp to satisfy their needs. Now at length, it turns out, thanks to Prof. K. Pearson, that the normal law admits of being regarded as nothing more than a very special case of a highly generalised theory, by whose aid curves may be drawn that shall fit every one of the observed curves he has tried as yet. The shapes of these are curiously varied. Their list includes the dimensions of shrimps and prawns, of American recruits and of school-girls, of Bavarian skulls, of frequency of enteric fever, and of divorces, of variation in house value, in butter-cups and in clover, in pauper percentages and in a mortality curve. Only those who have studied the delicate and oddly-shaped drawings of these observed curves on a large scale, upon which the equally delicate *fitted* curves have been superimposed, can adequately appreciate the wonderful closeness between the pairs of outlines. There can be no doubt that the descriptive efficiency of Prof. Karl Pearson's method is of the highest order.

The question of the utility of the method to ordinary statisticians has now to be considered. First, as to its descriptive powers. We are already able to describe the whole of any normal series by means of only two numbers; say, by the average of all the members of the series, and by the mean of the several departures of its individual members from that average. Henceforth, by the use of more constants, we shall be able to do the same to any series. A few figures will always serve as the equivalents of a vast amount of tabular matter.

The second and higher use is to afford a clue to the cause or causes of variety. It has long been a dream to me to select a peculiar and often recurring form of curve, and to study with all possible care the conditions under which it has been produced, so that whenever a new curve of that same form was met with, there should exist some guidance towards discovering the cause of its production. I have made not a few attempts from time to time, but was discouraged by the then impossibility of sufficiently defining the curves that were dealt with. That difficulty seems now removed. To explain myself further, let us suppose that a man finds the mark of a more or less incomplete circle on the ground, and wishes to discover how it was made. Various possibilities exist, which might have been recorded to help him: (1) The mark may have been made by a basin, &c., turned in a lathe, or, what come to the same thing in principle, by something revolving round a fixed centre. (2) It may have been stamped by a hoop, formed by bending an elastic rod until its ends met, the circular form depending on the equal distribution of stress. (3) It may have been the mark of a withy that had bound a faggot, which, after setting into shape, had broken away, the circular form arising from the compression of the sticks of the faggot within the smallest possible girth. (4) It may have been the mark of a warped sheet of bark, hide, &c., the circular form of which depended on the unequal contraction of its outer and inner layers. (5) It could have been made by a projecting nail, near the angle formed by two straight rods securely joined at one end; the apparatus being caused to straddle and press upon two pegs in the ground, and moved in the only way possible under those conditions. Here the fragment of a circle would be due to the constancy of the angle subtended by the same chord. A catalogue of these and other possibilities, which are numerous and include circular forms of animal and vegetable growth, would certainly enlarge the speculations of the observer as to the cause of the circular mark. So it would be with the curves of which I spoke. Each form of curve would be a serious study in itself; still the results would gradually accumulate, and it is reasonable to look forward to a time when a set of such curves, each defined by Prof. K. Pearson's, method, shall have been studied.

I venture upon one criticism as to the completeness of his generalisation. Variation of the normal kind is supposed to be due to the combined effect of (1) an infinite number of causes, that are (2) equally likely to err in excess or deficiency, and (3) that are independent of one another. These three restrictions are removed in the generalised curve, which bears a certain relation to the binomial point curve formed by the expansion of $(p+q)^n$ when (1) n need not be infinite, (2) p need not be equal to q, while (3) the binomial form which implies independence of the contributory causes, is modified. Now though the condition (3) is removed, it does not, as yet seem to me that the supposition which replaces it, and which is based on such considerations as the effect of withdrawing r cards from a pack of ns cards containing s suits, is analogous to what commonly occurs in *rerum naturâ*. Namely, the intermingling of contributory causes of various degrees of efficiency, some of which are very few in number and have large effects. Thus the number of persons who walk day by day down St. James' Street, is occasionally vastly augmented by some national spectacle, and it is considerably and irregularly affected by changes in the weather. It does not wholly depend on a multitude of equipotent causes. So again, the time of ripening of the fruit on a tree generally, is much affected by the aspects of the particular branches on which it grows. I therefore conclude that the effects of an aggregate of large and small causes, ought to be distinctly included in a thoroughly generalised formula of variation.

FRANCIS GALTON.

[1] "Mathematical Contributions to the Theory of Evolution" (Part ii.), by Karl Pearson. Read at the Royal Society, January 24, 1895.

The Kinetic Theory of Gases.

I THINK sufficient stress has not been laid on the distinction between the *purely mathematical* proof of the fundamental determinantal relation connecting the differentials of the coordinates and momenta of dynamical systems and the *purely statistical* applications of that relation which form the subject of the Kinetic Theory.

The well-known determinantal equation is perfectly general and applicable to any dynamical system whatever. It merely asserts that if the initial coordinates and momenta receive any small independent variations whatever, the resulting variations in the final coordinates and momenta after any fixed interval of time are so related to them that the differential product of the former variations is equal to that of the latter, conformably to the well-known laws of Jacobians, by which the variables are changed in a multiple differential or integral.

In general the variations in question are *purely hypothetical*, just as, in the principle of Least Action, the actual motion is compared with varied motions which have no real existence. If, for example, we consider the system to be the Earth, the variations could only be made real by making the Earth move differently to what it actually moves, and doing this in every possible way.

But when it is required to assign any physical meaning to the determinantal relation, these hypothetically varied motions must be represented by actual motions, and this can only be done by taking an indefinitely large number of independent systems, all similar to the one we started with, and setting them moving in all possible ways. The determinantal relation then tells us that if the coordinates and momenta of these systems are initially distributed according to what in my Report I have called the Boltzmann-Maxwell distribution, they will be so distributed at any subsequent instant. But in the absence of collisions or encounters between the system, this distribution will *not* be unique. There exist other distributions equally well satisfying the condition of permanence.

The case of two or more molecules of gas in the process of encounter can be deduced, as shown in my Report (§ 30), by taking each "system" to represent a pair of molecules, there being at every instant an indefinitely large number of such pairs having different coordinates and momenta. It now seems definitely settled that if the molecules are rigid bodies, the only possible permanent distribution unaffected by encounters is the Boltzmann-Maxwell distribution combined with motions of pure translation and pure rotation of the mass of gas as a whole (Report, § 46).

Many writers have limited their investigations to the case where all the encounters are binary, and I see that Prof. Fitzgerald has emphasised this point in his recent letter. I do not think this is the right place to draw the line. I can see no difficulty in taking account of encounters between three, four, or more molecules, provided that such encounters are sufficiently numerous to have a law of distribution. Where the line must be drawn is indicated in my Report, § 30 (iii.). The molecules which act on one another in any one encounter must form an infinitesimal fraction of the whole mass of gas, or the gas must at any instant be divisible into an infinitely large number of independent molecules and groups of molecules, each molecule or group thus constituting for the time being a free system by itself. When the molecules act on each other at all distances, or it is impossible to divide them into small independent groups, the whole of our theory breaks down.

It is this limitation which, to my mind, precludes our applying the Kinetic Theory in its present state, *not only* to molecules moving about in a continuous medium, such as the ether may be, but *also* to solids and, probably, liquids.

A good deal of confusion has, I fear, arisen with regard to what I have called Maxwell's Law of Partition of Kinetic Energy, *i.e.* the statement that "if the kinetic energy of a system be expressed as a sum of squares, the mean values of these squares are equal," from the fact that the term "*mean value*" may be taken to represent "time average for a single system"; and I fancy this may be the point Prof. Fitzgerald had in view when he asked if the conclusions would not apply to the Earth or a "finite number of particles moving about for an indefinitely long time." It cannot be too strongly emphasised that this interpretation of mean values involves assumptions which have hardly been sufficiently justified in any general class of cases, and which have been repeatedly proved to be invalid in simple cases (Report, §§ 9–12).[1] To give a simple (if not quite analogous) illustration: suppose that on drawing counters out of a bag, we were to obtain on the average an equal number of red, white, and green counters. We should *not* be justified in inferring that if we kept a single counter sufficiently long it would change colour and become in turn red, white, and green.

As an illustration of a case where the Boltzmann-Maxwell Law is inapplicable, consider a sphere of density σ moving in a perfect liquid of density ρ. The kinetic energies of the sphere and liquid are in the ratio of $\sigma : \frac{1}{2}\rho$, as we know from hydrodynamical considerations, and the same is true for any number of spheres whose distances apart are very large compared with their radii. This is not a case where *no* transference of energy takes place between the sphere and liquid, and it is not therefore open to Prof. Fitzgerald's objection to the case I previously cited. Whenever the motion of the solid is varied, energy *is* transferred to or from the liquid.

If a *gaseous* ether will satisfy the requirements of physicists, then the Boltzmann-Maxwell Law is undoubtedly applicable to the ether. If not, the ether falls entirely beyond the scope of our investigation. The Kinetic Theory is obviously a theory framed to account for one class of physical phenomena only, viz. the thermal properties of gases. If any observed phenomena are not deducible from the results of the theory, it is to my mind sufficient to show that this is because the fundamental assumptions of the theory are not satisfied, *i.e.* that the phenomena in question are *not inconsistent* with the Kinetic Theory.

G. H. Bryan.

Peterhouse, Cambridge, January 16.

Boltzmann's Minimum Function.

I said in my first letter on this subject that the condition A on which, or its equivalent, the proof is based, could not apply to the reversed motion. As that assertion has been questioned, may I confirm it thus?

The initial distribution of R, the relative velocity, *i.e.* the number of pairs of spheres for which it has given direction, is arbitrary—condition A is fulfilled. Then, as proved, whatever the initial distribution, after collisions, the distribution of R is uniform, *i.e.* all directions equally probable. Now reverse the velocities. If condition A is fulfilled in the reversed motion, then after the reversed collisions the distribution of R is uniform. It is equally certain that it must be the same as the initial distribution.

If, therefore, condition A is fulfilled in the reverse motion as well as in the direct, that can only be because the distribution of R was uniform to begin with. But that means that H was minimum to begin with, and therefore $\frac{dH}{dt} = 0$ throughout.

Boltzmann's theorem can be applied to both motions only on condition that it has no effect in either.

1 New-square, Lincoln's Inn. S. H. Burbury.

Electroscopes in Lecture.

I suppose teachers still use gold-leaf electroscopes for their junior lectures; certainly I have found nothing else so dead-beat, or so readily understood; and by projecting with a lens a shadow of the leaves on a square-foot translucent screen, the movements are perfectly visible to a large audience by daylight. But the one objection to the instrument, when used for explaining the fundamental facts, say, of induction, is that it indicates similarly positive and negative potentials. Yesterday, however, my assistant, Mr. E. E. Robinson, ingeniously stood the metal-cased instrument on a cake of paraffin wax, and electrified its outside negatively. By this process the zero of deflection is changed; the leaves stand apart for zero potential, diverge more for positive, and collapse for negative. A zero shadow-pointer and rough scale may be readily used. and I propose now to mount a projection electroscope in a suitable slightly-charged Leyden jar, whose outer coat can then be treated as the usual earthed terminal of the instrument, whose case is connected to or formed by the inner coat of the jar. The insulated or variable terminal is conveniently arranged as an insulated sphere or other shaped body on the lecture table, not far from the small screen, attached by a long enough thin wire to the leaves—of which it is perhaps best to have only one movable.

Oliver J. Lodge.

January 25.

The Perseid Meteors.

Your interesting reference (Nature, January 24, p. 301) to Dr. Bredichin's investigation of the Perseid shower, induces me to offer one or two remarks on the subject. In the paragraph alluded to, it is stated that the radiant was observed from July 22 to September 12, 1893; but this long duration cannot possibly refer to the same system as that which furnishes the abundant maximum on August 10. It is true there are radiants in Perseus in September, and the succeeding months of October, November, and December supply many others, but, after the end of the third week in August, nothing is seen of the real Perseids. I cannot say exactly on how many nights the display continues active, but it is certainly visible from July 19 to August 18, and the diurnal motion of the radiant is about 1° to the E.N.E.

There are really very few of the true Perseids seen after August 12, for the shower dies rapidly away after the maximum. On August 15, 1893, during a watch of three hours, I saw only one Perseid. On August 16, 1893, during a watch of 4½ hours, I noted only four Perseids. I mention these facts to prove the extreme tenuity of the stream at the middle of August. But there are differences from year to year. An observer watching the heavens for a similar interval on the same dates in succeeding years will get a varied experience. Thus one year cannot be regarded as the criterion of all.

Some years ago I recorded a few swift streak-leaving meteors between August 19 and 24, from a radiant at 78° + 56° on the northern borders of Auriga, and supposed they might be late

Perseids, but subsequent observations have convinced me that they had no relation with the great August shower. They probably formed the early members of a well-defined radiant of September Aurigids which I found at 76° + 56° in 1879, and at 77° + 57° in 1885.

It appears to me that observations of the Perseids, and of other meteor showers, are often undertaken and discussed while losing sight of a most important circumstance. I refer to the necessity of thorough training on the part of the observer, before he can possibly hope to attain a high degree of precision in recording meteor paths. Many month , if not years, of diligent practice are required to render the observer proficient, and even then there are many students who, being deficient in natural aptitude, will never succeed in the work. It seems to be the fashion at certain observatories to set a number of observers (some of whom have perhaps never registered a meteor path before) watching and recording meteors, and then to investigate their results as though they could be thoroughly depended upon. Such results are, however, practically useless when employed to test any complicated point in meteoric astronomy. It is similar to placing a man, who has never played in a cricket match before, as wicket-keeper to fast bowlers like Mold, Richardson, and Woods, and expect his performance to be creditable! In meteoric astronomy, as in many other spheres of action, skill is only to be acquired by long practice; indeed, it is difficult to single out any other branch of observation where the eye and the judgment have to be so quickly and accurately brought into play to afford the best results. W. F. DENNING.

Bristol, January 27.

The Artificial Spectrum Top.

IN the interesting letters on the above subject, which have recently appeared in NATURE, there does not seem to have been any reference to the experiments of Helmholtz, as described in his "Handbuch der Physiologischen Optik," 1866, § 23. He describes the facts in minute detail, and illustrates them with numerous diagrams.

One important point not yet referred to, and described in detail by Helmholtz, is that if a disc, marked with black and white sections, be rotated with a certain rapidity, the field appears to be covered with a pattern composed of hexagonal spots; at the part of the field of vision corresponding to the yellow spot, a transverse oval figure is seen. In the centre of this figure is a dark spot surrounded by a black circle.

Each of the hexagonal spots is dark with a lighter spot in the centre, and surrounded by a red thread, which appears to be moving in minute drops. The field seems to be pervaded by a greenish hue, which flows towards the yellow spot.

These experiments, which I have verified on every point, have a very important bearing on the photo-chemistry of the retina and on colour vision.

Hendon, January 26. F. W. EDRIDGE-GREEN.

IN reference to your Belfast correspondents' interesting experiments with the artificial spectrum, which were long ago included in my own experiments, a little reflection will show that when the speed of rotation is increased, we do *not* retain unaltered the resultant proportion of stimulus and anti-stimulus on the retina. With a slow rotation we have simultaneously on the retina a persistence image of the lines and a real image of the white card. When the speed is greater, we get simultaneously these two, and in addition a persistence image of the white card. Hence, according to my theory, the rise in scale with increased rapidity of revolution.

Colchester, January 26. CHARLES E. BENHAM.

Snake Cannibalism.

THE reading of a paragraph and a letter printed in the *Mail* for October 24 and 29, reminds me of a case of one snake swallowing another, the consequences of which I witnessed. While engaged in running a survey line for a railway across a wood in this district, I noticed a snake close to me, doing its best to get out of my way, but almost unable to do so. One of my men struck at its neck with his "macheti," and succeeded in cutting the snake's head clean off. Immediately, to our great surprise, another snake of the same species slowly emerged head first, and, after a few struggles to escape, remained motionless on the ground; a gash in its cranium, which had been cut by the same stroke that killed the larger snake, being, no doubt, the cause of death, as the body was otherwise intact. A measuring tape showed that the larger snake was 6 feet in length, and the smaller 5 feet. In this case the snake was swallowed tail first, and therefore it seems highly probable that the larger snake simply devoured it, and did not commence by trying to dispute a portion of food, such as the pigeon and frog cited in other instances. H. TSNAGAL.

Sancti Spiritue, Cuba, November 23, 1894.

More about Moths.

(*Communicated by Prof. S. Garman, of the Museum of Comparative Zoology, Cambridge, U.S.A.*)

IN NATURE for December 6, 1894 (p. 127), Mr. Henry Cecil publishes a criticism on a previous letter of mine, which I cannot accept without a few words of remonstrance. His explanation may be correct in part, but it certainly does not cover all the ground.

That resistance alone is not necessary for the expansion of the wings of moths, may be inferred from the fact that they will often expand after an interval of several days, when the moths have been prematurely released, the irregularity in outline arising, I think, from the evaporation of moisture from the wings, and in the consequent loss of elasticity. If the newly-hatched insects are confined in a warm moist box, this trouble seems to be obviated in a large degree, and the wings occasionally attain to nearly the normal dimensions.

In raising moths artificially, it cannot be assumed that the lack of proper pressure is entirely responsible for the frequent occurrence of cripples.

All the conditions of feeding, moisture, and heat, must first be carefully considered, since departures from the normal, on any one of these lines, might so lower the vitality of the insect, that perfect development would become impossible.

The writer also speaks of the wings of the moth in the cocoon as "folded and crumpled," a statement which is entirely at variance with my own observations. In all the cases which I have noticed, the wings are perfectly smooth and unfolded from the first, the increase in size resulting from a true expansion, the nature of which has, so far as I know, never been fully explained. L. C. JONES.

Melrose, Massachusetts.

THE PHYSICAL SOCIETY'S ABSTRACTS OF PHYSICAL PAPERS FROM FOREIGN SOURCES.

THE days when learning meant dead languages, and science meant collecting beetles, have passed away; science has grown and spread until it is impossible for the most comprehensive intellect to grasp more than a few twigs on its numerous branches. Organised specialisation has become necessary to scientific progress. Each subject now has its special society, and each society has as much as it can do. Every sort of time-saving arrangement is necessary if the workers in any one branch of knowledge are to be kept informed as to what others are doing.

English chemists have long been supplied by the Chemical Society with excellent abstracts of the current literature of their subject, but up to the present the only available work of the same kind on Physics has been the *Beiblätter* of *Wiedemann's Annalen*. Admirable as these are, it is impossible that a German periodical can fully meet the wants of Anglo-Saxon physicists. It is therefore most desirable that abstracts of physical papers should be published in English. The Physical Society has now set itself to supply this want, and the first number of the new volume of "Abstracts" appeared early in the present month. The *Proceedings* of the Society will in future be issued monthly, and the abstracts of foreign papers on physics will be included under the same cover. They will, however, be paged separately, so that they can be bound separately at the end of the year, when full indices, both to the subjects and the names of authors, will be added. At present the *Proceedings* contain approximately fifty pages of original matter, and fifty pages of abstracts from foreign and American sources.

It is an open secret that it is intended to enlarge the abstracts later, so as to include English work. They will then be an epitome of the work done in physics throughout the world. The preparation of a large number of abstracts on all sorts of subjects involves a great deal of work and some organisation, and it is thus better to be content with abstracts of half the extent of those of the Chemical Society or the *Beiblätter* at first, at any rate. The financial risk is also very heavy for a society which is not rich, however energetic it may be. The British Association has come forward with a helping hand, and is aiding the Physical Society with a very considerable money grant.

Mr. Swinburne has undertaken the office of editor. He is assisted by a strong body of abstractors, many of whom are recognised authorities on their own subjects, and authors of well-known books on physics. In the January number there are abstracts of 114 papers, of which 25 are on General Physics, 22 on Light, 12 on Heat, 1 on Sound, 34 on Electricity and Magnetism, and 19 on Chemical Physics. The price to non-members of the Society is two shillings and sixpence; but as the cost for a year at this rate exceeds the subscription to the Society, it is probable that the number of members will increase for this, if for no other reason. It is hoped that this will be so. Many branches of physics, unlike chemistry and electricity, have no great industry behind them. It is therefore necessary that all who care for the study of pure physics should rally to the support of the Physical Society in its new undertaking. The meetings of the Society are now held in Burlington House, in rooms hospitably put at its disposal by the Chemical Society. They are held at five o'clock on Fridays, so that persons who may come to town to attend them, can afterwards go on to the Royal Institution. If an author so desires, the publication of his paper will not be delayed for reading. Copies of the paper are circulated before the meeting, so that the discussion can begin early and with adequate knowledge. As soon as a paper has been read, an abstract and a short account of the discussion is published in NATURE, in the *Electrician*, and other journals. The paper itself is also communicated to the *Philosophical Magazine*, and is published with an abstract of the discussion in the Society's *Proceedings*.

THE NATURAL HISTORY OF THE SOLWAY.

ALMOST all corners of the British Islands have been so thoroughly investigated by naturalists and collectors, that I may be excused for directing attention to one which seems to have been somewhat overlooked—the southern shore of Kirkcudbrightshire and Wigtownshire. I, at least, do not know of any work which has been done there of late years. The Solway itself, so far as I know, has received no attention at all—its shallow, sandy character not offering much attraction to the student of marine zoology.

Yet the surrounding district is, in other respects than its natural history, an extremely interesting one—very varied and beautiful in its scenery, secluded and quiet, and out of the usual track of tourists; with many picturesque and ruinous relics of a bygone age, abounding in streams and lochs suited both to naturalist and angler, and associated ineffaceably with two, at least, of Sir Walter Scott's finest works, "Guy Mannering" and "Redgauntlet," to say nothing of the "Raiders" of a more recent author, Mr. Crockett. It is, moreover, easily accessible, and I suppose it is probably due to the lack of hotels and other tourist accommodation that it is so little known except to residents in the immediate neighbourhood.

The bit of the district best known to me extends from the estuary of the Nith—separating Dumfriesshire from Kirkcudbrightshire—on the east, to the Water of Fleet, which empties itself into Wigtown Bay, on the west. This coast-line is of very diversified character, flat and sandy eastward, where it has behind it a large tract of marsh-land, the haunt of innumerable wild fowl, but rising eastward into precipitous cliffs of sandstone and limestone, which form in some places isolated pillars of considerable height, and in others are hollowed out into caverns, some of which are locally associated with the name of Scott's piratical hero, Dirk Hatteraick. Some of the streams—notably the Water of Urr—come down through a background of granitic hills, bringing with them a vast amount of fine detritus which is deposited on the sides of their estuaries and in the Solway itself, round about their mouths. In such cases the natural result is a very flat shore, composed of soft muddy sand, stretching out very far seaward, and at low water uncovered for stretches of many miles—a state of things not unlike that which is found in the more familiar Morecambe Bay at Grange-over-Sands. These muddy expanses, when left by the tide, are seen to be covered with the contorted mounds thrown up by innumerable lug-worms, and so closely packed are these that there is rarely a space of more than a few inches untenanted by its worm. They form, in fact, quite a conspicuous feature in photographs taken under these conditions, and I do not doubt that the worms themselves, passing through their bodies so much mud laden with decomposing organic matter, which they thus absorb and assimilate, contribute materially to the sanitary purification of what would otherwise become a reeking, pestiferous swamp. Beyond these lug-worms, I am unable to say anything about the larger mud-inhabiting fauna of the district. I thought it very likely that *Echinocardium cordatum* and, perhaps, *Synapta* might be found, as they are in some similar localities in the Firth of Clyde, but the little time which I spent in digging for them did not suffice to disclose any specimens; nor have I had any opportunity of dredging in the Solway Firth. The water is shallow, and the bottom uniformly sandy. I think it would be sure to yield interesting microzoa belonging to such groups as Copepoda and Ostracoda; perhaps also Cumacea and Mysidæ, but the absence of cast-up débris on the shore, either of the larger Crustacea or Mollusca, seems to indicate a dearth of those creatures outside. The littoral zone being chiefly of the flat sandy or muddy character already described, there is not, except in certain restricted areas, much opportunity for shore-hunting of the ordinary kind. But, away from the "sphere of influence" of the estuarine mud, there occur occasional patches of inter-tidal rock with promising-looking pools; these are, however, fearfully storm-swept, and incapable of affording sufficiently secure attachment for many adherent animals. A few common Hydrozoa, such as *Sestulariæ* and *Campanulariæ*, a few patches of "*Hydratuba*" and Ascidians were, I think, with *Alcyonidium gelatinosum*, about all that I noticed. Among swimming things were, however, many Amphipoda and Copepoda, and I took also several specimens of *Mysis Lamornæ*. But my most interesting captures were made by washing the muddy deposit found on the bottoms of some rock-pools, and by netting amongst the weeds of pools situated above ordinary high-water-mark, though still subject to occasional tidal influx. The Copepoda found in such pools will be described elsewhere, but it may be noted here that in some of the inland peaty pools and ditches of the neighbourhood occurred an interesting Ostracod, *Cyclocypris globosa;* and in the White Loch, a species still more interesting and more capricious in its distribution, *Darwinula Stevensoni*.

As regards the botany of the district, I can say very little. My last two visits were made about midsummer, and at that time the sea banks were gorgeous with masses of thrift and red cranesbill (*Geranium sanguineum*), the marshy flats with golden fields of water-flag, the fells with thickets of *Rosa spinosissima* and numerous orchids, the most conspicuous of which was the sweet-scented species, *Gymnadenia conopsea*. These, of course, are all flowers which cannot be overlooked, and are an ever-present delight to the eye and mind: less alluring species, which need to be hunted for, were for the most part passed unnoticed, and such as I did gather were of no particular interest.

G. STEWARDSON BRADY.

PROFESSOR ARTHUR CAYLEY, F.R.S.

MATHEMATICAL science has suffered a grievous loss by the death of Prof. Cayley, which occurred on Saturday last, at Cambridge. There is hardly a branch of pure mathematics which is not indebted to him for original contributions of the highest value, while the important problems which have been elucidated by him are so numerous, and cover so wide a field, that he was certainly one of the greatest mathematicans which the world has ever known.

It was in September 1883, when Cayley was President of the British Association, that he was ranked among our "Scientific Worthies," Dr. G. Salmon being his biographer. We refrain, therefore, from giving a long notice of his life, and content ourselves with a brief sketch of his scientific work.

Cayley was born August 16, 1821, at Richmond, Surrey. At a very early age he showed great liking and aptitude for arithmetical calculations. He entered King's College School, London, at the age of fourteen, and three years later went to Cambridge, where he entered Trinity College. In 1842 he came out as Senior Wrangler and First Smith's Prizeman. Sir George Stokes had been Senior Wrangler in the previous year, and the late Prof. Adams obtained the distinction in 1843.

While still an undergraduate, Cayley commenced his career of mathematical publication by a paper in the *Cambridge Mathematical Journal* for 1841, but it was not until 1852 that he addressed a memoir to the Royal Society, of which he was elected a Fellow in the same year. Very soon after taking his degree at Cambridge, he entered the legal profession, and was called to the Bar in 1849. But during his career as a barrister, he was constant to his first love, mathematics, and it was while in legal practice that some of his most brilliant mathematical discoveries were made. In 1863, after fourteen years of chamber life in Lincoln's Inn, he returned to Cambridge to fill the newly-instituted Sadlerian Professorship of Mathematics, and no one could have been better fitted than he to discharge the duties of the holder of the chair, viz. "to explain and teach the principles of pure mathematics, and to apply himself to the advancement of the science."

With regard to Cayley as an original investigator, his special merit has been described by Mr. Glaisher who termed him "the greatest living master of algebra." It is difficult to select the work for which he will be the best remembered, but Prof. Salmon defined it as "his creation of an entirely new branch of mathematics by his discovery of the theory of invariants, which has given quite a new aspect to several departments of mathematics . . . And the effect has been that the knowledge which mathematicians now possess of the structure of algebraic forms is as different from what it was before Cayley's time as the knowledge of the human body possessed by one who has dissected it and knows its internal structure is different from that of one who has only seen it from the outside."

Among the honours which Cayley received, may be mentioned the Royal Medal of the Royal Society, awarded to him in 1859, and the Copley Medal in 1882. He was a correspondent in the section of Astronomy of the Paris Academy of Sciences, and was a Fellow or Foreign Member of many other societies and academies, both at home and abroad. He was given the honorary degrees of D.C.L. by the University of Oxford in 1864, and the LL.D. by Dublin University in the following year. Later, the University of Edinburgh conferred upon him a similar honour, and he received the degree of Sc.D. from his own University. The Universities of Leyden, Göttingen, and Bologna also conferred upon him the degree of Ph.D. In 1890, the President of the French Republic made him an officer of the Legion of Honour. This distinction was granted in consequence of a request addressed to the French Minister of Foreign Affairs by the President and other members of the Academy of Sciences.

Cayley's mathematical papers, commencing in the year 1841, have appeared in every periodical mathematical publication of importance in Europe and America. In the year 1887 he undertook the work of editing the series of ten quarto volumes, in which the Syndics of the Cambridge University Press are publishing his collected mathematical papers. The publication of these volumes commenced in 1889, and six of the volumes were reviewed in these columns a year ago (NATURE, January 18, 1894). The number of papers which appear in the six volumes is 416. Altogether seven volumes have as yet appeared. As Cayley is responsible for 724 titles in the Royal Society Catalogue down to 1883, and he has since produced a considerable amount of mathematical work, it seems improbable that ten volumes will be sufficient to contain the results of his prodigious activity and enormous literary industry.

What more need be said about this great master of mathematics? He sacrificed prospects of advancement in the law in order to follow the mathematical work to which he was devoted. He had the power to teach, and the ability to extend the boundaries of knowledge. He was "as distinguished for the amount and universality of his reading as for his power of original work." Truly, his memory will "outlive the life of dust and breath."

The funeral service will take place in the Chapel of Trinity College to-morrow (Friday). Lord Kelvin will be present to represent the Royal Society, and other men of science will probably attend to do honour to the memory of their brilliant fellow-worker.

NOTES.

WE are enabled to state that the communication to the Royal Society on "Argon, a new Constituent of Air," by Lord Rayleigh and Prof. Ramsay, to be given at the Royal Society to-day, will refer to the density of nitrogen from various sources; to methods for removing free nitrogen from air; to the separation of argon from air by diffusion; to the density of argon; to its spectrum (on which a short paper will be read by Mr. Crookes); and to its behaviour at low temperatures. It is interesting to note that Prof. Olszewski, of Cracow, has liquefied and solidified the gas, and will communicate a short paper on the subject. The solubility in water is also recorded. Various attempts to induce chemical combination are described, and general conclusions are drawn in a final section. The ratio of its specific heats shows it to be a monatomic gas, and proves that its atomic weight is approximately 40. The meeting will not be held in the apartments of the Royal Society, but in the theatre of the University of London.

THE metric system of weights and measures is to be introduced into Tunis on March 1.

DR. BREDICHIN has resigned the Directorship of the Pulkova Observatory, on account of ill-health.

DR. E. KÜLZ, Professor of Physiology in the University of Marburg, has just died. He carried out a number of important researches in physiological and pathological chemistry.

SIR JAMES COCKLE, who held the post of Chief Justice of Queensland from 1862 to 1879, died on Monday, at the age of seventy-six. He was elected a Fellow of the Royal Society in June 1865.

PROF. LEWIS R. GIBBES, of the College of Charleston, South Carolina, U.S.A., whose death occurred towards the end of last year, was born August 14, 1810. He was a Professor in the above-mentioned College for more than fifty years, from 1838 to 1892; at first as Professor of Mathematics, afterwards of Astronomy, Chemistry and Physics. Prof. Gibbes published a number of articles on astronomy, natural history, &c., in various journals and in the publications of scientific societies.

IT will be remembered by our electrical readers, that at the contest organised by the City of Paris in 1889 for the best electric meter, Prof. Elihu Thomson was awarded the prize of five thousand francs. Desiring that this sum should serve for the development of the theoretical knowledge of electricity, Prof. Thomson arranged to offer a prize for the best work on one of four important questions in electricity. The papers had to be sent in by the middle of September 1893, but the decision of the Committee organised to adjudicate upon them has only lately been made known. Four memoirs were received, one written in German, one in French, and two in English. It was decided that each of the two memoirs in English deserved the prize. One was by Dr. A. Webster, of the Clark University, Worcester, U.S.A., the subject being "An experimental determination of the period of electric oscillations." The subject of the other memoir was "An examination of the absolute accuracy of the formula for calculating the period of free oscillation of a discharge condenser under circumstances such that the resistance of the circuit has no appreciable disturbing effect." This memoir dealt practically with a determination of "v" by a method of free oscillations, and the authors were Prof. O. Lodge and Mr. R. T. Glazebrook. Ultimately it was decided to award a prize of five thousand francs for each of these papers, the money for the purpose having been collected. The collection of the additional money caused the delay in the publication of the decision of the Committee.

THE opinion has often been expressed that corn or at least grass could be profitably cultivated on the high plateaux of Norway. Dr. Hans Reusch, the Director of the Norwegian Geological Survey, concludes, however, in a recent publication, that the soil which once existed, was nearly all scraped away during the Ice Age, and that cultivation could not now be carried on with much success.

THE Royal Photographic Society, which became incorporated on January 1 in this year, have determined that the Society shall hereafter consist of two classes, Members and Fellows. In future, no members will be admitted to the fellowship until they have given the Council satisfactory proof of the possession by them of suitable qualifications for the title F.R.P.S., which in this way will become a guarantee of ability on the part of its holder in either scientific or artistic photography.

DURING the past week, snow has fallen over all parts of the British Islands; in Scotland and the north of Ireland the amounts have been large, and even in the Channel Islands a depth of six inches was recorded. Very sharp frosts have also been experienced in all parts, and for some days the thermometer in places has not risen above the freezing point. The following low readings have been notified to the Meteorological Office: 8° at Llandovery, on the 25th; 2° at Hillington (Norfolk), and 11° at Yarmouth, on the 27th; and 9° at Loughborough, on the 29th January. At Haparanda, in the Gulf of Bothnia, a temperature of – 24° was recorded on January 26 and 29, and over Europe generally the weather was very cold, frost and snow occuring as far south as Nice and Biarritz. A dense fog occurred in London on the afternoon of January 29.

THE twenty-fifth anniversary of the transfer of the telegraph to the State in the United Kingdom was celebrated on Monday, by a banquet at the Hôtel Métropole, under the presidency of the Postmaster-General, Mr. Arnold Morley. The very remarkable developments of telegraphy during the last quarter of a century is shown by some statistical information furnished to the guests. The telegrams have risen from 6,830,000 to 71,465,000, the mileage of line from 14,776 to 32,881, the mileage of wire from 59,430 to 205,304, the instruments in use from 670 to 8500, the number of words per minute capable of being transmitted on the fastest form of instrument from 70 to 600, and the offices from 2932 to 9637.

ON Wednesday, February 6, the Hon. T. F. Bayard, United States Ambassador, will distribute the prizes to evening students of the People's Palace, Mile End Road, E.

THE following are the names of the candidates who passed the recent examination of the Institute of Chemistry:—A. E. Bell, C. S. Ellis, Dr. M. O. Forster, J. Lones, G. H. Russell, W. H. Sodeau, W. L. Sutton, and W. G. Young.

ON Thursday afternoon, February 14, Mr. L. Fletcher, F.R.S., Keeper of Minerals at the British Museum, will begin a course of three lectures at the Royal Institution on Meteorites. The Friday evening discourse on February 8 will be delivered by Dr. G. Sims Woodhead, his subject being "The Anti-toxin Serum Treatment of Diphtheria."

IN accordance with the scheme recommended by the Royal Commission, telegraphic and telephonic communication has been established by the Post Office authorities in connection with the Liverpool life-boat service and look-out stations, and also at various points on the Welsh coast.

ACCORDING to the Paris correspondent of the *Lancet*, a survey of the statistics hitherto published in divers countries of the results of the application of Behring and Roux's method in the treatment of diphtheria up to the last day of December 1894, gives a total of 2700 cases with 433 deaths, or a mortality of 16 per cent.

A GENERAL meeting of the members of the Federated Institution of Mining Engineers will be held on Tuesday, February 12, at 10.30 a.m., in the Examination Hall of the Mason Science College, Birmingham. Arrangements have been made for visits to collieries, &c., on the following day.

THE third series of lectures arranged by the Sunday Lecture Society begins next Sunday afternoon, in St. George's Hall, Langham Place, at 4 p.m., when Mr. A. Smith Woodward will lecture on "The Restoration of Extinct Animals." Lectures will subsequently be given by Dr. R. D. Roberts, Prof. Henry E. Armstrong, F.R.S., Mr. C. T. Whitmell, Dr. C. W. Kimmins, Mr. Douglas Carnegie, and Mr. W. Mayhowe Heller.

THE twenty-second annual dinner of the old students of the Royal School of Mines took place on Friday evening, at the Criterion Restaurant, under the presidency of Mr. W. H. Greenwood. A large number of guests were present, among them being General F. T. Lloyd, Mr. Jeremiah Head, Prof. J. W. Judd, Prof. Roberts-Austen, Mr. H. A. Wiggin, Mr. E. Matthey, Prof. W. A. Tilden, Prof. A. W. Rücker, Prof. G. B. Howes, Mr. W. Gowland, Dr. W. P. Wynne, Prof. C. V. Boys, Prof. J. B. Farmer, and Prof. A. R. Huntingdon.

THE following arrangements have been made for lectures at the Royal Victoria Hall, Waterloo Bridge Road, S.E., during February: Sir Colin Scott Moncrieff on "Egypt and the Nile"; Mr. Smith Woodward on "A Visit to Russia"; Dr. J. Norman Collie on "The Alps around Mont Blanc"; Prof. Ramsay, F.R.S., on "Some New Discoveries about the Air." This lecture will have special reference to the investigations by Lord Rayleigh and Prof. Ramsay, which resulted in the discovery of a new constituent of the atmosphere.

THE twenty-first general meeting of the Association for the Improvement of Geometrical Teaching was held at University College on January 19, Dr. R. Wormell, the President, in the chair. The report of the Council, proposing the continuation of the *Mathematical Gazette*, and the Treasurer's report were read and adopted. Dr. Larmor, of St. John's College, Cambridge, was elected President in the place of Dr. Wormell, who retires; the other members of the Council, including the hon. secs., R. Holmes (The Avenue, St. Margaret's, Twickenham) and C. Pendlebury (53 Gunterstone Road, West Kensington), were re-elected. After the elections, Mr. E. M. Langley gave some geometrical notes, and Mr. G. E. Heppel read a paper on "Algebra in Schools." After an adjournment, Dr. Larmor took the chair, and papers were read by Rev. C. Taylor ("The A. I. G. T. Syllabus of Geometrical Conics") and Rev. J. J. Milne ("The Conics of Apollonius"), and Prof. Lodge gave some notes on Mensuration. Interesting discussions followed these. All communications with respect to the *Mathematical Gazette* should be addressed to the Editor, 16, Adelaide Square, Bedford.

COLONEL A. T. FRASER, writing to us from Bagdad, says that while travelling lately on the right bank of the Euphrates, he noticed a pair of caves near the usual black woollen cloth tent lived in by the Arabs, and found that, as evening drew in, a number of cows were driven down, and the caves shut with plugs of straw and thorns. "It was evident," he says, "that this must have been the primary use to which those early types of man of the flint and bronze ages, about whom we know so little, put the so-called cave dwellings, that of sepulture being an after-thought. One would imagine, reasoning hastily, that cows and Arabs should have more properly changed places. But the Arabs bring the experience of thousands of years to bear on this question, and prefer the free air to a confined atmosphere suitable only to ruminant beasts, and tents to caves. Having alluvial soil to deal with, the Arabs in this instance dug pits about four feet deep, and domed over the top with brushwood and straw to complete the caves, the whole showing but little above the surface. There was no need of permanence, as encampments shift with the seasons. Under other circumstances the old "cave" races would have dug the entire cavity out of the solid, but still put in their cattle, and remain outside themselves."

FOR some classes of observations involving the use of a spectroscope, the movement of either collimator or observing telescope is objectionable, and for such work it becomes necessary to rotate the prism in order to bring different parts of the spectrum into the field of view. If the condition of minimum deviation be of no importance, as in the case of Mr. Tutton's apparatus for obtaining monochromatic illumination, there is no objection to turning the prism in this way, but if the condition of minimum deviation for the central ray in the field is to be retained, some special device is essential. This has already been accomplished in various more or less elaborate ways, but Mr. F. L. O. Wadsworth has now indicated a means of satisfying this condition very simply (*Astronomy and Astrophysics*, December 1894). The general solution of the problem is effected by the introduction of a mirror into some part of the spectroscopic train between the slit and the focal plane of the observing lens, the mirror having an angular movement equal to one half the change in angular motion of the ray refracted at minimum deviation. The mirror may be disposed in several ways, but that finally adopted for use with the spectro-bolometer is to place it in continuation of the back face of the prism. With this arrangement the emergent ray is parallel to the incident one, so that a direct vision spectroscope is obtained by the use of a single prism. The prism and mirror are together mounted on the graduated circle of the spectrometer, and by making the axis of rotation of the system coincident with the intersection of the plane bisecting the refracting angle of the prism and the plane of the mirror, there is no lateral displacement of the ray at minimum deviation. The idea seems to be an excellent one, and capable of wide application.

THAT gales have a considerable effect upon the heights of tides is very well known. The gale of January 23, furnished an example of this at the East India Dock. According to a letter in the *Times*, high water was due at the Dock at 12.46 a.m. on January 24. At ten o'clock on the previous evening, however, the tide had risen three inches above Trinity datum, and then fell 5 feet 4 inches to midnight. It again rose five inches to 1 a.m., when it went away altogether. The phenomena suggest that, probably, the records of self-registering tide gauges, when discussed in connection with high winds and cyclones, will furnish useful results. Prof. Cleveland Abbe notes in the *Monthly Weather Review* that, during a hurricane at Charleston last September, the excess of the actual over the normal high water mark increased gradually until it reached more than five feet. In this connection some observations on the indication of distant storms by tides are of interest. Captain E. Jones, who for many years kept logs of deep-water voyages of Lieutenant Maury, states that, previous to a cyclonic storm which occurred early in September, he noticed that at low water the tide did not fall near as low as under ordinary conditions, and he came to the conclusion that a cyclone was approaching, as he had noticed before that under these conditions such storms are very certain to make their appearance. He testifies "that this abnormal condition is an infallible indication of a storm approaching or passing by. A storm directly in from seaward generally affects the flood tide even more than a low water tide, but in the present case the high water was about normal. A long experience gives me great confidence in the barometer as affording valuable prognostication of a storm, but this tidal wave along the coast preceding a cyclone must, as it seems to me, give absolute proof that some kind of storm is in progress; the astonishing thing is that the ocean level is affected by the cyclone at such a great distance, and especially ahead of it."

IN the *American Engineer* for January, Prof. H. A. Hazen gives some of the results of a very interesting balloon ascent made in the "Svea" at Stockholm, by S. A. Andrée. The account is taken from the *Proceedings* of the Swedish Academy, vol. 20, part ii., No. 3. The balloon travelled for 136 miles east over the Baltic, the highest point reached being 9900 feet, and at the time of the ascent, Stockholm was nearly in the centre of a high barometric area; this fact, in connection with the position of the balloon over a wide expanse of water, adds great interest to the observations. The diminution of temperature with height, allowing for increasing heat during the day, was about 1° in 250 feet, in the first 4000 feet, which is noteworthy, as the sea surface causes less diminution with height. Above 4000 feet, clouds were encountered, and these changed the rate of diminution, while at the highest point, the result was 1° in 400 feet. The most interesting feature is the great dryness of the air above 7500 feet; at 6000 feet the relative humidity was 100 per cent., and at 1800 feet higher it was only 4 per cent. Prof. Hazen states that this is the most extraordinary fall in humidity ever observed, and it shows how little we really know of atmospheric conditions, even at very low heights. The value of the results to be obtained by balloon ascents in determining the laws of storms is beyond doubt, and Prof. Hazen strongly advocates that such researches should be undertaken.

THE origin of the Alpine Serpentines has always been a subject for wide differences of opinion. The Italian school of geologists until lately upheld the view that they were metamorphosed sedimentary rocks, while English and German geologists maintain their intrusive nature. One of the latest contributions to this subject comes from Dr. Ernst Weinschenk who, in the *Abhandlungen* of the Bavarian Academy of Sciences (Munich, 1894) describes the occurrence and petrography of the serpentines of the Great Venediger, a mountain in the Eastern Alps of North Tyrol. He finds that they are undoubtedly intrusive rocks, formed by the consolidation of a peridotite magma that was squeezed in between the foliation-planes of the neighbouring mica-schists during the great Alpine earth-movements. They thus occur as a series of laccolites (*linsen*), which, we may observe, resemble in their origin those of Shropshire rather than the typical laccolites of the Henry Mountains, which were intruded into horizontal strata. After their first consolidation, the peridotites were crushed by the continuation of the earth-movements, and by the continued action of superheated vapours and solutions were gradually converted into their present condition. The evidence of these changes is seen in the minute structure of the rocks, which, as well as the nature of the metamorphism they have produced in the surrounding schists, is exhaustively described in the paper, and illustrated by a number of micro-photographs.

A SECOND paper, by the same author, deals with the gneiss and granite of the same part of the Alps. These have also been studied by Prof. Löwl, whose results are published in the *Verlag der k.k. geol. Reichsanstalt* (Vienna, 1894). This author treats the subject from a structural point of view, and his memoir is illustrated by a map and several sections; while Dr. Weinschenk describes the petrography in detail. Both authors assert the undoubtedly intrusive origin of these rocks, and incline to class them with the pre-carboniferous "Protogine" of the Western Alps. Dr. Weinschenk regards certain peculiarities in the granite as due to lateral pressure during the period of consolidation, and proposes the term *Piezocrystallisation* for the development of structures under such conditions.

THE elasticity of solid gelatine solutions is the subject of an investigation by Erwin Fraas, in *Wiedemann's Annalen*. Sticks of aqueous gelatine were obtained in the following manner. Brass tubes, about a foot long and half an inch thick, were cut in two at the centre and joined by wire rings. They were closed at one end with a cork, and were placed vertically. The gelatine solutions were then poured in, care being taken to prevent adhesion by rubbing with olive oil. The suspension of the sticks was a matter of some difficulty, but it was accomplished by brass clamps of the shape of a cylinder, cut along its length on both sides and roughened inside, which were gently pressed on the gelatine by a spring. It was found that in no case did the volume change by stretching, the diminution girth being compensated by the increase of length. The addition of common salt impaired the elasticity and strength of the sticks very considerably, making them unfit to support a pound weight, while part of the water could be replaced by glycerine, cane sugar, or gum arabic, without making any difference.

THE *Comptes-rendus* of the Paris Academy, of January 14, give an account of some modifications of an electrical anemometer formerly used by the Rev. Marc Dechevrens, at Zi-ka-wei, for recording the horizontal and vertical movements of the atmosphere. The instrument, which is being constructed by M. Richard, is to be erected at the observatory of the Jesuit College in Jersey, and possesses some novel contrivances intended to ensure its satisfactory performance. The fan of the anemometer, which gives the horizontal component, is formed by portions of a cylinder; this arrangement was devised by M. Dechevrens, and is said to give excellent results. There is also an arrangement which assures sufficient duration to the electric contacts, to excite the electromagnets, while preventing prolonged contacts, which exhaust the batteries without doing any good. Two wires out of seven which exist in similar instruments are dispensed with; this is also an important simplification if the registrations are to be recorded at a distance.

THE current number of *Wiedemann's Annalen* contains a paper by Max Weber, on electromagnet pull. The author has measured the pull exerted on a long iron wire, one end of which projects within a helix, when a known current flows through this helix, producing a magnetic field of known intensity. The wire under examination is suspended horizontally by four silk fibres in the same way as in a ballistic pendulum. The displacement of the wire under the action of the coil is measured by means of a microscope, and from a knowledge of the weight of the wire and the length of the suspending fibres the pull can be calculated. The author has investigated the connection between the pull per unit cross-section of the wire ($p_{\parallel}$), the strength of the field within the helix (H), and the intensity of magnetisation (J), and finds that $p_{\parallel} = JH$, when the length of the wire is parallel to the lines of force of the helix, and the diameter of the wire is very small compared with its length. The author has also examined the pull perpendicular to the lines of force, by using two coaxial magnetising coils separated by a small interval, the wire being placed with its length perpendicular to the axes of these coils, and its end passing through the space left between them. If the pull per unit area of cross-section of the wire under these conditions is called $p\perp$, then $p\perp$ is always, in the case of iron, less than $p_{\parallel}$. For fields having an intensity of about 100, the ratio $p_{\parallel}/p\perp$ is about 100, but decreases rapidly with increasing field strengths, and appears to approach unity as a limit. Thus for $H = 12{,}000$ $p_{\parallel}/p\perp = 1{\cdot}11$.

IT is known that the direction of the pendulum line shows a considerable anomaly around Moscow. The line is deviated at Moscow by 10"·6 to the north; at Tsaritsino, in the south-east, the deviation is only 0"·5 in the same direction; and at Podolsk, which is twenty-one miles from the capital, the deviation takes the opposite direction, to the south, and attains −2"·7. It has been supposed that beneath the neutral zone, at Tsaritsino, there must be great cavities in the rocks, or that the rocks, as a whole, have a density below the average. We now learn from a note by General Stebnitskiy, in the last issue of the *Izvestia* of the Russian Geographical Society (1894, No. 4), that the pendulum observations which have been made around Moscow by M. Iveronoff, give full support to the above supposition. The differences between the lengths of the second-beating pendulum, observed and calculated, being positive at Moscow and at Podolsk (+0·0108 and +0·0064 millimetres respectively), the same difference is negative above the neutral zone of Tsaritsino (−0·0228 millimetres), thus showing a deficiency in the acceleration due to gravitation to the amount of 1/30,000th of the total force.

THE last number of the *Isvestia* of the Russian Geographical Society contains a very interesting account of Baron Toll's expedition to Arctic Siberia and the New Siberia Islands. Baron Toll was sent out by the Academy of Sciences to examine the body of a mammoth which was said to have been discovered on the banks of the Balakhna, a tributary of the Khatanga Bay, and altogether to continue the work which had been entrusted to Chersky, but was interrupted by his death. Lieut. Shileiko undertook the surveys, as well as the astronomical and magnetical observations. After a three months' journey the two explorers reached the village Kazachiye, at the mouth of the Yana, in 71° north latitude. A visit to the mammoth soon proved that there was nothing left but a few pieces of skin with its hair clothing, parts of the extremities, and a broken skull of a young mammoth. A number of remarkable explorations and surveys, astronomical and magnetical observations, and geological explorations were, however, carried out. The chief geological result is the settling of the real positions of the layers which contain relics of the mammoth. They are undoubtedly Post-Glacial, as they overlie the masses of underground ice which form the chief rock of the great Lyakhoff Island, and which, as Baron Toll's observations now prove, are remains of the great ice-sheet which formerly covered both the islands and the mainland, and whose moraines have now been discovered on the mainland. Moreover, these ice masses have the typical granulated structure of the glacier ice, which proves that they have originated from the snow-cover, and could not have originated from any sort of running water. As to the Post-Glacial layers which overlie the above, they contain, besides shells of *Cyclas* and *Valvata* and well-preserved insects, full trees of *Alnus fruticosa*, willows, and birch, fifteen feet high, and bearing perfectly well-preserved leaves and cones. The northern limit of tree vegetation thus spread during the Mammoth period full three degrees of latitude higher than it spreads now, *i.e.* up to the 74th degree, and the mammoths and rhinoceroses of the time lived upon the patches of meadow clothed with the above bushes. It is worthy of note, that the masses of underground ice are not found in the lower parts of the Arctic coast which are known to have been covered by the Post-Pliocene sea, and that they only occur where the land rises a few hundred feet above the present level of the sea—that is, above the evel of the Post-Pliocene ocean.

AFTER considerable delay, Murray's "Handbook for Hertfordshire, Bedfordshire, and Huntingdonshire" has been published. Brief notes on the geology, botany, and antiquities of these counties are given in an introduction.

THE Matriculation Directory (No. xvii.) of the University Correspondence College has just been received. It contains the examination papers (together with solutions) set at the recent matriculation examination, and also articles on the special subjects for next June, and for January 1896.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Miss Teresa M. L. Monteath; two Little Auks (*Mergulus alle*) from Norfolk, presented respectively by Mr. Hamon Le Strange and Colonel Feilden; a Cardinal Grosbeak (*Cardinalis virginianus*) from North America, presented by Mr. F. Beresford Wright; two Leopard Tortoises (*Testudo pardalis*), a Cape Bucephalus (*Bucephalus capensis*) from South Africa, presented by Mr. J. E. Matcham; two Mantells Apteryx (*Apteryx mantelli*) from New Zealand, a Black Iguana (*Metopoceros cornutus*) from San Domingo, deposited; a Hog Deer (*Cervus porcinus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE NATAL OBSERVATORY.—Mr. Nevill's report upon the work of the Natal Observatory, during the fiscal year ending last June, has been issued. The staff of the Observatory consists of an astronomical assistant, a meteorological assistant, and a computor, all of them ladies. In spite of such limited assistance, much important work has been accomplished. The observations of Mars during the opposition of 1892 have been completely reduced; and as soon as the corresponding observations made at the northern observatories have been reduced and published, it is proposed to compare the two series, and obtain from them a new determination of the distance of the sun. A contribution to the knowledge of the variation of latitude is included in the report. Since 1884 a number of observations have been made, by Talcott's method, to determine the latitude of the observatory. The observations invite consideration, on account of the fact that they were made and reduced before any special attention had been directed to the variation, arising from the suspected periodical inequality, in the direction of the polar axis of the earth. The mean latitude, deduced from the 1023 observations made during the six years 1884-1890, was 29° 51′ 46″·68. The results obtained, from the separate observations of each year, show a steady gradual decrease since 1885. The observed latitude of the Observatory seems to have reached a maximum in that year, and to have steadily decreased since, at a nearly uniform rate of 0″·27 per annum. The rate of decrease up to 1890, however, appears to have quickly diminished, indicating a periodical irregularity in the apparent value of the latitude of the Observatory. Mr. Nevill remarks that a great deal of important work has accumulated at the Observatory, but the Government of Natal will not afford the necessary facilities for printing and publishing it.

THE NEW DUDLEY OBSERVATORY.—The disadvantages of the old situation of the Dudley Observatory had long been recognised, but it was not until 1892 that the generosity of Miss Bruce and other "friends and neighbours of the observatory," permitted the removal of the observatory to its present more favourable site. From an account given by the Director, Mr. Lewis Boss, in the *Astronomical Journal* No. 334, we learn that the observatory grounds consist of six acres, situated in an area of about forty acres, designed to form part of the park system of the City of Albany. The buildings appear to be all that can be desired, and many advantages will no doubt be derived from the provision of dwelling accommodation for the observers. The Transit Circle provided in 1857 has been re-erected with some slight additions, and it is satisfactory to learn that its large aperture of 0·203 m. and focal length of 3 metres, is no detriment to its excellence. A new equatorial, denominated the Pruyn, having an aperture of 31 centimetres, has been presented by the sons of a former President of the Board of Trustees. In this instrument, a photographic combination is obtained by replacing the flint glass of the visual telescope with a second one, and it is believed that this arrangement will be a complete success.

No elaborate programme of work is promised, but "the logic of events and inclination invites the observatory to undertake the comprehensive observation and discussion of stars known to have sensible proper motions." The Transit Circle will accordingly be devoted to this work, and the equatorial will take a subordinate place, "though it is expected that the zealous young assistants will continue to give a good account of themselves in work with this instrument, so far as circumstances permit."

THE MILKY WAY.—Returning to the subject of the distribution of stars in the celestial sphere, C. Easton (*Ast. Nach.* 3270) has derived some results of considerable interest by limiting his attention to two comparatively small regions of the Milky Way, one in Aquila, and another in Cygnus, the latter embracing a specially dark as well as a notably bright region. For each of these regions he finds that the general luminosity of the Milky Way corresponds very much more closely with Argelander's stars of magnitudes 9·1–9·5, than with the stars of greater brightness. A diagram in which all the stars of the Bonn maps have been reduced to the corresponding number of stars of mag. 9·5, shows very little similarity with the features of the Milky Way. Extending his inquiries to the photographs taken by Dr. Max Wolf, showing stars down to mag. 15, he shows that the very feeble stars followed the same law of distribution as those of mags. 9·1–9·5. This correlation appears to indicate that the faintest stars and those of the 9th or 10th mag. probably form part of one system, and are at nearly the same distance from us. At the same time, some stars brighter than 9th mag. seem to be intimately associated with the Milky Way.

The hypothesis of an annular system, relatively isolated from the central part of the great galactic system, is regarded as not incompatible with the distribution of stars which he has found. For if, at nearly the same distance from us, stars vary so much in size or intrinsic brightness as to give magnitudes ranging from 9 to 15, there seems no reason why some should not be of greater brightness than 9th mag.

There is nothing to prove, however that the various parts of the Milky Way are at an equal distance from us, nor even that it may be an enclosed ring. It does not appear improbable that subsequent researches may show the existence of one or several spirals emanating from a central accumulation, and recurving so as to form a nearly annular system, or one consisting of nearly concentric rings. However it may be, Mr. Easton's results seem to indicate that the portion of the Milky Way accessible to our means of observation, has but little thickness in relation to the diameter.

In a paper on the same subject (*Knowledge*, February), Mr. Maunder finds it difficult to resist the conclusion that the "dark lanes" of the Milky Way are really regions of barrenness, and regards these features as indications of a process of condensation going on in the stellar as well as in the nebulous matter.

THE SYSTEM OF ALGOL.—Quite recently (NATURE, vol. xlv. p. 446) Mr. Chandler credited Algol with an obscure companion in addition to that which was recognised by Goodricke, and the existence of which has been fully confirmed by the investigations of Pickering and Vogel. Mr. Chandler's conclusions were based on a discussion of the systematic irregularities of the epochs of minima, and were apparently confirmed by a later discussion of the proper motion of Algol itself (NATURE, vol. xlix. p. 349). The evidence of irregular proper motion, however, is not regarded as conclusive by some authorities, and M. Tisserand, the Director of the Paris Observatory, is apparently one of the unconvinced. He has therefore attempted to find some other explanation of the phase variations (*Comptes-Rendus*, January 21, 1895), and the result is to show that they can be simply and sufficiently explained by supposing a single dark companion moving in an elliptic, instead of a circular, orbit; and, in addition, that the bright star exhibits a sensible polar compression. The result of this departure from the spherical form would be a movement of the periastron point, and this would explain the apparent irregularities.

Assuming that the plane of the orbit is coincident with the equator of Algol, its eccentricity is found to be 0·132, and the polar diameter is shorter than the equatorial by $\frac{1}{310}$.

The consequences of these conditions would be a very slight variation of minimum brightness in the long period of 140 years, and an entirely negligible difference in the time of passage to minimum and recovery of normal brightness. The total duration of the eclipse, however, will vary very considerably. Taking the mean epochs 1800 and 1884 for the observations of Wurm and Schonfeld respectively, M. Tisserand finds that the duration would be increased in this time by 1·63 hours. Since the times given by these observers are 6·5h. and 9·0h. respectively, M. Tisserand is entitled to regard this as confirmation of his hypothesis. He points out the importance of spectroscopic observations at short intervals from minimum, in connection with his explanation.

The irregularities in U Ophiuchi and U Cephei are probably to be explained in the same way.

THE EXPLOSIVE NATURE OF THE SODIUM AND POTASSIUM DERIVATIVES OF NITROMETHANE.

SOME additional information of an interesting character concerning the extremely explosive sodium and potassium compounds of nitromethane, is contributed to the current *Berichte* of the German Chemical Society by Prof. Zelinsky of Moscow. A short time ago Prof. Victor Meyer described (*Berichte*, 27, 1601) a mode of preparing the sodium compound CH_2NaNO_2 in a state of purity. The process consists in diluting a quantity of nitromethane, CH_3NO_2, with ether and treating the liquid with a solution of sodium in alcohol, when the sodium compound is precipitated. The precipitate requires to be washed with ether, and is then dried over oil of vitriol; the dry compound thus obtained affords numbers on analysis agreeing with the anhydrous formula above given. In a former method of preparation described by Prof. Meyer, alcoholic soda was employed as precipitant, but the sodium nitromethane obtained invariably contained either water or alcohol; the use of sodium ethylate affords it anhydrous. Even the hydrated compound first isolated proved to be explosive; but upon placing a small quantity of it upon a watch-glass, and warming over a water-bath, in a short time it became suddenly converted into the anhydrous compound which immediately exploded with great violence. When a small quantity of the anhydrous compound prepared by use of sodium ethylate was placed in a test-tube, gently compressed, and then warmed, an explosion of so violent a nature occurred that the test-tube was completely pulverised.

Prof. Zelinsky has recently had occasion to prepare considerable quantities of sodium and potassium nitromethane, and has had the opportunity of testing and observing their explosive power upon a larger scale. He appears to have adopted essentially the same process for the preparation of sodium nitromethane as that described by Prof. Meyer, employing an alcoholic solution of sodium ethylate as precipitating reagent. Being desirous of obtaining the sodium compound perfectly anhydrous, an attempt was made to achieve this object by use of the water bath, but for the sake of precaution only about a gram of the substance was employed as a preliminary test of the efficacy of this method of dehydration. It was fortunate that such was the case, for within five minutes an explosion of so violent a nature occurred, that the watch-glass upon which the compound was supported was reduced to powder, and the water-bath considerably injured. In order to demonstrate the explosive nature of this compound without danger upon the lecture table, Prof. Zelinsky recommends the following experiment:—A thick clock-glass, or better a stout metal plate, is sprinkled with small drops of water, and a very small piece of sodium nitromethane dropped upon it. After a few seconds, provided the amount of water has not been excessive, a deafening detonation occurs, with production of flame and projection of a thick cloud of smoke. The experiment may be varied by placing the substance upon the perfectly dry plate, and invoking its explosion by means of a smart blow with a hard object.

M. Nef has previously (*Ann. der Chemie*, 280, 273) described several of the metallic derivates of the nitroparaffins, and has referred to the instability of the sodium compound, and the possibility of occasional explosions. Prof. Zelinsky now supplements this statement by remarking that an explosion always results from the contact of the dry sodium compound with a minute quantity of water. One of his assistants upon one occasion incautiously placed about five grams of sodium nitromethane in a glass vessel whose surface happened to be moist, with the result that a terrific explosion instantly occurred, which shattered every piece of apparatus upon the table, and the atmospheric wave produced occasioned the sudden extinction of the whole of the gas flames in the laboratory. The assistant fortunately escaped more than trifling injury, but a second such occurrence might have a very different result. This incident will doubtless serve to emphasise the great precaution which is necessary in handling these compounds.

The potassium compound, CH_2KNO_2, has been prepared in a similar manner, and found to be even more unstable than the sodium compound, exploding at the ordinary temperature shortly after its isolation. It separates upon the addition of the potassium ethylate in well-defined crystals. The crystalline form, however, soon disappears, and upon rapidly transferring to a filter, an explosion invariably occurs as soon as the compound becomes drained free of most of the mother liquor. The instability of the potassium compound at the ordinary temperature may also be readily demonstrated upon the lecture table. It is, of course, necessary to prepare it freshly on the spot, because of the impossibility of preserving it for any length of time. An ethereal solution of nitromethane is mixed with a solution of potassium ethylate in alcohol, the supernatant liquid rapidly decanted from the precipitate produced, the latter dried as quickly as possible between filter-paper, and left quietly resting upon the paper. After a few minutes the substance explodes with a loud detonation.

These experiments will serve to indicate the extreme instability of the alkali-metal derivatives of nitromethane, and the violence of the explosions produced by their disruption.

A. E. TUTTON.

RECENT WORK AT HARVARD COLLEGE OBSERVATORY.

THE forty-ninth annual report of the Director of the Harvard College Astronomical Observatory, by Prof. E. C. Pickering, has come to hand. Omitting matters of administration and some of the details, the following summary shows the most important events of the year covered by the report.

PHOTOMETRIC OBSERVATIONS.

The reduction of the photometric measures of the southern stars observed by Prof. S. I. Bailey in Peru, is now completed, and the catalogue containing the resulting magnitudes is in print. The observations of the first investigation undertaken with this instrument since its return from Peru are nearly completed. About six thousand stars have each been observed on at least three evenings. This catalogue includes all the stars of the Harvard Photometry, eighty lists of comparison stars for variables of long periods, and various stars the magnitudes of which are desired by other astronomers. A study has been made of the atmospheric absorption, especially for very low stars, and its coefficient has been derived on each evening, both for the southern and the northern stars. These values are now applied as corrections to the individual observations, instead of adopting a mean value of the absorption. A new working list has been prepared of the stars north of $-40°$ having magnitudes 7·5 or brighter, and which have not already been observed with the meridian photometer. This list contains about fourteen thousand stars, of which about two thousand have been observed during the last year.

Prof. Pickering refers to Mr. S. C. Chandler's criticisms on the photometric observations made with the meridian photometer. (*Astron. Nach.* vol. cxxxiv. p. 355, and vol. cxxxvi. p. 85.) It is maintained that the meridian photometer possesses the same advantages in measuring the light of a star that the meridian circle does in measuring its position. In both instruments absolute values are determined directly, and they are obtained very rapidly. Stars are identified in the same way in both, rapidly and accurately, and in both the systematic errors are small, even if the accidental errors are in some cases larger than those resulting from other methods. Stars can be observed with the meridian photometer under favourable circumstances nearly at the rate of one a minute, and the average deviation of the results thus obtained does not generally exceed one-tenth of a magnitude.

ASTRONOMICAL PHOTOGRAPHY.

The number of photographs taken with the 8-inch Draper telescope is 1657. The number taken in Peru with the 8-inch Bache telescope is 1708. All of the spectra photographed with these instruments have been examined by Mrs. Fleming. As a result seven variable stars, U Puppis, V Cancri, V Leonis, T Sagittarii, R Delphini, R Vulpeculæ, and R Phœnicis, have been shown to have the hydrogen lines bright in their photographic spectra. Unsuccessful attempts have been made to photograph the spectra of many other variables of long period when at maximum, and no image has been obtained. This has been found to be due in many cases to large errors in the ephemerides, and has been remedied by depending upon the observations of Mr. W. M. Reed, and making the time of photographing each star depend upon its observed, instead of its predicted, brightness. Eleven new variables have been discovered in the year, from the presence of bright hydrogen lines in their spectra, besides three the variability of which was discovered from changes in their photographic images. The number of stars of the fifth type has been increased by seven, making the total number of these objects 62. Five nebulæ have been discovered from their spectra. The hydrogen line Hβ has been discovered to be bright in the spectra of five stars, and twelve stars have been shown to belong to the fourth type. The spectra of A. G. C. 18049 and 22640 are peculiar. Several photographs have been obtained of the new star in the constellation Norma. At the Lick Observatory it was shown from visual observations that its spectrum, as in the case of the new star in Auriga, had become that of a gaseous nebula. This has been confirmed from photographs taken at Arequipa, which also show that this object is now gradually becoming fainter. The spectra of 4557 stars on thirty plates have been classified for the new Draper Catalogue. On one of these plates covering the region of the variable star η Carinæ, 1161 spectra have been measured.

The number of photographs taken with the 11-inch Draper telescope is 912. The lines in the spectrum of ζ Ursæ Majoris are found to be double in 59 out of 340 images, and of β Aurigae in 47 out of 65.

An investigation has been in progress for some time for the detection of stars having large parallaxes or proper motions. Photographs are taken in the usual position with the film towards the object glass, and also with the plate reversed, the photograph being taken through the glass. These are repeated at intervals of six months at the times when the effect of parallax on their right ascension would have its greatest value. Plates thus obtained may then be superposed so that the films shall be in contact, and the two images of each star made to appear like a close double with components north and south. Small changes in position may be detected by changes in the position angle, and the amount of the parallax or proper motion may be measured with great accuracy. Several hundred stars have thus been shown to have no parallax exceeding half a second.

OBSERVATION IN PERU.

The meteorological station on the summit of Misti, at a height of 19,200 feet, was successfully conducted for several months, one of the assistants, generally Mr. Waterbury, visiting it every ten days, and readjusting the self-recording instruments. Unfortunately, early in September, the shelter containing the instruments was found to have been broken into, and a number of the instruments carried off. Apparently the robbery was committed by two Indians, whose tracks were followed to a considerable distance. The property stolen would, of course, be of no use to the thieves, and its intrinsic value would be a small part of the actual loss. The work at this station was conducted with great labour; a mule path had been built to the summit, and the entire expenditure had been large. It will be a serious loss to science if it proves impossible to maintain the station.

The number of photographs obtained by Prof. Bailey with the 13-inch Boyden telescope is 561, including some remarkable charts. Among them may be mentioned photographs of the Nebula of Orion with an exposure of eight hours, of the cluster ω Centauri with an exposure of six hours, and of η Carinæ with exposures of six and fourteen hours respectively. In some of these, notwithstanding the long exposure, the image shows no deviation from the circular form. This is mainly due to substituting for a finder two eyepieces attached to the main telescope. One of them serves to follow a guiding star in the usual way; the other, directed to another star, shows if the plate needs to be rotated in its own plane. This appears to be an important improvement in making the best photographic charts of long exposure, especially of the polar regions. By the ordinary methods it is impossible to entirely correct such errors as those due to flexure and refraction, which do not depend upon the direction of the axis of the earth.

Attention is again drawn to the importance of making use of the admirable atmospheric conditions at Arequipa. A telescope of the largest size would not only have most favourable opportunities for work, but a field unexplored with such an instrument in the southern sky. Much could be done with a smaller instrument, as is shown by the work already accomplished with the 13-inch Boyden telescope. Out of a list of thirty telescopes having aperture exceeding 14 inches or more, but one is mounted south of latitude + 35°, and this one is not in use. A moderate expense only would be required to carry out this plan.

WORK WITH THE NEW TELESCOPE.

One of the most important events of the year was a careful trial of the Bruce photographic telescope. Nearly a thousand photographs have been obtained with it. The spectra of the faint stars prove very satisfactory, and stars too faint to be photographed with the other instruments can thus be studied. Bright hydrogen lines have been found in the spectra of S Orionis, S Bootis, W Virginis and S Libræ, and the spectrum of V Ophiuchi has been shown to be of the fourth type. The length of these spectra is about a quarter of an inch, which is sufficient to show much detail in the spectra of fairly bright stars. To study still fainter spectra a prism of crown glass and of smaller angle has been ordered. The absorption of the photographic rays is less for this material, and it is expected that much fainter spectra can be photographed, since the dispersion will also be less. The contract has not yet been filled for the Bruce telescope, since difficulty is still experienced in making charts in which the images shall be circular. Experiments are in progress in this direction, and it is hoped that the method described above as applied to the 13-inch Boyden telescope will prove equally successful with this instrument.

A variety of experiments have been made to determine the photographic magnitudes of the brighter stars on a uniform scale. It is now expected that this can be done with the transit photometer for stars brighter than the third magnitude, and that the scale can be extended to stars from the third to the sixth magnitude by a series of photographs which are being taken with a portrait lens having an aperture of 2·5 inches. The images are thrown out of focus, and the intensity of the circular discs thus obtained can be accurately measured.

ELECTRIC DISCHARGE THROUGH GASES.[1]

ONE of the most important and interesting branches of physical science is that which deals with the connection between electrical and chemical effects.

The investigations on electrolysis made within these walls by Davy and Faraday proved that the important class of electrical phenomena associated with the passage of electricity through liquids, are connected in the closest way with chemical action. They proved that no electricity will pass through most liquids unless chemical action occurs, and that for each unit of electricity which passes through the liquid there is a definite amount of chemical decomposition.

This case, though it is one where the laws are most accurately known, is but one among many electrical phenomena which are inseparable from chemical action.

So many instances of this kind have been discovered, that we may perhaps venture to hope that we are not far from the time when it will be universally recognised that many of the most fundamental questions in chemistry and electricity are but different aspects of one and the same phenomenon.

Anything which throws light on the connection between electricity and matter, interesting as it is on its own account, acquires additional interest when regarded as elucidating the connection between chemical and electrical effects, and no phenomena seem more suitable for this purpose than those which are the subject of the discourse this evening—the discharge of electricity through gases. For in gases we have matter in the state in which its properties have been most carefully studied, while the investigation of the electrical effects is facilitated by the visibility of the discharge, affording us ocular, and not merely circumstantial, evidence of what is taking place.

The points to which I wish to refer particularly this evening are, firstly, some phenomena connected with the passage of electricity from the gas to the electrode, or from the electrode to the gas; and secondly, some of the properties of the discharge when its course lies entirely in the gas.

By taking a long discharge tube, say, one fifty feet long, and observing the luminous discharge through a rotating mirror, we can trace the course of the luminosity due to a single discharge, say, one due to once breaking the primary circuit of an induction coil; if we do so, we find that the luminosity follows the direction of the positive current through the tube. That is, the luminosity begins at the positive electrode, it then rushes down the tube with enormous velocity, but when it gets to the negative electrode, it receives a check; it does not disappear at once in that electrode like a rabbit going down a hole, but lingers around the electrode some time before entering it. In consequence of this delay in the positive discharge in getting out of the gas, there is an accumulation of positive electricity in the neighbourhood of the negative electrode until the potential fall at this electrode increases to about 200 or 300 volts.

The positive electricity which accompanies the discharge thus finds considerable difficulty in getting from the gas to the metal, though, as I hope to show you later on, as long as it keeps in the gas, it meets with what we may, in consideration of the views sometimes enunciated on this subject, call a ridiculously small amount of resistance, its real difficulty is to get out of the gas.

Though this effect has long been known, it is so important that I will venture to show one or two experiments which illustrate it. The arrangement of the first experiment is shown in Fig. 1. The apparatus consists of a main discharge tube, across which is fastened a diaphragm made of excessively thin platinum leaf; there is a side passage from the tube, leading from one side of the diaphragm to the other, this is connected to a barometer tube, and by raising the cistern containing the mercury I can stop up the passage by a pellet of mercury. We will first observe the discharge when the side passage is open; you see that the discharge, instead of passing across the thin piece of platinum leaf, takes the very much longer route round the side tube, so as to avoid crossing the metal. We will now raise the mercury cistern, and close the side tube by a pellet of mercury; the discharge now has no alternative but to cross the metal at some part of its course, and you see that the main portion of the discharge goes back into the main tube.

Fig. 1.

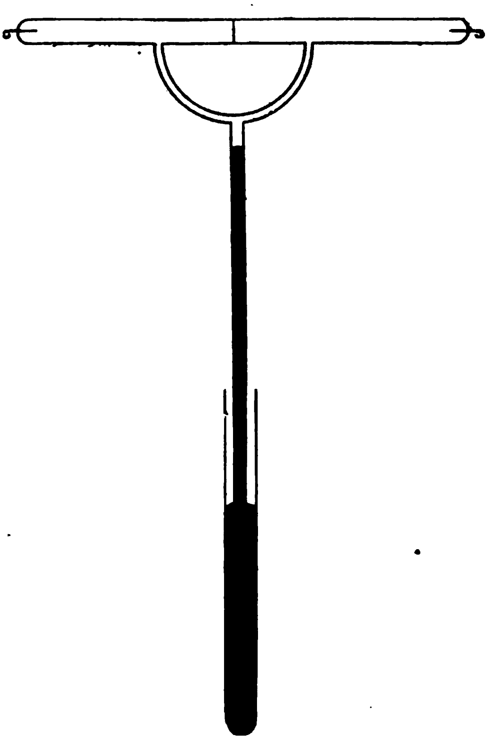

Fig. 2.

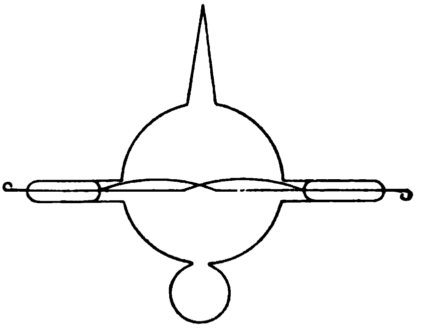


In the second experiment the metal diaphragm is replaced by a very thin plate of mica; when the side passage is opened the discharge goes round, but when this is closed by a pellet of mercury the discharge prefers to go across the mica than through the mercury.

[1] Lecture delivered at the Royal Institution by Prof. J. J. Thomson, F.R.S.

A second experiment which shows the same thing is the following. Two long electrodes are fused into a bulb, so that the tip of an electrode is a considerable distance from the place where it passes through the glass. We will now send an alternating discharge through the tube, and you will see, I think, that the discharge, instead of going straight across the short distance between the ends of the electrodes, goes from the tip of one electrode to the place where the other passes through the glass, thus staying as long as possible in the gas before passing into the metal. The appearance of the discharge shows that the positive electrode is at the end of the wire, the negative at the junction of the wire with the glass.

Another interesting example of the difficulty the discharge experiences in passing from gas to metal is the discovery made by Profs. Liveing and Dewar, that when the discharge passes through a gas containing a large quantity of metallic dust, the light from the discharge, when examined in the spectroscope, does not show any of the lines of the metal.

The difficulty which the positive electricity finds in passing from the gas to the electrode depends a great deal upon the nature of the gas, as well as upon that of the electrode; it is influenced by the position of the gas and the electrode relatively to one another in the electro-chemical series.

I have lately made a series of experiments on this point in the following way. An alternating discharge from a high tension transformer was made to pass between two electrodes fused into a bulb, which could be filled with the gases under examination. Another electrode connected to an electrometer, passed into the bulb, and was arranged so that it could be moved about from one part of it to the other. When the electrodes were metal and the bulb was filled with the electronegative gas oxygen, the electrode received a positive charge in whatever part of the bulb it was situated; if now the bulb was filled with hydrogen at atmospheric pressure, then in the regions remote from the arc the electrode received a positive charge, but in the immediate neighbourhood of the arc itself it received a negative charge. When the pressure was reduced the region in which the charge was negative contracted, and finally at pressures about one-third of an atmosphere, seemed to disappear, and the electrode got a slight positive charge in whatever position it was placed. If now, instead of using metallic electrodes we use well-oxidised copper ones, and repeat the experiment in hydrogen, working at a pressure when there was only positive electricity, when the electrodes were bright and polished, we find that with the oxidised electrodes every particle of positive electricity is taken out of the tube, and a negative charge is left. This negative charge remains until the copper oxide is completely reduced; when this occurs the negative charge disappears, and is replaced by positive. Thus, under the same conditions as to the nature of the gas and the pressure, the bright copper electrodes leave a positive charge in the gas, while the oxidised ones leave a negative charge.

The most probable explanation of these results seems to me to be the view that the communication of electricity from gas to the electrode, or from the electrode to gas, is facilitated by the temporary formation of something of the nature of a chemical compound between the gas and the metal. In all such compounds the metal is the electro-positive element, and has the positive charge, the gas being the electro-negative and carrying the negative charge. Now consider the case when the negative charge is on the gas, and the positive charge on the metal; then the gas and metal have got the charges proper to them in any compound they may form, and are thus in a fit state to combine, or according to this view, allow the negative electricity to pass from the gas to the copper. But, now, suppose the gas was positively electrified, the gas and the metal have now opposite charges to those proper to them in a compound, and before the union of gas and metal in this state could result in anything but a most unstable compound, an additional process must be gone through —*i.e.* the charges on the gas and metal must be interchanged. Thus the conditions for the combination of the gas and metal are more complex when the gas is positively electrified than when it is negatively electrified, and thus, on the view that the communication of electricity between the gas and the metal involves a sort of chemical combination, we see that the negative electricity will escape more easily from the gas to the metal than the positive. Now consider the case when the gas was hydrogen, the electrodes oxidised copper; the hydrogen combines now not with the metal, but with the oxygen, forming water, in which hydrogen is the electro-positive element; thus, in this case, it is the positively charged hydrogen which is in the state best fitted for pairing. The consequence is, the positive charge would be most readily removed from the gas and the negative left—exactly the opposite to that which occurred when the electrodes were bright. This reversal, as I stated before, is verified by experiment.

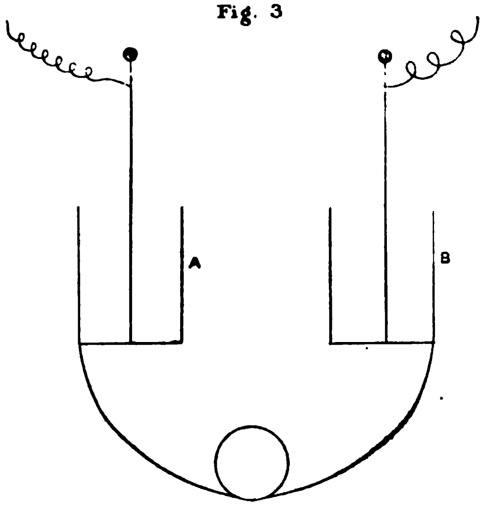
I have hitherto only spoken of the phenomena which accompany the passage of electricity from the electrode to the gas, or from the gas to the electrode.

I shall now pass on to consider the properties of the discharge when it is entirely confined to the gas.

We may produce a discharge which, during the whole of its course, shall be confined to the gas in the way represented in the diagram.

The two poles of a Wimshurst machine are connected to the insides of two jars A and B, while the outsides of these jars are connected together by a metal wire wound so as to form a coil. The electricity from the Wimshurst machine charges up the jars, the difference of potential between the poles increases until a spark passes. The passage of the spark puts the insides of the two jars in connection, and the jars are discharged. The discharge of the jar, as was proved from the theory of electromagnet action by Lord Kelvin more than forty years ago, and shortly afterwards confirmed by the experiments of Feddersen, is an oscillatory one, producing currents surging backwards and forwards through the wires with extraordinary rapidity. The

Fig. 3



subject of these oscillatory currents is one which is tinged with melancholy. In the beginning of 1894 we lost Hertz, whose splendid work on these electrical oscillations is known to you all. The Managers of this Institution have marked their sense of the importance of this work by devoting a special lecture to this work alone, and they have entrusted that lecture to a most distinguished worker in the same field as Hertz. It would therefore be presumptuous on my part to refer in any detail to Hertz's work; but no physicist, and least of all one who is a member of Maxwell's University, could pass over in silence the death of Hertz.

When Hertz began his magnificent experiments on electric oscillations, there were many theories of electrical action. When he had finished them there was only one, Clerk Maxwell's.

Hertz's work was done with very much quicker vibrations than those produced by the apparatus now on the screen; this, however, gives rise to currents through the coil changing their direction some million times a second. If we place in the coil an exhausted bulb, the bulb in reality will be the secondary of an induction coil, and will be exposed to electromotive forces tending to produce circular currents parallel to the plane of the coil.

I will now place a bulb inside this coil, and you see that a circular ring discharge passes through it, and this discharge passes entirely in the gas.

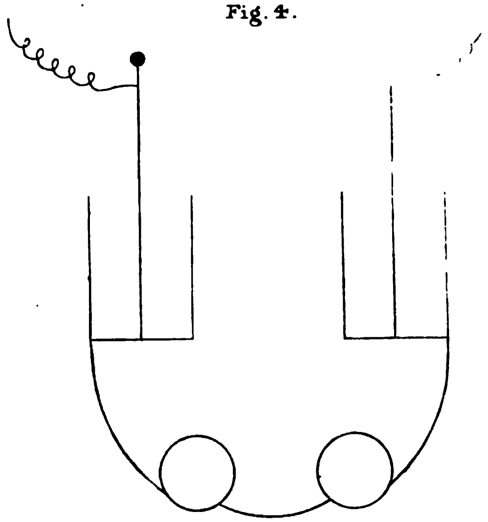
The gas in the bulb now in the coil is the vapour of silicon tetrachloride; it happens to be the bulb which gives a brighter ring than any others I possess.

If this ring discharge passes through air at different pressures, the colour of the discharge changes very considerably. The first bulb I put in was at fairly high pressure, about $\frac{1}{10}$ of a millimetre or so. I will now put in another at a lower pressure, and then one at a still lower pressure. Mr. Newall, who has been working at the spectra of these discharges, finds that at the pressure in the first bulb the spectrum is due to nitrogen; at the second stage it is due to mercury vapour; the bulb was pumped by a mercury pump, so that there is in the bulb a certain quantity of mercury vapour.

The apple-green colour in the more highly exhausted bulb is due to some compound of sulphur, which has got into the bulb from the sulphuric acid used to dry the gas. Mr. Newall finds that if the ordinary discharge from a coil between electrodes is taken in such a bulb, there is no trace of this sulphur spectrum. He has also found that when the bulb is at a pressure intermediate between what I may call the mercury and the sulphur stage, when the mercury and sulphur lines are both visible, these sets of lines come from different layers, the sulphur lines coming from a layer nearer the surface than the other.

If we take the discharge through a bulb containing oxygen, you will see that the ring discharge is succeeded by a bright glow; at first the colour is somewhat opaque, but gradually gets more transparent and changes colour. This gives a continuous spectrum crossed by a few bright lines. If we take the discharge through cyanogen, you see that the glow is even more persistent than the oxygen, though it is not so bright; all the gases which

Fig. 4.



show this glow belong to the class of substances which polymerise—that is, whose molecules can combine with each other. I imagine that what takes place in bulbs filled with these substances is that the discharge produces a polymeric modification, and that this gradually returns to its original state, and while doing so gives out a phosphorescent light. It is in accordance with this that at a high temperature where ozone cannot exist a discharge through an oxygen bulb does not show any glow.

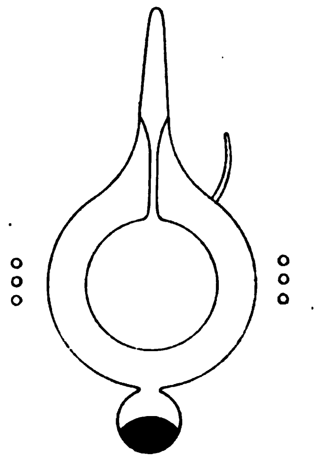
I said at the beginning of this discourse that gases were exceedingly good conductors of electricity. I will now endeavour to show an experiment which proves that statement. The apparatus which I shall use for this purpose is a slight modification of the one I have used for producing the ring discharge; the only difference is that in the wire connecting the two coatings of the jars there are two loops instead of one. In one of these loops an exhausted bulb is placed to serve as a kind of galvanometer; the brightness of the discharge is an indication of the strength of the current flowing round the coil. If I place a second conductor in the other loop, currents will be started in it, and part of the energy of the discharge will be absorbed; this will leave less energy available for the bulb in the first, so that the discharge in this bulb will be dimmer. The effect produced on the discharge will depend upon the conductivity of the substance placed in the second loop.

The effect is not directly proportional to the conductivity; in fact, a perfect conductor would not produce any diminution, nor would an absolute non-conductor; for a given period, and with apparatus of given dimensions, there is a certain conductivity which gives a maximum effect; this follows easily from the theory of induction of currents, but at this late period in the evening I will take a shorter course and prove it by an experiment.

I put a piece of brass in this loop, and you see it produces but a small effect upon the brightness of the discharge. Instead of brass I now insert a plumbago crucible, which, though a conductor, is not nearly so good a one as the brass, and you see the discharge in the indicating bulb is completely stopped.

I will now place in the second loop an exhausted bulb; you see it produces a decided diminution in the intensity of the discharge in the galvanometer bulb. I now replace the bulb by another of the same size containing dilute sulphuric acid; you see it does not produce nearly so large an effect as the exhausted bulb; this might be due, as we have seen, to the sulphuric acid being either too good or too bad a conductor. I can show that it is the latter by putting a bulb in filled with a stronger solution, which has a higher conductivity than the weak solution; if the smallness of the effect produced by the weak acid were due to its being a better conductor than the gas, then increasing the conductivity would still further diminish the effect of the acid; you see, on the contrary, that the strong acid produces a distinctly greater effect than the weak, hence the rarefied gas in the bulb is a better conductor even than the strong electrolyte. Let us consider for a moment the molecular conductivities of the two substances, the rarefied gas and the electrolyte. The

Fig. 5.

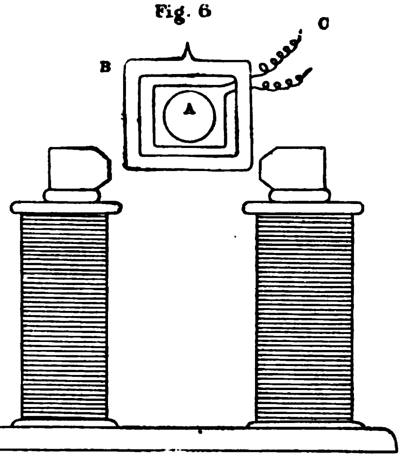


pressure of the gas is about $\frac{1}{100}$ of a millimetre, while in the electrolyte there are sufficient molecules of the acid to produce, if they were in the gaseous state, a pressure of more than 100 atmospheres; thus the conductivity of the gas estimated per molecule is about 10 million times that of the acid, this is greater than the molecular conductivity of even the best conducting metals.

If the pressure of the gas is diminished below a certain point, the conductivity begins to diminish. I have here an experiment which I hope will show this. The apparatus (Fig. 5) consists of two bulbs, one outside the other; the inner bulb contains air at a low pressure, while the space between the two bulbs is a very high vacuum containing practically nothing but a little mercury and its vapour. The amount of mercury vapour in this space is, at the temperature of the room, exceedingly small, but as the apparatus is heated the vapour pressure increases, and we are thus able to produce a fairly wide range of pressure in the space between the bulbs. The outer sphere is surrounded by the coil connecting the outer coatings of the two Leyden jars. When the space between the bulbs is a conductor, the alternating currents circulating in the coil will induce in this conductor currents whose inductive effect is opposite to that of the currents in the coil; and in this case this layer will screen off from the inner bulb the electromotive force due to the alternating currents in the coil. If, on the other hand, the space between the bulbs is a non-conductor, the inner bulb will be exposed to the full effect of these forces. We now try the experiment: you observe that when the mercury is cold, and consequently the pressure in the space between the bulbs very low, a bright discharge passes through the inner bulb, while the space between the bulbs remains quite dark; when we heat the mercury so as to increase the pressure of its vapour, a bright discharge passes through the outer layer, while the inner bulb is quite dark; the outer layer is now a conductor, and by its action screens off from the inner bulb the induction of the coil.

The last experiment I have to show is one on the effect produced by a magnetic field on the discharge. When the discharge has to flow across the lines of magnetic force, the pressure of the magnetic field retards the discharge; when, however,

Fig. 6



the discharge flows along the lines of magnetic force, the discharge is helped by the magnetic field. This is shown in the following experiment. A is a bulb; B a square tube, one side of which is placed between the poles of an electromagnet; the coil C, which connects the outside coatings of the jars, can be adjusted so that when the magnet is "off," the discharge passes through the bulb but not round the square tube; when, however, the magnet is "on," the discharge passes in the square tube but not in the bulb. In the square tube the discharge passes along the lines of magnetic force and is helped; in the bulb it passes across them and is retarded.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In a Convocation held on Tuesday, January 29, the degree of Doctor of Medicine, by decree of the House, was conferred on J. S. Burdon Sanderson, F.R.S., Regius Professor of Medicine. Prof. Sanderson was at the same time empowered to discharge the duties of the Waynflete Professor of Physiology, and to dispose of the income of the department during the vacancy in the Waynflete Professorship.

The amendments to the proposed form of statute on degrees for research will be submitted to Congregation on Tuesday, February 12. There are no less than sixty-three amendments, most of which are consequential. The chief amendments propose that the degree of Bachelor of Arts shall be substituted for the proposed degrees of Bachelor of Letters and Bachelor of Science; that the delegacy for the supervision of candidates shall be chosen from among a limited number of University officials, and that there shall be no such delegacy, but that the supervision shall be entrusted to the Boards of Studies.

The Sibthorpian Professor of Rural Economy will deliver an inaugural lecture on Monday, February 4, at 5.30 p.m., on "The Present Relations of Agricultural Art and Natural Science."

Mr. A. B. Trevor Battye will give a lecture before the Ashmolean Society on Monday, February 4, at 8.30 p.m., on his experiences in Kolguev Island.

The Vice-Chancellor has received for the University a bequest from the late Miss Susan Kidd of a portrait of her father, Dr. John Kidd, of Christ Church, formerly Regius Professor of Medicine.

CAMBRIDGE.—The Special Board for Biology and Geology propose that in future the Walsingham Medal, given by the Lord High Steward annually for biological research, shall be open to graduates of the University up to the standing of Master of Arts. Of the three Medals offered, two have been awarded—one for a zoological and the other for a botanical essay. It is also proposed that the Medal shall not be awarded twice to the same person.

The funeral of the late Prof. Cayley will take place on Friday, February 1, in Trinity College Chapel, and the Mill Road Cemetery. Members of the University desiring to be present, are requested to assemble in the College Hall at 1.45 p.m.

The Sedgwick Memorial Syndicate have been empowered to reconsider the plans, or prepare new ones, for the Geological Museum. The estimates for Mr. Jackson's plan exceeded the means at the disposal of the University.

Dr. L. E. Shore, St. John's College, has been appointed an additional member of the Medical Board. Dr. A. Ransome, F.R.S., Dr. J. L. Notter, Dr. T. Stevenson, F.R.S., and Dr. R. Thorne Thorne, C.B., F.R.S., have been appointed Examiners in State Medicine for the current year.

At the Matriculation on January 28, seventeen new students were entered. This brings the total for the present academical year up to 894.

THE Executive Committee of the City and Guilds of London Institute have awarded the first Salters' Company Research Fellowship for the encouragement of higher research in chemistry in its relation to manufactures, to Dr. Martin O. Foster. Dr. M. O. Foster is an old student of the City and Guilds Technical College, Finsbury, and Doctor of Philosophy of the University of Würzburg. For several months he has been engaged in investigating some new derivatives of camphor in the Research Laboratory of the City and Guilds Central Technical College and by the aid of the Salters' Company's Research Fellowship, he proposes to pursue this line of work.

THE Organised Science Schools of the Department of Science and Art are schools in which the instruction is carried on methodically according to one or other of the courses laid down by the Department, or which has been specially submitted to and approved by it. It can easily be understood that such schools represent a very important stage in the system of scientific education which Mr. Acland is doing so much to improve. A number of new regulations, relating to these schools, have just been issued, to come into force after the examinations next May. The most important feature of the new scheme is the introduction of payment on inspection instead of payment on results, for by far the larger part of the instruction given in organised science schools. This modification, which applies to 120 science schools in the United Kingdom, has only become possible since the appointment of a staff of Science and Art inspectors. Another noteworthy feature is that reasonable latitude will be allowed to the teacher as to the nature of the course he may pursue provided the instruction is sound, satisfactory in amount, and combined with proper practical work. Even more satisfactory are the instructions that the practical chemistry for the first year's course should include the setting up of apparatus—weighing and other chemical manipulations, the preparation of gases, the estimation of volume, and so on. Analysis will, in future, occupy a secondary position in introductory courses. The mechanical test-tubing, which has hitherto formed the greater part of practical chemistry in Departmental schools, will thus give place to practical work of real educational value. We also observe that provision is made for a certain amount of literary instruction being given whilst the student is pursuing his science curriculum; that a choice of advanced courses is given; and that an alternative programme suitable for women is formulated, and instruction in subjects specially adapted to them is demanded; that practical instruction must be given in the subjects of science simultaneously with the theoretical instruction. Clearly, the new rules will greatly assist the development and better organisation of scientific education.

SCIENTIFIC SERIALS.

American Journal of Science, January.—Late glacial or Champlain subsidence and reëlevation of the St. Lawrence River basin, by Warren Upham. From the Champlain submergence the Atlantic coast of North America was raised somewhat higher than now; and its latest movement from New Jersey to Greenland has been a moderate depression. As in Scandinavia, the restoration of isostatic equilibrium is attended by minor oscillations, the conditions requisite for repose having been overpassed by the early reëlevation of outer portions of each of these great glaciated areas. The close of the Ice Age was not long ago, geologically speaking, for equilibrium of the disturbed areas has not yet been restored.—An automatic mercury vacuum pump, by M. I. Pupin. This pump is a combination of a suction pump capable of raising mercury to practically any height, and an ordinary Sprengel pump, the two being connected by a siphon barometer. Mercury is pumped into the Sprengel reservoir by the suction pump. The reservoir of the latter is provided with two vertical tubes dipping into two mercury vessels. The end of one of these is higher than that of the other, so that when the mercury has fallen to the level of the end, no more mercury enters the tube, and the column already in it is bodily drawn up into the siphon barometer.—Graphical thermodynamics, by René de Saussure. The author recommends the adoption of new coordinates instead of P and V. Instead of these, he advocates the variables ϕ and s, defined by the equations $\phi = \pi/i^2$ and $s = \pi a^2$, where i is the period and a the amplitude of the vibratory motion constituting heat. Then the value of each variable depending upon the phenomenon can be obtained graphically.—Solutions of salts in organic liquids, by C. E. Linebarger. The law enunciated by Schroeder and Le Chatelier, that the solubilities at equal intervals from the temperature of fusion for different solid bodies and in different solvents are the same, although approximately true for the cases investigated by them, is not applicable to the case of inorganic salts in normal organic solvents.

Wiedemann's Annalen der Physik und Chemie, No. 13, 1894.—A new spectrum photometer, by Arthur König. Between the telescope and the collimator, which is provided with two parallel slits, are introduced, besides the refracting flint-glass prism, a twin prism and a Rochon polarising prism. One of the slits is provided with a total-reflection prism, in order to admit the standard light from the side. The field of view shows two semicircles, one for each of the sources of light, and their relative intensities can be adjusted and measured by a Nicoll prism near the eye. The observer notes the angle through which the Nicoll prism must be rotated in order to give equal intensities to the two halves of the field.—Spectra of various sources of light, by Else Köttgen. By means of König's spectrum photometer, various petroleum and gas lamps were spectroscopically studied.—On the process of light emission, by G. Jaumann. The author shows that the emissive vibrations of a luminous body exhibit a damping which may be measured.—Capillary electrometers and drop electrodes, by G. Meyer. The surface tension of mercury and some, but not all, amalgams is reduced by the addition of a solution of a salt of mercury, or of a salt of the metal contained in the amalgam. The reduction of surface tension which takes place during anodic polarisation is due to the formation of such mercuric or metallic salts.—Thermo-electricity of chemically pure metals, by K. Noll. This paper gives an account of a careful redetermination of the thermo-electric forces of pure Cd, Sn, Ag, Au, Cu, Zn, Al, Pt, Mg, Fe, Ni, Hg, and German silver.—Influence of magnetisation and temperature upon the electric conductivity of bismuth, by J. B. Henderson. The author shows that, before bismuth spirals can be employed to measure magnetic fields by their change of resistance, it will be necessary to find a ready means of testing their temperature, as the resistance is profoundly affected by changes in the latter.—High temperature thermometers of Jena glass No. 59^{III}, by Alfons Mahlke. These thermometers have to be filled partly with liquid carbonic acid, after which they may be employed for temperatures up to 550°, the carbonic acid keeping the mercury from boiling. The author describes how he found the expansion of the glass and the mercury for such high temperatures, and calibrated one of the thermometers with reference to the air thermometer.

Bulletin de la Société des Naturalistes de Moscou, 1894, No. 1.—Contributions to the Moss flora of Russia, by Dr. Ernst Zickendrath, being an enumeration of 202 species collected by the author in European Russia proper (in German).—The formation of the primary blastoderms and the origin of the chord and the mesoderm in the Vertebrates, by B. Lwoff (in German, with six plates). A work which already has been partially published in *Biologisches Centralblatt* for 1892; it is based on the study of the embryology of the *Amphioxus*, the *Petromyzon*, the *Axolotl*, the *Pristiurus* and *Torpedo*, several fishes and the *Lacerta*, and the author comes to the conclusion that the whole of the process is quite different from what is usually described as gastrulation. The paper is to be continued.—A general expression of the Thermodynamic Potential, by N. Oumoff.—Meteorological observations at the Petrovsk Agricultural Academy for the year 1893.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 17.—"The Latent Heat of Evaporation of Water." By E. H. Griffiths, M.A., Sidney Sussex College, Cambridge.

A calorimeter was suspended within a chamber the walls of which were kept at a constant temperature in the manner described in a previous paper.[1] The calorimeter was filled with a singularly limpid oil, which was stirred by paddles revolving about 320 times per minute, and immersed in the oil was a silver flask, which contained the water to be evaporated. The ends of a platinum-silver coil, within the calorimeter, were maintained at a known constant potential difference, and the rate of evaporation so controlled as to exactly balance the heat supplied by the electric current. The advantages of this method are that the results are not appreciably affected by (1) errors in thermometry; (2) changes in the specific heat of water; (3) errors in the determination of the water equivalent; (4) loss or gain by convection, &c. Differential platinum-thermometers were used, in order to ascertain the equality of the calorimeter temperature and that of the surrounding walls, thus differences of 0·0004° C. could be accurately measured, and smaller differences detected.[2]

A series of experiments in which the saturated vapour was removed from the flask by a stream of dry gas, gave the following results.

Temp. (Nitrogen Scale).	L (in terms of a thermal unit at 15°).
24°·96	581·9
39°·99	572·4
49°·82	566·5

The method of experiment was then altered; rapid evaporation was caused by removal of pressure, and the mass of water evaporated determined in a different manner.

A considerable number of experiments gave the following results.

Temp. (N. Scale).	Extreme values of L.	Mean L.
30°.00	578·58 – 578·90	578·70
40°·15	572·12 – 573·01	572·60

The conditions as to rate of evaporation, &c., were varied greatly during the experiments.

The results are expressed by the following formula:

$$L = 596{\cdot}73 - 0{\cdot}6010\,\theta$$

This formula would give

$$L = 596{\cdot}73 \text{ when } \theta = 0°$$

and $$L = 536{\cdot}63 \quad ,, \quad \theta = 100°.$$

And these values are almost identical with those obtained by Dieterici at 0° (596·73) and Regnault at 100° (536·60). A study of the results leads the author to the conclusion that the "thermal unit at 15°" must be almost identical with the "mean thermal unit between 0° and 100°." It has been shown by Rowland, by Bartoli and Stracciati, and by the author, that at low temperatures the specific heat of water decreases as the temperature rises, and it is probable that it arrives at a minimum between 30° and 40°, afterwards increasing with rise of temperature. There is, therefore, nothing impossible in the above supposition.

An investigation into the density of aqueous vapour (assuming the author's values of L and J) indicates that at low pressures the density of the saturated vapour is that of a perfect gas, and that at higher pressures (above 140 m.m.) it attains a density about 1·02 times as great as the "theoretical density."

January 24.—"Mathematical Contributions to the Theory of Evolution. II. Skew Variation in Homogeneous Material." By Prof. Karl Pearson, University College, London. (See p. 319).

Royal Microscopical Society, January 16.—Annual meeting.—A. D. Michael, President, in the chair.—After the report of the Council for the past year and the treasurer's statement of accounts had been read and adopted, the President announced that the following were elected as officers and Council for the ensuing year :—President, A. D. Michael; vice presidents, Prof. L. S. Beale, F.R.S., Dr. R. G. Hebb, E. M. Nelson, T. H. Powell; treasurer, W. T. Suffolk; secretaries, Prof. F. Jeffrey Bell, Dr. W. H. Dallinger, F.R.S.; ordinary members of Council, T. D. Aldous, C. Beck, A. W. Bennett, Dr. R. Braithwaite, Rev. E. Carr. Frank Crisp, E. Dadswell, G. C. Karop, C. F. Rousselet, Dr. H. C. Sorby, F.R.S., J. J. Vezey, and T. Charters White. The President then delivered the address, the subject being, "The History of the Royal Microscopical Society." The President said that if any of his hearers would leave that West-end abode of science, and journey eastward to Tower Hill, and thence by Sparrow Corner along Royal Mint Street, he would find himself in Cable Street, St. George's-in-the East, not a very quiet or a very clean locality; turning down Shorter Street he would emerge opposite a space of green, where once stood the Danish Church, with its Royal closet reserved for the use of the King of Denmark when visiting this country; the space is surrounded by houses which have seen better days, and amongst them, between a pickle-factory and a brewery, stands a rather dilapidated erection which is 50 Wellclose Square; where, in 1839, lived Edwin J. Quekett, Professor of Botany at the London Hospital; and there, on September 3 of that year, seventeen gentlemen assembled "to take into consideration the propriety of forming a society for the promotion of microscopical investigation and for the introduction and improvement of the microscope as a scientific instrument." Among the seventeen were N. B. Ward, the inventor of the Wardian-case, which is not only an ornament to town houses, but was the means of introducing the tea-plant into Assam and the chinchonas into India, and who became treasurer of the society; Bowerbank Lister, who has been called the creator of the modern microscope; Dr. Farre, Dr. George Jackson, the Rev. J. B. Reade, and the enterprising and scientific nurseryman George Loddiges. Most of these subsequently became presidents of the Society. A public meeting was held on December 20, 1839, at the rooms of the Horticultural Society, then at 21 Regent-street, when the "Microscopical Society of London" was formally started. Prof. Richard Owen (not Sir Richard at that time) took the chair and became the first president, and shortly after the famous John Quekett became secretary, an office which he held almost to his death. At this moment Schleiden in Germany was commenting upon the paucity of British microscopical research, and attributing it to the want of efficient instruments, not knowing that a society was then forming which was to raise British microscopes to probably the first position in the world. The President then traced the history of the Society through the presidencies of Dr. Lindley the botanist, Prof. Thomas Bell the zoologist, Dr. Bowerbank, Dr. George Busk, Dr. Carpenter, Dr. Lankester, Prof. W. Kitchen Parker (all deceased), and of others equally famous who are still living; and showed how, under its influence and by its assistance, the vast improvements in the microscope, and the enormous extension of its use had gradually arisen; he also described its connection with the origin of the *Quarterly Journal of Microscopical Science*, the *Monthly Microscopical Journal*, and other publications, besides its own present widely circulated journal with its exhaustive summary of microscopical and biological work. He related how on John Quekett's death certain members of the Society subscribed to purchase for the Society's collection a curious microscope which Quekett possessed, and which had been made by the celebrated Benjamin Martin about 1770, probably for George III., and how they extended their subscription so as to provide a medal to be called "the Quekett medal" to be given from time to time to eminent microscopists; and how, difficulties having arisen, it happened that the only Quekett medal ever awarded was given to Sir John Lubbock. Finally, the President considered the future of the microscope and the prospects of further improvements. He said that many people were of opinion that the instrument is now perfect, and that consequently the most important *raison d'être* of the Society was over; he by no means agreed in that view, he believed that there was as much scope for progress in the future as there had been in the past; it was not by any means the first time that this idea had been put forward. In 1829 Dr. Goring, then a great authority on the subject, wrote in one of his published works: "Microscopes are now placed completely on a level with telescopes, and like them must remain stationary in their construction." In 1830, less than a year after, appeared Lister's epoch-making paper, "On the improvement of achromatic compound microscopes," and we have been improving ever since.—Mr. H. V. Tebbs proposed a vote of thanks to the President for his address; this, having been seconded by Prof. Bell, was carried.

EDINBURGH.

Royal Society, December 17, 1894.—The Hon. Lord M'Laren, Vice-President, in the chair.—Mr. Patrick Murray read an obituary notice of the late Mr. Donald Beith.—In a paper on germination in ponds and rivers, Mr. H. B. Guppy described observations on the germination of semi-aquatic and aquatic plants, and discussed the effects of temperature and light. —A paper on the Hall effect and some related actions in bismuth, by Mr. J. C. Beattie, was read. Mr. Beattie finds, with high fields, a reversal of the Hall effect in certain specimens of bismuth.—Mr. George Romanes communicated a paper on attraction treated by graphic processes, with deductions.

January 7.—The Rev. Prof. Flint, Vice-President, in the chair.—Dr. W. Peddie read a paper on a case of yellow-blue blindness, and its bearings on the theories of dichromasy. The historical aspect of the Young-Helmholtz theory is as follows: (1) Young gave his theory of colour-blindness by lapse of one sensation, stating that this seemed to him to be simpler than any other assumption. But, as with his theory of colour-vision, he meant this theory to be given up if it were subsequently found to be inconsistent with experiment. (2) Helmholtz added his ideas regarding the nature of the mechanism, adopting *implicitly* Young's reservations, and stating *explicitly* that his ideas, if false, did not affect the basis of Young's theory. (3) In accordance with the above facts, when E. Rose brought forward the evidence of his observations, Helmholtz at once indicated the probable direction in which the statement of the theory had to be modified. (4) Subsequently, Helmholtz's pupils, König and Dieterici, working presumably under his direction, made a crucial test to find if it were absolutely essential to abandon the idea of lapse of a fundamental sensation, and found that it was necessary to do so. (5) König investigated, at different parts of the spectrum, the mean error of wave-length which could be made in adjusting light from different near parts of the spectrum to equality. (6) Helmholtz gave an expression, in terms of the unknown fundamentals, for the rate at which the total "sensation" varies with wave-length. He wrote down three linear equations, with unknown coefficients, expressing the three fundamental sensations in terms of those chosen (arbitrarily so far) by König and Dieterici. The latter were known in terms of the wave-length by means of the observations of these two investigators. Therefore, if Helmholtz could determine the unknown coefficients, he could express the other fundamentals in terms of the wave-length. Now an obvious assumption to make is this: the mean error of wave-length which can be made in adjusting two very narrow strips, one from each of two similar spectra, to apparent equality corresponds to a constant difference of total "sensation." Helmholtz made this assumption in order to determine the unknown coefficients by means of König's observations on the mean error. And he further justified this by showing that there was a close correspondence between the mean errors found by König and the mean errors calculated from his own theory on the assumption of a constant difference of sensation. Thus the new fundamentals, given by Helmholtz as "provisional," may be regarded as having been determined upon a purely experimental basis, with no assumption other than the radical assumption of three fundamental sensations. The whole thing is a beautiful example of the cautious, steady, scientific development of a theory. There has not been, by Helmholtz, any violent upholding of a weakened theory, followed by a sudden facing round after defeat. In violet, or yellow-blue, blindness, the two colours of the spectrum are red and bluish-green, and the spectrum is shortened at the blue end with a sharp limit near the line G. Blindness of this type is rare. The case described in this paper presents the peculiarity that there is no shortening of the spectrum at either end. The range extends beyond the line *a* at the red end, and beyond the line H at the violet end. The neutral point is near the line D, on the more refrangible side. The maximum intensity of the red colour is reached at a point near C on the less refrangible side, and the maximum intensity of the green colour is reached at a point rather nearer to F than the mid-distance from b to F. There is no second neutral point in the blue. It does not seem that the phenomena can be readily, if at all, accounted for on Hering's theory. On the other hand, it is easily accounted for on the Young-Helmholtz theory by fusion of the fundamental sensations.—Dr. Noël Paton read a paper, by Dr. John Douglas, on metabolism in thyroid feeding.—Dr. Richard Berry read a paper on the anatomy of vermiform process and cæcum.—Prof. Tait communicated a paper on the ultimate state of a system of colliding particles, and the rate of approach to it.

PARIS.

Academy of Sciences, January 21.—M. Marey in the chair.—On the variable star β (Algol) in Perseus, by M. F. Tisserand. The author represents the variation in apparent magnitude as being due to (1) the existence of one obscure satellite with an elliptical orbit, and (2) a slight oblateness of the principal star, and shows that on these assumptions the variation periods can be satisfactorily represented (see "Our Astromical Column").—On boron steel, by MM. H. Moissan and G. Charpy. As the result of a series of comparative tests, it is found that boron (0·58 per cent. in alloy used) imparts the property of a great increase in tensile strength by tempering without a corresponding increase of hardness. A sample of carbon steel giving similar increase of tensile strength on tempering, became so hard as to require working on the emery-bob, whereas the boron-steel could still be worked with a file.—Morphology of the lymphatic system. On the origin of the lymphatics in the skin of the frog, by M. L. Ranvier.—On the perforation of armour-plates, by M. E. Vallier.—On the production of the glycolytic ferment, by M. R. Lépine. The author is of opinion that the glycolytic ferment is produced from diastase. He relies on the increase of glycolytic power of pancreas when treated with dilute sulphuric acid, in conjunction with the loss of saccharifying power and gain of glycolytic power suffered by maltine when similarly treated with dilute acid.—*Résumé* of solar observations, made at the Royal Observatory of the Roman College, during the three last quarters of 1894. A letter from M. P. Tacchini sent to the President.—On the convergence of determinants of infinite order and of continued fractions, by M. H. von Koch.—Influence of the rhythm of successions of interruptions on the sensitiveness to light, by M. Charles Henry. The investigation had for object the determination of the sensitiveness of the eye to interrupted light-rays of different types. The conclusion is drawn that it is possible to augment the luminous range of a signal by means of a succession of interrupted rays following a sufficiently complex non-rhythmic law.—Influence of temperature on the transformation of amorphous zinc sulphide, by M. A. Villiers.—Failure of the Kjeldahl method for estimation of nitrogen when applied to chloroplatinates, by M. Delépine. In the cases of trimethylamine and ammonium platinochlorides, the author finds by the permanganate modification of the Kjeldahl process a considerable deficiency in ammonia obtained. This deficiency is attributed to a reaction of free chlorine with the ammonia, as follows:

$$(NH_4)_2PtCl_6 + 3Cl_2 = PtCl_4 + 8HCl + N_2.$$

—On arabinochloral and xylochloral, by M. Hanriot.—A new synthesis of anthracene, by M. Delacre. Anthracene is produced from benzyl trichloracetate and benzene, by heating these substances in presence of aluminium chloride, and distilling the resultant ether, when it decomposes giving carbon dioxide and anthracene.—A contribution to the study of the ethereal salts of the tartaric acids, by MM. Ph. A. Guye and J. Fayollat. A study of the rotatory power of nine of these esters in the light of the theory of the product of asymmetry.—On a parasite of *Lampyris splendidula*, by M. A. Gruvel. The author names the newly-described parasite *Stylogamasus lampyridis*.—On some bacteria from the *Dinantien* (Culm), by M. B. Renault. —On the development of sieve-tubes in the Angiosperms, by M. Chauveaud. The author concludes that (1) the rule of indirect development of sieve-tubes is far from general. Both direct and indirect methods of development may occur in the same bundle. (2) The presence of companion-cells is not absolutely characteristic of the sieve-tubes of Angiosperms.—On the Chili-Argentine earthquake of October 27, 1894, by M. A. F. Nogués.—Note on *Uredo viticida*, by M. L. Daille.

Stapf (Linnean Society).—Ergebnisse der Beobachtungsstationen an den Deutschen Küsten über die Physikalischen Eigenschaften der Ostsee und Nordsee und die Fischerei, Heft 1–6 (Kiel, Lipsius).

CONTENTS.

THURSDAY, FEBRUARY 7, 1895.

ARGON.

THE scene in the theatre of the University of London on Thursday last was in many respects unique. It will certainly be historical. It was unique in that the Royal Society had formally invited members of two other scientific bodies to attend the meeting, and had left the comparative seclusion of Burlington House to meet, in Burlington Gardens, an audience numbering at least eight hundred. It was the first of a series of discussion meetings to which, we suppose, similar invitations will be issued; but it will be long before the same eagerness to obtain a ticket is displayed—long before those who gain admission, will listen to so much worth hearing.

The previous history of the subject to be "discussed" is known to most of our readers. Lord Rayleigh has for some years been engaged on one of the most difficult of physical measurements, namely, the determination of the densities of some of the more permanent gases. In the case of nitrogen, he was confronted with the fact that if obtained from chemical compounds, it was about one half per cent. lighter than if extracted from the atmosphere. This result he published in the spring of last year, and the cause of the discrepancy was a subject of general conversation in scientific circles. Lord Rayleigh himself discussed it with some of his chemical friends. Prof. Ramsay was interested, and since last Thursday he has confided to an interviewer some details as to the part he played in solving the problem. It appears that he asked Lord Rayleigh's permission to investigate the matter, that using a chemical method he succeeded in separating a heavier constituent from atmospheric nitrogen, and that on writing to Lord Rayleigh, he learned that he, too, had achieved the same result by a process of "sparking."

The fact of the discovery was announced in a semi-public way at the meeting of the British Association at Oxford. Of course it attracted great attention, and curiosity was further stimulated by the silence of the discoverers during the five succeeding months. Towards the end of last year it was announced that they would give their results to the world in January. On Thursday last the promise was fulfilled, and all that is known of "Argon" was told to all.

Three papers were read, which showed that the period of silence had been devoted to strenuous work. It was proved beyond possibility of doubt or question that the atmosphere contains a hitherto unknown constituent. It has been separated from the air by atmolysis, by red-hot magnesium, and by "sparking." Its density has been determined to be about 19·7. It is very soluble in water, and it has been proved that the nitrogen extracted from rain-water is twice as rich in argon as that which exists in the air.

Mr. Crookes has found that the new substance has two spectra, marked by red and blue lines respectively. Both he and Prof. Schuster certify that the principal lines are identical in the case of two specimens obtained by different methods. The properties at very low temperatures have been determined by Prof. K. Olszewski, of Cracow. The critical temperature is $-121°$ C., the critical pressure 50·6 atmospheres. The liquid boils under a pressure of 740·5m.m. at $-186°·9$, having at the boiling point a density of about 1·5. The melting point is about $-189°·6$, and it has been frozen into a white solid resembling ice. Last, but not least, the ratio of the specific heats of the gas is approximately 1·66, and all attempts to induce it to enter into chemical combination with other substances have up to the present entirely failed.

After this torrent of well-established facts, it cannot reasonably be doubted that Lord Rayleigh and Prof. Ramsay have really discovered a substance, which, though existing in enormous quantity, has hitherto defied detection. Lord Rayleigh's work first showed that there was something to explain; the patience and masterly skill which he displayed throughout years devoted to weary weighings, must command universal admiration. As has been well said, the result is "the triumph of the last place of decimals," that is, of work done so well that the worker knew that he could not be wrong. Prof. Ramsay, too, is to be congratulated in that when this preliminary stage had been accomplished, his energy and skill enabled him to take such a share in the hunt after the unknown cause of the difficulty, that he rightly ranks as a co-discoverer of the new gas.

In scientific investigations, however, the answer to one question always suggests others, and interest in a discovery quickly precipitates into interest in its results. Seldom have a series of facts and figures raised more important issues. The ratio of the specific heats is 1·66, which points to the conclusion that the substance is monatomic. If it is monatomic, it must be an element or a mixture of elements. If it is a single element, its atomic weight must be about 40, and in that case no place is ready for it in Mendeléeff's table. The easiest way out of the difficulty is to suppose that argon is a mixture, and the authors point out that there is evidence for and against this view; "for, owing to Mr. Crookes observations of the dual character of its spectrum; against, because of Prof. Olszewski's statement that it has a definite melting point, a definite boiling point, and a definite critical temperature and pressure; and because on compressing the gas in presence of its liquid, pressure remains sensibly constant until all gas has condensed to liquid. The latter experiments are the well-known criteria of a pure substance, the former is not known with certainty to be characteristic of a mixture." The question is to be further investigated, but at present the authors conclude that the balance of evidence is in favour of simplicity.

On this hypothesis a very awkward question is no doubt raised. The periodic classification of the elements cannot, and ought not, to be abandoned at the first challenge, and till further evidence is forthcoming a heavy strain is thrown on the link of the chain of argument which connects the ratio of the specific heats with the monatomicity of the gas.

On the other hand, the conclusion that if the ratio of the specific heats is 1·66 the gas can be diatomic, is directly contrary to all analogy. Merely to say that mercury is monatomic, that Kundt found that the ratio of the specific heats is one and two-thirds, and that therefore a similar relation must hold for argon, is to understate the case. Taking the very outside values, no diatomic gas has a ratio greater than about 1·42; and to place among these a substance for which the ratio is 1·66, would be entirely opposed to all the other indications of a theory which, though admittedly only approximate, nevertheless in all other cases accords fairly with the conceptions of the chemist. The behaviour of mercury vapour suggests that there are two classes of phenomena which occur within the molecule—a coarser group with which the ordinary mechanical theory of gases is concerned, and a more refined type detected by the spectroscope. It is the former, and not the latter, which are of the same order as the chemical facts which lead to conclusions as to the number of atoms in the molecule.

Thus, in the case of mercury vapour, the mechanical theory of gases ignores the vibrations, whether mechanical or electrical, which produce the spectrum, and gives the precise value of the ratio of the specific heats which corresponds to three degrees of freedom. Whether we frame a mental picture of a Boscovitch point, or are content with the more usual contradictory image of a smooth sphere, perfectly elastic, and yet incapable of internal vibrations, is for the present purpose comparatively unimportant. It is impossible to connect the conception of three degrees of freedom with anything that does not behave as one single thing, incapable of being set in rotation, and incapable of internal vibration. That such a thing may have structure is not denied. It is only affirmed that as far as the phenomena under investigation are concerned, structure is not recognisable. It is not denied that it may be subject to internal changes. It is only affirmed that these changes are of different order from the causes which affect the behaviour of the molecule in what may be called the pressure-producing machinery of a gas. Where the ordinary dynamical theory stops, there, and there precisely, chemical analysis stops also. The chemical facts which prove that mercury is monatomic have nothing to do with its spectrum. The arguments used would be valid if it had no spectrum at all. Analysis recognises no structure in the indivisible molecule of mercury. In chemistry, and in the approximate theory of gases, "monatomic" means—in this case, at all events—the same thing.

Next take the case of the diatomic gases.

The results of the dynamical theory can be most easily represented if we suppose the atoms to be smooth spheres, which may, if it is desired, be regarded as mere geometrical surfaces surrounding Boscovitch centres.

The theory shows that unless the two atoms when united can be fairly represented by a single point or a single smooth sphere, the ratio of the specific heats ought not to be greater, but may be less, than 1·4. This value would correspond to the case of two smooth spheres the surfaces of which were maintained in contact, or to two points maintained at a certain fixed distance apart, but otherwise free. Smaller values would indicate greater internal freedom.

The gases may be divided into two classes, viz. firstly, O_2, N_2, H_2, CO, NO and HCl, and secondly, Cl_2, Br_2 and I_2. The mean of the ratios of the specific heats for the first six is, according to Masson,[1] 1·399. The corresponding figure deduced from Regnault's experiments is 1·410. The highest value obtained from Regnault is 1·42 in the case of HCl, but Masson's value for the same gas is only 1·392, the mean being 1·406. In the cases of Cl_2, Br_2 and I_2 the values are lower, lying between 1·293 and 1·323. The larger values thus in some cases slightly exceed, but are in all cases very close to, the limit fixed by the theory on the assumption that the dual character of the molecule can be recognised by it. The smaller values fall well within the limit.

The ratio of the specific heats has not been directly determined for many substances, but it can be calculated by well-known formulæ for all gases of which the specific heat at constant pressure is known, and though the values thus obtained are only approximate, they are sufficient to prove that the molecules of the more complex gases have always more than the minimum number of degrees of freedom which are consistent with the idea of their being built of smooth spheres constrained to remain in contact, and equal in number to the number of atoms within the molecule. Whereas, if argon is a diatomic substance, the molecule has fewer degrees of freedom than the theory indicates, and is thus the single exception to a universal rule. In that event it is not too much to say that the result will indicate a connection between its atoms of a kind absolutely different from that in any other known substance. In all other cases the approximate dynamical theory is in close agreement with the view that molecular structures made up of the union of two or more like or unlike things, have a more or less irregular form, and are capable of rotation. If argon is not monatomic, this rule will for the first time be broken. Quite apart from the absolute validity of the theoretical grounds on which it is based, and regarded only as suggested and not as completely justified by theory, it is nevertheless an empirical generalisation which up to the present has stood every test.

It is not sufficient to explain the difficulty by saying that the bonds between the constituents of the argon molecules must be very strong, for we have already assumed that the tie which unites the centres of the hydrogen or oxygen atoms is proof against the collisions which occur in the gas—*i.e.* is for the purposes of the approximate theory infinitely strong. It is further necessary that the molecule must be incapable of rotation, that the two points must coincide, or the two spheres be crushed out of shape, so that the surface is spherical. Such violent assumptions would be quite unjustifiable unless we are driven to them by facts which cannot be disputed. Until it is directly proved that argon is diatomic, we must agree with the discoverers that the weight of evidence is in favour of the molecule being indivisible. Whether in the future other and more convincing evidence will be adduced on the other side, the future alone can show. The courts of science are always open, and every litigant has an unrestricted right of moving for a writ of error.

A TEXT-BOOK OF BOTANY.

Lehrbuch der Botanik. By Drs. E. Strasburger, F. Noll, H. Schenck, and A. F. W. Schimper. (Jena: Fischer, 1894.)

THIS book is intended for the use of students in the German *Hochschulen;* throughout it is written in a manner which is at once interesting and exact. According to the usual plan adopted in text-books of the kind, it is divided into two parts—the first dealing with general botany, and the second with special botany. In a general introduction a short *résumé* is given of the theories of descent and of natural selection, with a view to their bearing on the subject of the natural boundary between the animal and vegetable kingdoms.

The first division of the first part is devoted to the general morphology of plants. It is written by Prof. Strasburger. This whole subject he treats from a phylogenetic point of view, and so renders, what is in many botanies little more than a list of difficult names and their explanations, extremely interesting and suggestive reading. A good example of this will be found in his account (p. 26) of the leafy stipules of *Lathyrus aphaca.* In this connection it may be noticed that having once described the more important forms, he does not enlarge on the very various shapes and modifications assumed by leaves, stems, &c., as is often done in text-books, where the writers often appear to glory in the number of curious terms they collect descriptive of the forms of the members of plants—terms which, if it is necessary for the student to learn, might be more easily mastered if printed as a kind of botanical vocabulary or glossary, instead of rendering such an attractive subject as vegetable morphology a monotonous exercise of the memory. In the portion devoted to anatomy and histology we find the structure of the cell and its contents extremely lucidly described. The digression on p. 45, with regard to some of the properties of protoplasm and the effect of high temperatures and of reagents upon it, might have, perhaps, come more appropriately in the part of the book allotted to physiology. In the account of the systems of tissues in vascular plants, and their morphology, we are furnished with the results of recent work in this direction, of which so much is due to the author's own researches. With regard to the origin of these tissues, he disputes the theory according to which the meristematic apex of the stems and roots of phanerogamic plants is differentiated into three distinct initial layers. He urges that the arrangement of the cells in these regions is rather due to mechanical causes, and that the terms Dermatogen, Plerome, and Periblem should be used simply to facilitate the description of certain cell-layers in the vegetative cone, without involving the idea of the presence of distinct Histogens, as they have been called. Throughout this whole portion on general morphology, we feel that the space has been too limited, and we wish that the author had not restricted himself to the 126 pages allotted, but had allowed himself to enter more fully on the numerous points of interest in this subject which he, perhaps beyond all others, is capable of discussing.

The same remark may also apply to Dr. Noll's part on physiology. It is throughout too much abbreviated. Apart from this defect, which is involved in the nature of the book, it is very attractively written, and by its logical arrangement and clear descriptions does much to atone for the necessary crowding of facts. The chapter on the phenomena of movement in plants strikes us as suffering the least from the condensed nature of the writing, and seems to be a good account of both earlier and recent researches on the subject.

The special botany is the work of Dr. Schenck and Prof. Schimper. The classification adopted is that proposed by Braun, and elaborated by Eichler and others. Little need be said of this portion, except that much trouble appears to have been taken to make the descriptions, so far as possible, include the results of modern work. At the end of the book there is a list of medicinal and of poisonous plants, as well as a very complete index. It is to be regretted that the authors have not given some references to the literature of the subjects of which they treat, so that the student might be helped to pursue more fully his studies in the directions he desired. The book is throughout profusely illustrated by means of extremely good figures, many of which are tastefully coloured. The figures are, to a large extent, new, and those which are not specially designed for the book are well selected, in part, from Prof. Strasburger's other works and, in part, from sources which are not commonly familiar to English readers, so that in this way the value of the book is enhanced. With regard to the coloured figures, they have this novelty—that they are inserted in the text, and are not in the form of separate plates. H. H. D.

A NEW POPULAR BOOK ON BRITISH BUTTERFLIES AND MOTHS.

Butterflies and Moths (*British*). By W. Furneaux, F.R.G.S., author of "The Out-door World, or Young Collector's Handbook." With twelve coloured plates, and numerous illustrations in the text. (London: Longmans, Green, and Co., 1894.)

THE success of Mr. Furneaux's "Out-door World" was sufficiently marked to induce the publishers to make it the first of a series of popular illustrated works on British Natural History, to be called "The Out-door World Library." Of this series, the volume before us forms the second; and we observe that others are projected, on British Birds, Mammals and Reptiles, Pond-Life, &c.

This is pre-eminently a beginner's book, written in a popular style throughout, and it has also been nicely printed and illustrated, so as to make it as attractive-looking as possible. Hence the practical part of the subject is dealt with at length, while questions of a purely academic nature, such as synonymy, are wisely omitted almost entirely. English names are given the most prominent place; but the scientific names used in South's List are added in brackets.

The book is divided into four parts: Structure and Life-history of the Lepidoptera; Work at home and in the field; British Butterflies; and Common British Moths. The appendices include a list of British *Macro-Lepidoptera* according to South's "Synonymic List," as far as the end of the *Geometridæ* (the English names here being in brackets), and a Lepidopterist's Calendar.

The introductory chapters are very good, and the woodcuts are clear and instructive, especially that of the neuration of a butterfly, on p. 9. We could have wished that Mr. Furneaux had had space to treat of such important subjects as neuration and the scaling of the wings more fully. The early stages of *Lepidoptera* are also discussed and illustrated; and we notice that our author calls the head of a caterpillar the "first segment." We know that some hypercritical authors object to the head of an insect being called a segment, because it is morphologically considered to be made up of so many "somites." But to refuse to allow the head of an insect to be called the first segment (in the case of caterpillars, at least) appears to us as absurd as it would be to object to the skull being spoken of collectively, because it is morphologically regarded as composed of a number of modified vertebræ. On the other hand, we think that Mr. Furneaux has been injudicious in calling the five membranous pairs of legs of a caterpillar "claspers," a term properly applicable to the last pair only. We think the usual distinction made between the last pair and the others should be preserved in speaking of them, though the term by which the other legs are generally known (prolegs) is perhaps not quite correct.

The directions for collecting and preserving appear to have been written by an experienced practical collector, with his heart in his work. However, when insects are set flat, the groove is generally made deeper than is shown in the illustrations on p. 123. The advice to start at once with a cabinet, spaced out for all species, may be very good for those who can afford to buy a large cabinet off-hand; but many of Mr. Furneaux's readers will certainly find it too costly, and we fear that any beginner who commences in such a manner will find his patience exhausted at his slow progress, and might give up the study of insects prematurely in disgust.

No technical characters are given for species, genera, or even families; and, strangely enough, the Seraphims (*Lobophora*) are said to differ from the Pugs (*Eupithecia*) by their "covering their hind-wings when at rest"; no mention being made of the curious appendages to the hind-wings of the males in *Lobophora*, which gives them the appearance of having six wings, and has suggested the name of "Seraphims."

Generally speaking, however, the accounts of the various species discussed (all the butterflies and a good series of representative moths, at least among the *Macro-Lepidoptera*) are very good. Here and there, however, we meet with a doubtful statement, as that "the Black-veined White is hardly to be distinguished from the Common Large White on the wing." Those accustomed to see both would hardly confound them, nor would the former frequent open ground at a distance from trees.

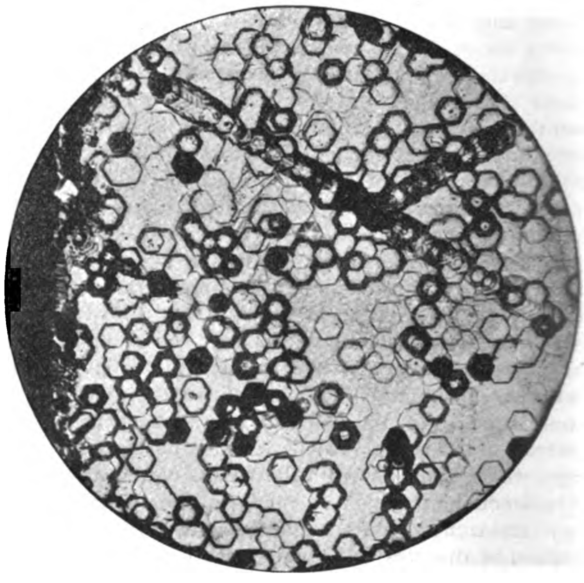
The numerous woodcuts are of unequal merit, but a fair standard of excellence is maintained throughout, and most of them are easily recognisable. The coloured plates, though recognisable too, are, we regret to say, not up to the standard of the woodcuts. Sometimes the colour is inaccurate, as in the case of the Purple Emperor, which has been represented as lilac rather than blue. It is, of course, a difficult insect to figure, but has been represented better in many popular books of late years. In the first two plates, an attempt has been made to throw up the colour of the insects (mostly whites and yellows) by shading. This has given rise to the appearance of an ugly smoky rim round the figures; and the experiment has been wisely abandoned in the remaining plates. We regret this the more, as the desired effect has been admirably attained by using a tinted background in Prof. Aurivillius' recent work on the butterflies and moths of Northern Europe; and we should like to see this improvement introduced into other books of a similar kind.

W. F. KIRBY.

OUR BOOK SHELF.

Die Resultate der Aetzmethode in der krystallographischen Forschung, an einer Reihe von krystallisirten Körpern dargestellt. Von Dr. H. Baumhauer. Mit 21 Textfiguren und einer Mappe mit 48 Mikrogrammen auf 12 Tafeln in Lichtdruck. Pp. 131. (Leipzig: Wilhelm Engelmann, 1894.)

It has long been known that the action of a reagent upon a smooth plane surface of a mineral substance may reveal details of structure previously invisible, and that such a mode of investigation has been extremely useful in the case of meteoric iron; indeed, the method is particularly valuable in that case by reason of the fact



that the structure thus revealed is different from the structure of terrestrial iron.

The researches of Leydolt, Baumhauer, and others, have shown us that the figures produced by reagents on the faces of the crystals which are met with among minerals, or are artificially prepared by the chemist, though dependent on the kind and strength of the reagent, are yet characterised by a symmetry which conforms with that of the crystalline structure; further, the etched figures serve to indicate by their forms the particular kind of symmetry (holosymmetry, hemisymmetry tetartosymmetry, twinning) belonging to the crystalline structure, in many cases where other characters, physical or morphological, are insufficient for the purpose; they are especially useful in the investigation of isomorphism.

The etched figures can be observed, for instance, in the case of a crystal of which the opacity renders investigation by means of transmitted polarised light impossible; and, even in the case of a transparent crystal, they often serve to determine the particular type of symmetry to which the structure belongs when polarised light may merely indicate whether the crystal is optically isotropic, uniaxal, or biaxal. Dr. Baumhauer has done a great service by preparing for publication a series of magnified photographs of the figures produced by etching different faces of crystals of the following substances:—Fluor, Blende, Cryolite, Apatite, Nepheline, Datolite, Zinnwaldite, Leucite, Boracite, Dolomite, Magnesite, Chalybite, Nickel sulphate, Strychnine sulphate.

The figure on the previous page shows the hexagonality of the depressions which, after etching, are seen on a basal plane of a crystal of Apatite.

These beautifully executed photographs are accompanied by detailed descriptions (85 pp.), and by a sketch of the history and development of the methods (46 pp.). Dr. Baumhauer has done such excellent work in this branch of science, that he is particularly qualified to select and describe examples which illustrate the potentiality of this mode of investigating crystalline structure. The photographs are mounted on twelve separate plates, so that they may be conveniently used in the classroom.

Summer Studies of Birds and Books. By W. Warde Fowler. Pp. 288. (London: Macmillan and Co., 1895.)

Forest Birds; their Haunts and Habits. By Harry F. Witherby. Pp. 98. (London: Kegan Paul, Trench, Trübner, and Co., 1894.)

IT would be difficult to find a worthier disciple of Gilbert White than Mr. Warde Fowler. Many of White's most exact and enduring observations were made on birds, and the "Natural History of Selborne" has furnished his imitators with descriptions of the characteristics of the Stone-curlew, the Ring-ousel, the House-martin, the Sand-martin, the Goat-sucker, and many more of the birds of which he recorded the habits and movements. But Mr. Fowler's writings are not mere paraphrases of his prototype's. He is gifted with the "nice observation and discernment" required by every student of nature; and he can express himself in attractive language—attractive because it is unaffected, and because it is devoid of thin sentiment and gush. The result is that the papers reprinted in this volume are really valuable contributions to ornithology. To remark that there is not a dull page in the book may be a trite saying; nevertheless, so far as we are concerned, it is a true one in this case. What could be more readable than the chapters on the birds of the Engstlen Alp, and the birds of Wales; and where will you find a better example of careful and painstaking observation than is afforded by the account of the Marsh Warbler in Oxfordshire and Switzerland? The chapter on the songs of birds is most interesting; that descriptive of Aristotle's writings on birds, (in which fact and fiction are given equal prominence), should be read by all naturalists; and the biography of Gilbert White shows that the author is saturated with the spirit of the naturalist whose work has had such a wide influence upon natural history during the last hundred years.

Little more need be said about this charming book. So many volumes on popular natural history have lately appeared, that the subject has probably begun to pall upon the public taste. Mr. Warde Fowler's work, however, is so full of interest; it breathes out the air of the fields and streams so pleasantly, that it carries its own welcome to the heart of every lover of nature.

The second of the two books of which the titles are given above, is of quite a different character from the first. It is remarkably well illustrated, is daintily bound, and is nicely printed, and therefore it forms an attractive volume, so far as appearances go. But the text is dull; for the author, while possessing the essential love of nature, lacks the words with which to express it eloquently. To him, "the Stock Dove is fourteen inches in length from the tip of the beak to the end of the tail, and its stretch of wing is twenty-six inches. Its general colour is bluish-grey. The head, wings, and back are of this colour, and the tail is the same, but tipped with leaden grey." There is much more of the same kind in the book; and we confess that after reading Mr. Warde Fowler's smooth phrases, Mr. Witherby's composition appears spiritless. The illustrations, however, are good enough to make up for deficiencies of the text, and for their sake alone, the book is worth buying.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Age of the Earth.

IN reference to Lord Kelvin's letter (NATURE, January 3, p. 227), he will, no doubt, presently communicate with you on the results of measurements which he is making on conductivity and temperature in rocks. I do not wish to forestall him by referring at present to his more recent correspondence with me. Three weeks ago I sent him the solution of the problem of a cooling sphere whose conductivity k and volumetric capacity c are any functions whatsoever of the temperature v, but which are always proportional to one another. As Mr. Heaviside had been writing to me, and had shown me that under certain circumstances the differential equation became linear, and as I had used his *operators* much as he himself uses the u, I cannot say to what extent I can claim credit for the work. I now venture to send you the more general case.

If

$$\int c \, . \, dv = u \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

so that u is the total amount of sensible heat in unit volume. The general equation is

$$\frac{d}{dx}\left(k\frac{dv}{dx}\right) + \frac{d}{dy}\left(k\frac{dv}{dy}\right) + \frac{d}{dz}\left(k\frac{dv}{dz}\right) = \frac{du}{dt} \quad . \quad . \quad . \quad (2)$$

Now let $k = c\kappa$ where κ is a constant, then

$$k = \kappa\frac{du}{dv} \text{ as } c = \frac{du}{dv},$$

and the equation becomes

$$\frac{d^2u}{dx^2} + \frac{d^2u}{dy^2} + \frac{d^2u}{dz^2} = \frac{1}{\kappa}\frac{du}{dt} \quad . \quad . \quad . \quad (3)$$

Any of the many problems that have been worked out on the distribution of u may be translated into temperature problems. Thus in a body before $t = 0$ let $u = u_1$ a constant everywhere, and after $t = 0$ let the surface have everywhere a constant $u = u_0$. Let the solution be

$$u = (u_1 - u_0)\text{F}\,(x, y, z, t) \quad . \quad . \quad . \quad . \quad (4)$$

In the body before $t = 0$ let $v = v_1$ a constant everywhere, and after $t = 0$ let the surface have everywhere $v = v_0$ a constant, then if v is the temperature anywhere

$$\int c \, . \, dv = (u_1 - u_0) \int (x, y, z, t) \quad . \quad . \quad . \quad . \quad . \quad (5)$$

so that a table of the values of $\int c \, . \, dv$ enables the temperature at any place to be calculated.

If $\frac{du}{dn}$ the rate of increase of u normally inward from the surface at any place, has been calculated, say that it is

$$\frac{du}{dn} = (u_1 - u_0)\text{F}(x, y, z, t) \quad . \quad . \quad . \quad . \quad . \quad (6)$$

as

$$\frac{du}{dn} = \frac{du}{dv} \cdot \frac{dv}{dn} = c\frac{dv}{dn}$$

$$\frac{dv}{dn} = g = \frac{u_1 - u_0}{c_0} F(x, y, z, t) \quad . \quad . \quad . \quad . \ (7)$$

where g is the temperature gradient inwards from the surface, and c_0 is the value of c at the surface.

If c and k are constant everywhere, say c_0 and k_0, let us call the surface gradient g_0; then as $u = c_0 v + C$

$$\frac{g}{g_0} = \frac{1}{c_0} \frac{u_1 - u_0}{v_1 - v_0},$$

for the same place at the same time after cooling began.

As an example, let

$$k = k_0(av + 1),$$

and

$$c = c_0(av + 1),$$

and measure v on the Centigrade scale, c_0 and k_0 are the actual capacities and conductivities at 0° C.,

$$u = c_0(\tfrac{1}{2}av^2 + v + C),$$

so that

$$\frac{g}{g_0} = \frac{\frac{1}{2}av_1^2 + v_1}{v_1} = \tfrac{1}{2}av_1 + 1.$$

Thus if c and k increase s per cent. per 100 degrees Centigrade, and if $v_1 = 4000$, as

$$a = 10^{-4}s, \ \frac{g}{g_0} = \frac{s}{5} + 1.$$

In the cooling of Lord Kelvin's infinite mass with a plane face the time which elapses until a particular surface gradient is reached is inversely proportional to the square of the gradient. If the time taken on the assumption of constant c and k be called t_0, and if the time taken on the assumption that c and k increase s per cent. for 100 degrees is t, then

$$t/t_0 = \left(\frac{s}{5} + 1\right)^2$$

Suppose

$$s = 50,$$

then

$$t/t_0 = 121.$$

So that Lord Kelvin's age of the Earth would be multiplied by 121.

It must be understood that my conclusions (NATURE, January 3, p. 224) are really independent of whether R. Weber's results are correct or not. Lord Kelvin has to prove the impossibility of the rocks inside the earth being better conductors (including convective conduction in case of liquid rock in crevices) than the surface rocks. If, however, Weber's results, as quoted by me, are trustworthy, the above solution is what I take Lord Kelvin to refer to in the first paragraph of his published letter. In considering all such measurements as those of R. Weber, it must be remembered that the rocks at twenty miles deep are not merely at a high temperature, but also under great pressure.

January 30. JOHN PERRY.

Oceanic Temperatures at Different Depths.

THE question of the persistence or otherwise of the temperature of different strata of water beneath the surface of the oceans, is one upon which so few observations have been made, that it will probably be interesting to students of oceanic phenomena to publish in NATURE the results obtained at one spot in the Atlantic, at periods extending over as much as twenty-one years.

At a position about 200 miles west-south-west from Cape Palmas, in Africa, where the depth of water is about 2500 fathoms, and where on the surface the Guinea current is running to the eastward, the *Challenger* in 1873 and 1876, the *Buccaneer* in 1886, and the *Waterwitch* in 1894, have all obtained serial temperatures; the first three to a depth of 200 fathoms, the last to 150 fathoms.

The result is given in the following table, and illustrated by the diagram.

Comparison of Ocean Temperatures obtained at Different Times in or near the same position, viz. 5° 48′ N., 14° 20′ W.

Depth in fathoms.	*Challenger* temperatures, 19/8/73.	*Challenger* temperatures, 10/4/76.	*Buccaneer* temperatures, 5/1/86.	*Waterwitch* temperatures, 22/9/94.

Exact Positions and Observation Spots.

Challenger, 19/8/73	...	Lat. 5° 48′ N.	...	Long. 14° 20′ W.
Challenger, 10/4/76	...	5 28		14 38
Buccaneer, 5/1/86	...	5 48		14 20
Waterwitch, 22/9/94	...	5 48		14 22

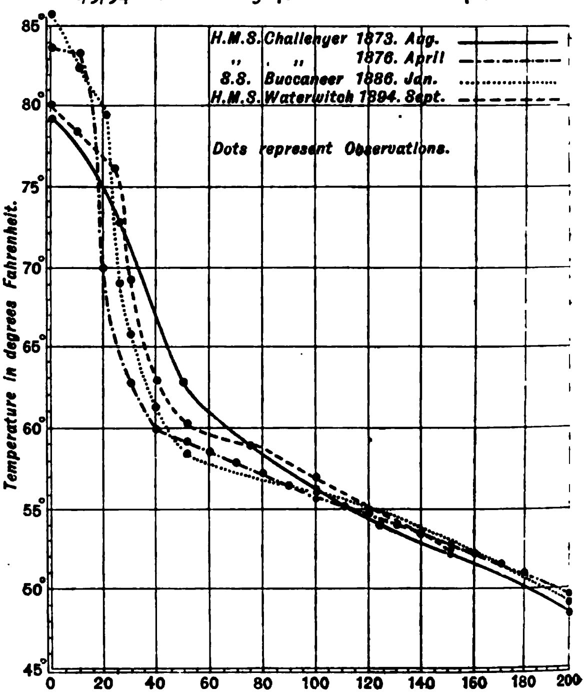

Diagram showing temperature at different depths obtained at various epochs in Lat. 5° 48′ N., Long. 14° 20′ W.

It will be observed that the temperatures at the surface vary by 6°·3 F.; at a depth of 20 fathoms, by 9°·6; at 40 fathoms, by about 6°; at 50 fathoms, by 3°·7; while at 100 fathoms, three of the results are within 0°·3 of one another, the fourth being 1°·1 above the lowest. From 100 to 200 fathoms, the temperatures, diminishing in the same ratio, differ by about the same amount.

It is difficult to say exactly what value can be placed on each individual observation. Many small errors may creep in; errors of reading, errors from movement of the indices, errors from insufficient time being given for the instrument to take up the true temperature, &c.

These should not, however, reach a degree in any instance, and it is pretty plain that below 100 fathoms the temperature at this spot remains fairly equable. This confirms the general view held by those who have studied the results obtained from observations at different depths, in different parts of the ocean.

While from one point of view it is unfortunate that the observations have been taken in different months, on the other hand, the variation in the surface temperature at different seasons of the year is given full value in the comparison.

January 26. W. J. L. WHARTON.

"The Bird-Winged Butterflies of the East."

PERMIT me to add a few notes supplementary to the very interesting and able article, by my friend Mr. Kirby, entitled "The Bird-Winged Butterflies of the East," which appeared in your issue of January 10, p. 254.

(1) If the male of either of the two species of my genus *Ætheoptera* is examined in the proper light and position, a long pupæ-form stigma, composed of raised scent-producing scales, will be very readily seen, of a more slender character, but in nearly the same relative position on the hind margin of the anterior wing, as in the males of the genus *Ornithoptera*, or, as Mr. Kirby prefers to call it, *Troides*. As I have pointed out in part viii. of my "Icones Ornithopterorum," this stigmatic sexual brand, being a densely black mark surrounded by the general velvet black of the wing, is very likely to be overlooked by a casual observer in some positions, while it is really very prominent in others; and I have called special attention to the lovely arrangements by which the latter result is attained; and a reference to the plates containing the figures of these species will suffice to show how very obtrusive the mark is, and how much more beautiful the insect becomes by the magical play of opalescent tints on the black which encloses the stigma, as the insect is moved into different positions against or opposite the light. To simply look at the insect as it stands in a cabinet drawer, is to miss all this glory and its *raison d'être*. As in all the species of Ornithoptera, the female possesses no such organ.

(2) *Æ.* (?) *Tithonus* (De Haan), as quoted by Mr. Kirby, is (as he evidently suspects) not a member of the genus *Ætheoptera* at all, but belongs to the first genus of the true Ornithoptera, viz. *Schoenbergia* (sub genus of Pagenstecher, and genus of *Rippon*); and I have no doubt that the female butterfly supposed to be its mate, is rightly assigned to it, as it is singularly like the female of *Sch. Paradisea* of Staudinger, and also co-generic with the large form described by M. Ch. Oberthür under the name *O. Goliath*. Neither in *Sch Paradisea* or *Sch. Tithonus* is the male furnished with a pupæ-form sexual mark as in *Ornithoptera* and *Ætheoptera*, nor with an abdominal marginal pouch or fold concealing the *androconia*, as in the males of *Pompeoptera*, or as Mr. Kirby calls them, *Ornithoptera* and *Trogonoptera*.

(3) I am compelled to regard the Ornithoptera as being naturally divided into three sub groups of unequal extent (so far as our present material indicates): (1) The African or *Acræoid* Ornithoptera, containing one genus (*Drurya*), and two species, *D. Antimachus* (Drury), and *D. Zalmoxis* of Hewitson; (2) the Oriental or true Ornithoptera, with the five genera *Schoenbergia*, *Ornithoptera*, *Ætheoptera*, *Trogonoptera*, and *Pompeoptera*; (3) the South and Central American *Ornithoptterina*, containing the numerous black and red, and black and green, and olive black Papilios, which are usually allowed to follow the true Ornithoptera in our systematic catalogues. The males of many of these possess an abdominal marginal fold concealing the *androconia*, an organ not found, as far as I am aware, on the abdominal margin of any other section of the Papilionidæ—though the sexual stigma can be found on the anterior wings of several males, as in *P. Ulysses* for example, though differing in form and position.

(4) My reasons for not adopting Hubner's name *Troides* in place of *Ornithoptera* for the Priamus group will be found by referring to "Icones Ornithopterorum." At the same time, I quite understand, and to some extent sympathise, with the severe and uncompromising application of the law of priority in nomenclature for which Mr. Kirby and several other naturalists contend.

(5) The wonderful iridescence of the yellow hind wings of *Pompeoptera Magellanus*, ♂, may be seen equally displayed on the under surface also.

Finally, I may safely say that the males of *Ætheoptera* and *Schoenbergia* are probably the most perfectly beautiful of the butterflies of the world. ROBERT H. F. RIPPON.

Upper Norwood, S.E., January 19.

Thirst-endurance in some Vertebrates.

WHEN an example of great ability to endure thirst is desired, the camel is usually suggested. Hibernating animals also are put forward in instance of existence without water for long periods. The camel carries a supply with it, so that what is most wonderful in its case is the tank. Torpid animals need little or no moisture beyond that in their systems, and, besides, they benefit from dampness around them. Better examples abound on the arid plains near the Rocky Mountains and the Sierras, in the innumerable active, noisy little rodents, miles away from streams or pools, and out of possible reach of water by burrowing. Any one who observes these creatures in their haunts in midsummer, will be pretty sure to inquire, like one of my companions, "What do those little wretches get to drink, anyhow?" The only reply appears to be, "They drink water when they get it, and do without at other times." For weeks and months, when the vegetation is shrivelled and parched, and the sands are at their hottest, these squirrels and their neighbours, with thickening blood, wait for the rain, that the currents in their veins may be thinned and quickened. But one need not go so far for a much better instance than the camel. The common mouse endures thirst quite as well as its allies in the desert. This has been proved repeatedly by mice kept here as a reserve supply of food for a lot of reptiles. Reducing the allowance of water prevented the foul odour by which mice are generally attended; this led to keeping some of them entirely without water, to note the effect. Last winter, a few were kept in a warm room more than three months before being fed to the snakes. On the first of last October, several were put aside to have no drink; at the time of writing, three months and a half later, they are eating heartily of the dryest of maize and grass seeds, on which alone they have been fed, and they act as if able to endure the experiment a month or two longer.

Cambridge, Mass., U.S.A., January 17.

Electroscopes in Lecture.

THE electroscope which Prof. Lodge proposes to use to indicate positive and negative potentials by different movements of the leaves (see p. 320), has the disadvantage that (assuming the case to be charged negatively), if too large a negative charge be given to the gold leaves they will diverge, and the inference will be that the potential is zero or positive, neither of which is the truth. For the purpose Prof. Lodge has in view, a Bohnenberger's electroscope would indicate more clearly positive, negative, or zero potential. Instead of the two dry piles, the inner and outer coatings of a charged insulated Leyden jar connected to two knobs, one on each side of the single gold leaf, might be substituted. J. REGINALD ASHWORTH.

The Owens College, Manchester.

Snake Cannibalism.

THE notice in NATURE, January 31, p. 321, on the above-mentioned subject, calls to my mind the following passage in Rénan's "Averroès," Paris, 1867, p. 310. He refers to the pre-Raphaelite pictures representing allegorically the "Seven Liberal Arts," and adds: "Dans une fresque récemment découverte à Puy . . . La Logique tient en main un lézard ou un scorpion. Dans un tableau d'Angelico elle tient *deux serpents qui se dévorent*." I have not succeeded in finding any further statement about this picture in the books on Art within my reach, nevertheless this may prove an interesting addition to the growing literature on cannibal snakes.

C. R. OSTEN SACKEN.

Heidelberg, February 3.

PIERRE DUCHARTRE.

As announced in our issue of November 8, 1894, the *doyen* of French botanists died on the 5th of that month, "having passed away without suffering, at the advanced age of eighty-three." Pierre Duchartre was pre-eminently a practical botanist, whose teachings were largely based upon actual knowledge, acquired by observation and experiment. Almost before the foundation of the present German school of botanists, of whom Sachs was one of the earliest exponents, Duchartre published (1867) the first edition of his well-known and highly esteemed "Éléments de Botanique." It was the result of thirty years' study and investigation; his first paper having appeared as early as 1836. It is true that Sachs's "Handbuch der Experimental Physiologie der Pflanzen" preceded it by one year; but for some years Duchartre's book held its own, not only in France but also in this country. As we learn from a sketch of his life by Mr. Gaston Bonnier,[1] Duchartre commenced his botanical studies under exceptionally difficult conditions, even for that period; but by great industry and perseverance he soon gained for himself a name and position which he maintained till the last. In 1843 he took up his abode in Paris, where he spent the last fifty years of his life, engaged in teaching, writing, and original research. In 1861 he replaced Payer at the Académie des Sciences, and succeeded him in the Botanical chair at the Sorbonne. For many years Duchartre was one of the principal supporters of the Société Nationale d'Horticulture, and he was seven times elected President of the Société Botanique de France, of which he was one of the founders. He was also President of the Société Nationale d'Agriculture, and the Académie des Sciences. Physiology and organology, including teratology, were his principal branches of study; but his very numerous contributions to botanical and horticultural literature cover a much wider field. Systematic botany, however, received comparatively little attention from him; a monograph of the Aristolochiaceæ being his chief work in this direction. His last work was a summary, from the German, of Engler's additions to Hehn's book on the native countries of cultivated plants. It appeared in the *Journal* of the French Horticultural Society a month before his death.

H.

NOTES.

The remains of the late Prof. Cayley were interred at Cambridge on Friday, and, notwithstanding the inclemency of the weather, snow having fallen heavily during the night, the proceedings were attended by a large number of persons. We are indebted to the *Times* for the following account of the funeral:—The body was brought from Garden House at two o'clock to Trinity College, and was met at the great gate by a procession numbering about 300 gentlemen, among them being many notable men of science. The pall-bearers were the Vice-Master of Trinity (Mr. Aldis Wright), Dr. Glaisher, the Right Hon. George Denman, Prof. Jebb, M.P., Prof. Sir Robert Ball, Prof. J. J. Thomson, Lord Kelvin, and Prof. Sir G. G. Stokes. The choir headed the procession. Then came the officiating clergy—the Master of Trinity, the Bishop of Durham, and the Rev. R. St. John Parry, senior dean. Following the mourners came the Fellows of Trinity College—Mr. J. Prior, Dr. Jackson, Mr. H. M. Taylor, Mr. B. E. Hammond, Dr. Kirkpatrick, Dr. Stanton, the Rev. A. H. F. Boughey, Dr. Verrall, Mr. W. W. R. Ball, Mr. R. D. Hicks, Mr. R. T. Glazebrook, Mr. F. J. H. Jenkinson, Dr. Postgate, Mr. Fraser, Mr. J. G. Fraser, Mr. J. D. Duff, Mr. A. N. Whitehead, Dr. Sidgwick, Mr. J. N. Langley, Mr. S. M. Leathes, Rev. C. Platts, Mr. C. Williams, Mr. A. A. Bevan, Mr. G. T. Walker, Mr. W. C. Whetham, Mr. G. A. Davies, Mr. Capstick, Mr. Innes, Mr. Nicholson, Mr. Cowell, Mr. Moore, and Mr. Wyse. Then came the Vice-Chancellor of the University and the representatives of the German and United States Embassies—viz. H.S.H. Prince Hermann von Schoenburg-Waldenburg for the German Ambassador, and Mr. D. D. Wells on behalf of the United States Ambassador. Baron d'Estournelles de Constant had intended to be present as representative of the French Ambassador, but was prevented at the last moment. The heads of Houses included the Masters of Peterhouse, Clare, Caius, St. Catharine's, Jesus, Christ's, St. John's, Emmanuel, Sidney Sussex, Downing, and Ayerst Hall, the President of Queens', and the Principal of Ridley Hall. The Royal Society was represented by Lord Rayleigh and Prof. Michael Foster; the Royal Astronomical Society by Mr. Knobel; the Mathematical Society by Major MacMahon, Mr. Kempe, Prof. Elliott, and Prof. Henrici; the Cambridge Philosophical Society by Mr. Larmor and Mr. Newall. The attendance likewise included Profs. J. R. Lumby, H. B. Swete, E. C. Clark, A. Macalister, T. M'Kenny Hughes, W. J. Lewis, H. E. Ryle, E. B. Cowell, J. E. B. Mayor, J. A. Ewing, W. W. Skeat, Sir G. M. Humphrey, and C. S. Roy; the Public Orator, the Registrary, Dr. Routh, and many others. An impressive service was held in the chapel of Trinity College. The concluding portion of the service took place at the Mill Road Cemetery, the Bishop of Durham committing the body to the grave.

We are glad to see that the Duke of Argyll has recovered sufficiently from his illness to remove from the residence of Lord Kelvin to Inverary Castle.

The very extensive and valuable botanical library of the late Prof. N. Pringsheim has been presented to the German Botanical Society, of which he was President, together with a sum of 25,000 marks for its maintenance.

The Berlin correspondent of the *British Medical Journal* reports that a gift of 1,500,000 marks (£75,000) has come to the German Royal Academy of Sciences from a widow lady, Frau Wenzel. The sum is to remain as a foundation, and the interest used to assist scientific inquiries of importance.

The death is announced of Dr. Lombard, the author of a standard work on Climatology from a medical point of view, and in 1882 the President of the International Congress of Hygiene at Geneva. An eminent German engineer—Hermann Gruson—has also just died, at Magdeburg.

Reuter's correspondent at Christiania reports that earthquake shocks were felt at Christiansund, Molde, Aalesund, and Bergen between 12.15 and 12.43 on the morning of Tuesday, February 5, causing windows to rattle and disturbing furniture. The direction of the vibrations was from south-east to north-west.

A deputation from the recent Indian Medical Congress has (says the *Lancet*) waited upon Sir Anthony MacDonnell, controlling the Home Department, to urge upon the Government of India the extension of facilities for the study of preventive medicine and the prosecution of scientific research in that country. Sir Anthony MacDonnell, in his reply, assured the deputation of his interest in the objects in view, and announced that, in addition to the bacteriological laboratory at Agra, a similar institution for experimental research was to be established at Lahore.

The United States Government has established an additional wind signal, to be known as the "Hurricane Signal," to be used in addition to the storm signals previously shown. The

[1] "La Vie et la Carrière Scientifique de M. Duchartre," *Revue Générale de Botanique*, Décembre 1894.

signal consists of two red flags with black centres, shown one above the other, and will be used to announce the expected approach of tropical hurricanes, and also of those extremely severe and dangerous storms which occasionally move across the Lakes and the northern Atlantic shore. Whenever instructions are received to show this signal at any station, every effort has to be made to distribute the information, and all vessels have to be notified that it is dangerous to leave port.

THE Academy of Natural Sciences of Philadelphia, acting on the report of the Committee on the Hayden Memorial Geological Award, have voted the Hayden medal, and the accumulated interest on the fund, to Prof. G. A. Daubrée. The recipient in 1893 was Prof. Huxley. Prof. Daubrée was born in Metz, June 25, 1814, and is therefore now in his eighty-second year. He graduated from the École Polytechnique in 1834, and immediately received a commission to assist in the geological exploration of Algeria. He was called to the chair of Geology in Strasburg in 1839, and was Dean of its Scientific Faculty in 1852. He was appointed Engineer-in-Chief in 1855. In 1861, upon the death of the distinguished Cordier, he was selected to replace him in the Museum of Natural History, and as Professor of Mineralogy in the École des Mines, as well as in the Académie des Sciences in Paris. His writings have been numerous, original, and important, and his researches into the intricate causes of crystalline structure, and in the domain of experimental geology, are of exceptional value.

BY the death of Dr. F. Buchanan White, which took place on December 3, 1894, at Perth, in his fifty-third year, Scotland has lost one of her most active naturalists. His special branches were entomology and botany. Dr. White was one of the founders of the Perthshire Society of Natural Sciences, of the Scottish Cryptogamic Society, and of the East of Scotland Union of Naturalists' Societies; and was the originator and first editor of the *Scottish Naturalist*. He left, at the time of his death, a nearly completed "Flora of Perthshire." The *Entomologist's Monthly Magazine* notes that his friends are endeavouring to raise a fund to erect a memorial to him. It is proposed to place a mural brass tablet in St. Ninian's Cathedral, and also to procure an enlarged photograph, to be hung in the lecture room of the Perthshire Society of Natural Science. Any who wish to contribute to this memorial may send subscriptions to either Vincent L. Rorison, Dean of St. Andrews, The Deanery, Perth; or Henry Coates, President of the Perthshire Society of Natural Science, Pitcullen House, Perth.

DR. HERMANN WEBER, a Fellow of the Royal College of Physicians and Surgeons, gave, last December, the sum of £2500 in trust for the purpose of founding a prize to be called the "Weber-Parkes" prize, to be given at intervals for the best essay on tubercular consumption. It has now been resolved that the prize be awarded triennially to the writer of the best essay upon some subject connected with the etiology, prevention, pathology, or treatment, of tuberculosis, especially with reference to pulmonary consumption in man; that, in making the award, the College have regard to careful collection of facts and original research; that the value of the prize be 150 guineas, or such sum as the interest accrued on the capital, after payment of expenses, will permit; that a bronze medal be awarded to the holder of the prize, and a similar medal, to be distinguished as the "second medal," to the essayist who comes next in order of merit. The competition will be open to members of the medical profession in all countries, the essays to be type-written, and, if written in a foreign language, to be accompanied by a translation in English. It is a condition of the competition that each prize essay shall become the property of the College, though the College may grant its author permission to publish it.

ON Friday last, a deputation from the British Medical Association and the Ophthalmological Society waited upon Mr. Bryce, President of the Board of Trade, to urge the adoption of more precise tests for eyesight in the examination for the mercantile marine and railway servants. Dr. Macnamara, in introducing the deputation, said that railway and merchant marine authorities did not insist upon proper precautions being taken to exclude men with imperfect eyesight from being employed as signalmen, and in the movement of trains and vessels. Dr. Argyll Robertson held it was necessary that the tests should be adequate and uniform, that they should be skilfully employed, and that they should be applied at regular intervals. The tests should elicit three conditions: (1) the acuteness of vision possessed by the applicant; (2) the state of refraction of the candidate's eye; and (3) his acuteness of colour perception. Mr. Bryce, in the course of his reply, said he was glad to gather from what had been said by members of the deputation, that the tests embodied in the Board's circular of last September, to be applied to masters and mates, were recognised as being satisfactory, except in regard to the question of refraction. He was perfectly certain, however, that if the railway companies' examinations did not cover this defect, they would soon take steps to apply the test for it. But the Board of Trade had no statutory powers as regarded the companies in this matter, neither had they any power to apply the tests to all persons entering the merchant service.

IN June of last year, the Society for the Preservation of the Monuments of Ancient Egypt discussed the importance of having a thorough survey made of the Nile Valley from the First to the Second Cataract—that is to say, of the district which will be partially converted into a high reservoir when the dam at Assouan, even in its reduced proportions, is constructed. A draft scheme for such an archæological survey has been drawn up by the Committee appointed to decide upon the regions to be investigated and the work to be done. A list has been compiled to show the most important antiquities along the Nile Valley which require examination and copying. The Committee propose that the survey should commence with a preliminary reconnaissance, providing a general map and maps of sites, to be followed by plans of the buildings and special inquiries indicated in subsequent sections. It is probable that, under the special circumstances of the case, if the maps and plans referred to cannot be prepared for publication in Egypt, application to the Board of Agriculture might secure their multiplication and reduction by the Ordnance Survey. Such a course would secure perfect reproduction and a great economy. It is proposed that illustrations, other than plans, should be based on photographs, to be subsequently processed in printer's ink. This would secure permanency and great economy, and avoid all the expenses of hand illustration, which alone was available in the expeditions of 1789 and 1844. The Committee suggest that a non-commissioned officer of the Royal Engineers, who has passed through the Photographic School at Chatham, should be attached to one of the companies of Royal Engineers stationed in Egypt, and be employed in obtaining the photographs. It is understood that the preliminary reconnaissance is now about to commence, under the direction of the Public Works, Irrigation, and Archæological Departments of the Egyptian Government, very much in accordance with the detailed scheme, printed copies of which have been forwarded to Egypt.

A PAPER on boiler explosions, read at the Institution of Civil Engineers on January 29, by Mr. William H. Fowler, presents some points of interest. The theories, such as "deferred ebullition," "disassociation of water," "spheroidal condition," which have been propounded to account for such explosions, are well known. Mr. Fowler showed that it was the hot water, rather than the steam, in the boiler which formed the source of destructive energy. In regard to the causes of boiler explosions, there is nothing occult or mysterious. They can, as a rule, be traced by patient investigation to the operation of simple and well-known facts. Thus when a boiler-shell is normally in a state of high tension, if once a rupture takes place by the action of static stresses on a locally weak spot, the stored-up energy is capable not only of tearing the boiler to pieces, but of producing all the other destructive effects observed in connection with such disasters. Prominent among the principal causes of explosions is the corrosion of the boiler-shell. Some explosions have their origin in the stresses arising from expansion and contraction due to the action of the fire. As an illustration of the stresses set up by unequal expansion and contraction in a boiler, a case was mentioned in which an explosion occurred two hours after the fires were drawn. A frequent source of boiler explosions in the past is the practice of cutting large openings in boiler-shells, without providing compensating strengthening-rings. Overheating from shortness of water is a common cause of boiler explosions; but the operation of this cause is different from the reason formerly assigned to it. Explosions are not the result of turning cold water on to red-hot plates. What takes place is that the overheated plates become gradually softened, with the result that they bulge downwards and are rent at the ordinary working pressure: explosions of this kind are of a relatively mild character. Many explosions arise from excessive pressure in consequence of the defective action of the safety-valve. This may occur in a variety of ways, but the type of valve loaded with a spring-balance is the most prolific source. Finally, explosions sometimes arise from faulty material and construction. As a result of using iron of poor quality with punched holes, incipient flaws are occasionally set up in the seams, and several cases have occurred in which these inherent defects were so situated as to forbid detection when the boiler was put together, and were only revealed by the explosion. These defects show the value in connection with new work of a careful hydraulic test.

THE barometer has been very high over north-west Europe during the past week, and the type of weather over these islands has been anti-cyclonic, with strong easterly winds or gales at several places on our coasts. In the neighbourhood of London the maximum day temperatures have not exceeded 35°, and at night sharp frosts have occurred. In the suburbs a reading of 15° has been recorded, and a few miles distant the temperature fell several degrees lower, with a radiation temperature of 6°·5, while over the midland districts of England the thermometer in the shade has fallen 24° below the freezing point. The *Weekly Weather Report* published by the Meteorological Office states that during the week ending the 2nd inst. the absolute shade minima recorded were—2° at Llandovery on January 28, 1° at Braemar on January 30, and 2° at Hillington on January 27. Over the whole country the temperature ranged from 8° to 13° below the mean for the week. Snow has fallen at many places in different parts of the kingdom.

THE beautiful Alpine phenomenon which the Swiss call "Alpenglühen," is not a simple red glow of the snowy peaks at sunset, but is sometimes intermittent, the glow returning once or twice after it has apparently died away. Dr. J. Amsler, in a recent communication to the Swiss Natural Science Society, explains this repetition by taking into account the various deviations undergone by the sun's rays in passing through the rapidly cooling atmosphere. Since the air is colder in the higher, and warmer in the lower strata, the solar rays undergo a kind of total reflection which makes them pass upwards again, so that when the sun has reached a certain position they will no longer strike the summits. This is the end of the first glow. As the lower air cools, the rays become once more rectilinear, and the second glow sets in. When the sun sinks still lower, its rays are thrown down upon the glaciers by ordinary refraction. This refraction may be intensified by warm air from below reaching the upper regions of the air, which would give rise to the third glow. But the latter is only rarely observed.

IT is gratifying to learn that the Italian Government has appointed a commission to study the violent earthquake which occurred in South Italy on November 16. In the meantime, Prof. Tacchini has established one result of great interest and, possibly, of much practical importance (*R. Accad. dei Lincei, Rend.* iii. 1894, pp. 365–367). The earthquake was registered at Rome by three pendulums in the Collegio Romano. The maximum displacement occurred at 5h. 55m. p.m., Greenwich mean time; but the first movement was registered by the great seismometrograph (length 16m., mass 200 kg.) at 5h. 52m. 25s., by another (length 6m., mass 100 kg.) at 5h. 52m. 30s., and by a third still less delicate (length 1½m., mass 10 kg.) at 5h. 53m. 20s. Now a clock was stopped at the observatory of Messina at 5h. 52m., there being no slight shock previously, and the maximum disturbance was registered at the same moment at the observatory of Catania. It may be inferred, therefore, that before the great shock took place, there was a microseismic motion insensible to man and to ordinary apparatus. But, if an instrument as delicate as that at Rome had been installed at Messina, the beginning of the motion would have been recorded 2½ minutes before the occurrence of the sensible shock.

WE learn from the *Journal of Botany*, that a "Flora of Berkshire," by Mr. Druce, will shortly be published.

THE constant communication kept up by the central authorities at Kew with the directors of the various colonial botanic gardens, is bearing fruit in the numerous botanical publications which proceed from the Colonies. We have on our table the *Bulletin of Miscellaneous Information* from the Royal Botanic Garden, Trinidad, for January 1895; the *Agricultural Journal* of the Leeward Islands for October 1894; and *Notes on Antigua Grasses*, by Mr. C. A. Barber, Superintendent of Agriculture for the Leeward Islands; all containing notes and information of value for the dwellers in the Tropics.

FIVE *Bulletins* of the University of Wisconsin have come to us. One, the first of a Science Series, is on the speed of the liberation of iodine in mixed solutions of potassium chlorate, potassium iodide, and hydrochloric acid, the author thereof being Mr. H. Schlundt. His experiments show that the speed of the reaction increases to a marked degree with temperature. The presence in the mixture of an excess of one or more of the components also increases the speed, and an increase in the degree of concentration acts in the same manner. The presence of hydrobromic acid accelerates the reaction; and, to a less extent, hydrochloric, nitric, and sulphuric acids. Organic acids, however, and boric acid, do not increase the speed. The four remaining *Bulletins* referred to belong to the Engineering Series. In one, Mr. L. F. Loree traces the development of railroads from 1825 to the present time, chiefly dealing with the construction of the permanent way. Some practical hints in dynamo design are given by Mr. Gilbert Wilkes in the second of the series. The next, by Mr. C. T. Purdy, refers to the steel construction of buildings; and the fourth, by Mr. A. V. Abbott, deals with telephones and switchboards.

Two further communications concerning the new iodine bases are contributed by pupils of Prof. Victor Meyer to the current issue of the *Berichte*. In the first, Mr. John McCrae describes the base and its salts derived from toluene, analogous to the compounds previously described by Prof. Meyer and Herr Hartmann derived from benzene. In the second memoir, Mr. Wilkinson describes a further series derived from para-chlor-iodo-benzene, C_6H_4ClI. The formation of both series occurs precisely as in the case of the benzene derivatives. The base derived from toluene was prepared from the para iodide of toluene as starting point. Its composition is $(C_6H_4 . CH_3)_2I . OH$, iodine apparently acting, as in the bases previously described, in a trivalent capacity, and forming the central element around which the two toluene radicles and the hydroxyl are grouped. The base itself has only been obtained in aqueous solution, but many of the salts crystallise well, and are consequently readily isolated. The iodide, $(C_6H_4 . CH_3)_2I . I$, is precipitated as a white powder, extremely sensitive to light, and melting at 146°. The corresponding chloride and bromide both crystallise from water in needles which melt at almost the same temperature in the neighbourhood of 178°. The bichromate is a particularly beautiful salt, crystallising from hot water in large orange-red plates. It is likewise explosive, detonating when heated. The nitrate, $(C_6H_4 . CH_3)_2I . NO_3$, is very soluble in water, and melts at 139°. The per-iodide is a remarkable compound, $(C_6H_4CH_3)_2I . I_2$, obtained by addition of two further atoms of iodine to the ordinary iodide above mentioned. It crystallises in dark red needles, endowed with a very brilliant lustre, and melting at 156°. In addition to these salts, double salts with the chlorides of gold, platinum and mercury are described, all of which crystallise well and exhibit definite melting points. The base of the series described by Mr. Wilkinson possesses the composition $(C_6H_4Cl)_2I . OH$, being derived from para chlor-iodo-benzene by reactions analogous to those by means of which the base above described was obtained, and similar to those previously described by Prof. Meyer. The iodide, chloride, bromide, nitrate and chromate, as well as double salts with the chlorides of mercury and platinum, have been obtained in well-defined crystals. Hence it would appear that the reactions discovered by Prof. Meyer and Herr Hartmann, between iodosobenzene and silver oxide, and between sulphuric acid and iodosobenzene, which resulted in the preparation of the first iodonium bases, are of pretty general application in the benzene series. These remarkable compounds containing iodine as the grouping element must now, therefore, be regarded as thoroughly well established, and the older idea as to the nature of the iodine atom must give place to a fuller conception of the capabilities of that element.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, presented by Captain Webster; a White-throated Capuchin (*Cebus hypoleucus*) from Central America, presented by Mr. H. W. Manning; a Senegal Parrot (*Pœocephalus senegalus*) from West Africa, presented by Miss Alice Firman.

OUR ASTRONOMICAL COLUMN.

NEW STARS AND NEBULÆ.—The first number of the *Astrophysical Journal* has come to hand. It is practically a continuation of *Astronomy and Astro-Physics* in a slightly different form, and is now published by the Chicago University Press. Among the contributions to the journal is a paper, by Prof. W. W. Campbell, on some interesting and significant changes which have occurred recently in the spectrum of Nova Aurigæ. The intensities of the two lines at λ 4360 and λ 5750 appear to have decreased very materially. When Prof. Campbell observed the Nova spectrum in 1892, these two lines were stronger in the Nova than in the nebulæ in the spectra of which they were seen and photographed. Observing last November, however, he found that this condition of things was reversed, the lines appearing relatively fainter in the Nova than in the nebulæ. As is now very well known, the spectra of nebulæ differ both as regards the number and intensity of the lines. The recent observations of the Nova seem to show that the spectrum is not only nebular, but it is approaching the average type of nebular spectrum. Prof. Campbell thus sums up the bearing of spectroscopic observations upon theories proposed to account for the genesis of new stars:—

"The Harvard College Observatory has shown that both Nova Aurigæ and Nova Normæ at discovery possessed substantially identical spectra of bright and dark lines, similarly and equally displaced. Both diminished in brightness and both assumed the nebular type of spectrum. The new star of 1876 in Cygnus probably had nearly an identical history: passing from a bright star with a spectrum of bright and dark lines, to a faint object with a spectrum consisting of one bright line (undoubtedly the nebular line λ 5010, or the two nebular lines λ 5010 and λ 4960 combined). We may say that only five 'new stars' have been discovered since the application of the spectroscope to astronomical investigations, and that three of these have had substantially identical spectroscopic histories. This is a remarkable fact. We cannot say what the full significance of this fact is. One result, however, is very clear: the *special* theories propounded by various spectroscopists to account for the phenomena observed in Nova Aurigæ must unquestionably give way to the more *general* theories."

THE DESIGNATION OF COMETS.—A uniform system of cometary notation is certainly needed. The *Observatory* points out that though the small letters *a*, *b*, *c*, &c., are now generally used to denote the order of discovery, and Roman numerals I., II., III., &c., to indicate the order of perihelion passage, astronomers are not agreed whether to write Comet *a* 1894, Brooks's Comet, or Comet Brooks. It is therefore suggested, and the suggestion deserves to be acted upon, that in the future the order shall be letter, year, Roman numeral, discoverer. The full name of the comet would then run as follows:—Comet *a* 1892, I. (Swift): and if any part of the name be quoted, this order should be preserved. Those who have had to search for observation of comets in astronomical publications, will welcome the system of uniformity in indexing, proposed by our contemporary.

THE NEW CONSTITUENT OF THE ATMOSPHERE.[1]

I. *Density of Nitrogen from Various Sources.*

In a former paper[2] it has been show that nitrogen extracted from chemical compounds is about ½ per cent. lighter than "atmospheric nitrogen."

The mean numbers for the weights of gas contained in the globe used were as follows:—

From nitric oxide	2·3001
From nitrous oxide	2·2990
From ammonium nitrite	2·2987

while for "atmospheric nitrogen" there was found—

By hot copper, 1892	2·3103
By hot iron, 1893	2·3100
By ferrous hydrate, 1894	2·3102

At the suggestion of Prof. Thorpe experiments were subsequently tried with nitrogen liberated from *urea* by the action of sodium hypobromite. The hypobromite was prepared from commercial materials in the proportions recommended for the analysis of urea. The reaction was well under control, and the gas could be liberated as slowly as desired.

In the first experiment the gas was submitted to no other treatment than slow passage through potash and phosphoric anhydride, but it soon became apparent that the nitrogen was contaminated. The "inert and inodorous" gas attacked vigorously the mercury of the Töpler pump, and was described as smelling like a dead rat. As to the weight, it proved to be in excess even of the weight of atmospheric nitrogen.

The corrosion of the mercury and the evil smell were in great

[1] Abstract of a paper by Lord Rayleigh, Sec. R.S., and Prof. William Ramsay, F.R.S., read before the Royal Society, at a special meeting, on January 31.

[2] Rayleigh, "On an Anomaly encountered in Determinations of the Density of Nitrogen Gas," *Roy. Soc. Proc.* vol. lv. p. 340, 1894.

degree obviated by passing the gas over hot metals. For the fillings of June 6, 9, and 13 the gas passed through a short length of tube containing copper in the form of fine wire heated by a flat Bunsen burner, then through the furnace over red-hot iron, and back over copper oxide. On June 19 the furnace tubes were omitted, the gas being treated with red hot copper only. The mean result, reduced so as to correspond with those above quoted, is 2·2985.

Without using heat, it has not been found possible to prevent the corrosion of the mercury. Even when no urea is employed, and air simply bubbled through, the hypobromite solution is allowed to pass with constant shaking over mercury contained in a U tube, the surface of the metal was soon fouled.

Although the results relating to urea nitrogen are interesting for comparison with that obtained from other nitrogen compounds, the original object was not attained on account of the necessity of retaining the treatment with hot metals. We have found, however, that nitrogen from ammonium nitrite may be prepared without the employment of hot tubes whose weight agrees with that above quoted. It is true that the gas smells slightly of ammonia, easily removable by sulphuric acid, and apparently also of oxides of nitrogen. The mean result from three fillings is 2·2987.

It will be seen that, in spite of the slight nitrous smell, there is no appreciable difference in the densities of gas prepared from ammonium nitrite with and without the treatment by hot metals. The result is interesting as showing that the agreement of numbers obtained for chemical nitrogen does not depend upon the use of a red heat in the process of purification.

The five results obtained in more or less distinct ways for chemical nitrogen stand thus:—

From nitric oxide	2·3001
From nitrous oxide	2·2990
From ammonium nitrite purified at a red heat	2·2987
From urea	2·2985
From ammonium nitrite purified in the cold	2·2987
Mean	2·2990

These numbers, as well as those above quoted for "atmospheric nitrogen," are subject to a deduction of 0·0006 for the shrinkage of the globe when exhausted.[1] If they are then multiplied in the ratio of 2·3108 : 1·2572, they will express the weights of the gas in grams per litre. Thus, as regards the mean numbers, we find as the weight per litre under standard conditions of chemical nitrogen 1·2505, that of atmospheric nitrogen being 1·2572.

It is of interest to compare the density of nitrogen obtained from chemical compounds with that of oxygen. We have $N_2 : O_2 = 2·2984 : 2·6276 = 0·87471$; so that if $O_2 = 16$, $N_2 = 13·9954$. Thus, when the comparison is with chemical nitrogen, the ratio is very nearly that of 16 : 14; but if "atmospheric nitrogen" be substituted, the ratio of small integers is widely departed from.

To the above list may be added nitrogen prepared in yet another manner, whose weight has been determined subsequently to the isolation of the new dense constituent of the atmosphere. In this case nitrogen was actually extracted from air by means of magnesium. The nitrogen thus separated was then converted into ammonia by action of water upon the magnesium nitride, and afterwards liberated in the free state by means of calcium hypochlorite. The purification was conducted in the usual way, and included passage over red hot copper and copper oxide. The following was the result:—

Globe empty, October 30, November 5 ...	2·82313
Globe full, October 31	0·52395
Weight of gas	2·29918

It differs inappreciably from the mean of other results, viz. 2·2990, and is of special interest as relating to gas which at one stage of its history formed part of the atmosphere.

Another determination, with a different apparatus, of the density of "chemical" nitrogen from the same source, magnesium nitride, which had been prepared by passing "atmospheric" nitrogen over ignited magnesium, may here be recorded. The sample differed from that previously mentioned, inasmuch as it had not been subjected to treatment with red-hot copper. After treating the nitride with water, the resulting ammonia was distilled off, and collected in hydrochloric acid; the solution was evaporated by degrees, the dry ammonium chloride was dissolved in water, and its concentrated solution added to a freshly-prepared solution of sodium hypobromite. The nitrogen was collected in a gas-holder over water which had previously been boiled, so as, at all events, partially to expel air. The nitrogen passed into the vacuous globe through a solution of potassium hydroxide, and through two drying-tubes, one containing soda-lime, and the other phosphoric anhydride.

At 18·38° C. and 754·4 mm. pressure, 162·843 c.c. of this nitrogen weighed 0·18963 gram. Hence,

Weight of 1 litre at 0° C. and 760 mm. pressure = 1·2521 gram.

The mean result of the weight of 1 litre of "chemical" nitrogen has been found to equal 1·2505. It is therefore seen that "chemical" nitrogen, derived from "atmospheric" nitrogen, without any exposure to red hot copper, possesses the usual density.

Experiments were also made, which had for their object to prove that the ammonia produced from the magnesium nitride is identical with ordinary ammonia, and contains no other compound of a basic character. For this purpose the ammonia was converted into ammonium chloride, and the percentage of chlorine determined by titration with a solution of silver nitrate which had been standardised by titrating a specimen of pure sublimed ammonium chloride. The silver solution was of such a strength that 1 c.c. precipitated the chlorine from 0·001701 gram of ammonium chloride.

(1) Ammonium chloride from orange-coloured sample of magnesium nitride contained 66·35 per cent. of chlorine.

(2) Ammonium chloride from blackish magnesium nitride contained 66·35 per cent. of chlorine.

(3) Ammonium chloride from nitride containing a large amount of unattacked magnesium contained 66·30 per cent. of chlorine.

Taking for the atomic weights of hydrogen H = 1·0032, of nitrogen N = 14·04, and of chlorine Cl = 35·46, the theoretical amount of chlorine in ammonium chloride is 66·27 per cent.

From these results—that nitrogen prepared from magnesium nitride, obtained by passing "atmospheric" nitrogen over red-hot magnesium has the density of "chemical" nitrogen, and that ammonium chloride, prepared from magnesium nitride, contains practically the same percentage of chlorine as pure ammonium chloride—it may be concluded that red-hot magnesium withdraws from "atmospheric nitrogen" no substance other than nitrogen capable of forming a basic compound with hydrogen.

II. *Reasons for suspecting a hitherto Undiscovered Constituent in Air.*

When the discrepancy of weights was first encountered, attempts were naturally made to explain it by contamination with known impurities. Of these the most likely appeared to be hydrogen, present in the lighter gas in spite of the passage over red-hot cupric oxide. But inasmuch as the intentional introduction of hydrogen into the heavier gas, afterwards treated in the same way with cupric oxide, had no effect upon its weight, this explanation had to be abandoned, and finally it became clear that the difference could not be accounted for by the presence of any known impurity. At this stage it seemed not improbable that the lightness of the gas extracted from chemical compounds was to be explained by partial dissociation of nitrogen molecules N_2 into detached atoms. In order to test this suggestion both kinds of gas were submitted to the action of the silent electric discharge, with the result that both retained their weights unaltered. This was discouraging, and a further experiment pointed still more markedly in the negative direction. The chemical behaviour of nitrogen is such as to suggest that dissociated atoms would possess a high degree of activity, and that even though they might be formed in the first instance their life would probably be short. On standing they might be expected to disappear, in partial analogy with the known behaviour of ozone. With this idea in view, a sample of chemically prepared nitrogen was stored for eight months. But at the end of this time the density showed no sign of increase, remaining exactly as at first.[1]

[1] Rayleigh, "On the Densities of the Principal Gases," *Roy. Soc. Proc.* vol. liii. p. 134, 1893.

[1] *Roy. Soc. Proc.* vol. lv., p. 344, 1894.

Regarding it as established that one or other of the gases must be a mixture, containing, as the case might be, an ingredient much heavier or much lighter than ordinary nitrogen, we had to consider the relative probabilities of the various possible interpretations. Except upon the already discredited hypothesis of dissociation, it was difficult to see how the gas of chemical origin could be a mixture. To suppose this would be to admit two kinds of nitric acid, hardly reconcilable with the work of Stas and others upon the atomic weight of that substance. The simplest explanation in many respects was to admit the existence of a second ingredient in air from which oxygen, moisture, and carbonic anhydride had already been removed. The proportional amount required was not great. If the density of the supposed gas were double that of nitrogen ½ per cent. only by volume would be needed; or if the density were but half as much again as that of nitrogen, then 1 per cent. would still suffice. But in accepting this explanation, even provisionally, we had to face the improbability that a gas surrounding us on all sides, and present in enormous quantities, could have remained so long unsuspected.

The method of most universal application by which to test whether a gas is pure or a mixture of components of different densities is that of diffusion. By this means Graham succeeded in effecting a partial separation of the nitrogen and oxygen of the air, in spite of the comparatively small difference of densities. If the atmosphere contain an unknown gas of anything like the density supposed, it should be possible to prove the fact by operations conducted upon air which had undergone atmolysis. This experiment, although in view from the first, was not executed until a later stage of the inquiry (§ 6), when results were obtained sufficient of themselves to prove that the atmosphere contains a previously unknown gas.

But although the method of diffusion was capable of deciding the main, or at any rate the first question, it held out no prospect of isolating the new constituent of the atmosphere, and we, therefore, turned our attention in the first instance to the consideration of methods more strictly chemical. And here the question forced itself upon us as to what really was the evidence in favour of the prevalent doctrine that the inert residue from air after withdrawal of oxygen, water, and carbonic anhydride, is all of one kind.

The identification of "phlogisticated air" with the constituent of nitric acid is due to Cavendish, whose method consisted in operating with electric sparks upon a short column of gas confined with potash over mercury at the upper end of an inverted U tube.[1]

Attempts to repeat Cavendish's experiments in Cavendish's manner have only increased the admiration with which we regard this wonderful investigation. Working on almost microscopical quantities of material, and by operations extending over days and weeks, he thus established one of the most important facts in chemistry. And what is still more to the purpose, he raises as distinctly as we could do, and to a certain extent resolves, the question above suggested. The passage is so important that it will be desirable to quote it at full length.

"As far as the experiments hitherto published extend, we scarcely know more of the phlogisticated part of our atmosphere, than that it is not diminished by lime-water, caustic alkalies, or nitrous air; that it is unfit to support fire, or maintain life in animals; and that its specific gravity is not much less than that of common air: so that though the nitrous acid, by being united to phlogiston, is converted into air possessed of these properties, and consequently, though it was reasonable to suppose, that part at least of the phlogisticated air of the atmosphere consists of this acid united to phlogiston, yet it was fairly to be doubted whether the whole is of this kind, or whether there are not in reality many different substances compounded together by us under the name of phlogisticated air. I therefore made an experiment to determine whether the whole of a given portion of the phlogisticated air of the atmosphere could be reduced to nitrous acid, or whether there was not a part of a different nature to the rest, which would refuse to undergo that change. The foregoing experiments indeed in some measure decided this point, as much the greatest part of the air let up into the tube lost its elasticity; yet as some remained unabsorbed, it did not appear for certain whether that was of the same nature as the rest or not. For this purpose I diminished a similar mixture of dephlogisticated and common air, in the same manner as before, till it was reduced to a small part of its original bulk. I then, in order to decompound as much as I could of the phlogisticated air which remained in the tube, added some dephlogisticated air to it, and continued the spark until no further diminution took place. Having by these means condensed as much as I could of the phlogisticated air, I let up some solution of liver of sulphur to absorb the dephlogisticated air; after which only a small bubble of air remained unabsorbed, which certainly was not more than $\frac{1}{120}$ of the bulk of the phlogisticated air let up into the tube; so that if there is any part of the phlogisticated air of our atmosphere which differs from the rest, and cannot be reduced to nitrous acid, we may safely conclude that it is not more than $\frac{1}{120}$th part of the whole."

Although Cavendish was satisfied with his result, and does not decide whether the small residue was genuine, our experiments about to be related render it not improbable that his residue was really of a different kind from the main bulk of the "phlogisticated air," and contained the gas now called argon.

Cavendish gives data[1] from which it is possible to determine the rate of absorption of the mixed gases in his experiment. This was about 1 c.c. per hour, of which two-fifths would be nitrogen.

III. *Methods of Causing Free Nitrogen to Combine.*

To eliminate nitrogen from air, in order to ascertain whether any other gas could be detected, involves the use of some absorbent. The elements which have been found to combine directly with nitrogen are: boron, silicon, titanium, lithium, strontium, barium, magnesium, aluminium, mercury, and, under the influence of an electric discharge, hydrogen in presence of acid, and oxygen in presence of alkali. Besides these, a mixture of barium carbonate and carbon at a high temperature is known to be effective. Of those tried, magnesium in the form of turnings was found to be the best. When nitrogen is passed over magnesium, heated in a tube of hard glass to bright redness, combustion with incandescence begins at the end of the tube through which the gas is introduced, and proceeds regularly until all the metal has been converted into nitride. Between 7 and 8 litres of nitrogen can be absorbed in a single tube; the nitride formed is a porous, dirty orange-coloured substance.

IV. *Early Experiments on Sparking Nitrogen with Oxygen in presence of Alkali.*

In our earliest attempts to isolate the suspected gas by the method of Cavendish, we used a Ruhmkorff coil of medium size actuated by a battery of five Grove cells. The gases were contained in a test-tube standing over a large quantity of weak alkali, and the current was conveyed in wires insulated by U-shaped glass tubes passing through the liquid round the mouth of the test-tube. With the given battery and coil a somewhat short spark or arc of about 5 mm. was found to be more favourable than a longer one. When the mixed gases were in the right proportion the rate of absorption was about 30 c.c. per hour, or thirty times as fast as Cavendish could work with the electrical machine of his day.

To take an example, one experiment of this kind started with 50 c.c. of air. To this oxygen was gradually added, until oxygen being in excess, there was no perceptible contraction during an hour's sparking. The remaining gas was then transferred at the pneumatic trough to a small measuring vessel, sealed by mercury, in which the volume was found to be 1·0 c.c. On treatment with alkaline pyrogallate, the gas shrank to 0·32 c.c. That this small residue could not be nitrogen was argued from the fact that it had withstood the prolonged action of the spark, although mixed with oxygen in nearly the most favourable proportion.

The residue was then transferred to the test-tube with an addition of another 50 c.c. of air, and the whole worked up with oxygen as before. The residue was now 2·2 c.c., and, after removal of oxygen, 0·76 c.c.

Although it seemed almost impossible that these residues could be either nitrogen or hydrogen, some anxiety was not unnatural, seeing that the final sparking took place under somewhat abnormal conditions. The space was very restricted, and the temperature (and with it the proportion of aqueous vapour) was unduly high. But any doubts that were felt upon this score were removed by comparison experiments in which the whole quantity of air operated on was very small. Thus, when

[1] "Experiments on Air," *Phil. Trans.* vol. lxxv. p. 372, 1785.

[1] *Phil. Trans.* vol. lxxviii. p. 271, 1788.

a mixture of 5 c.c. of air with 7 c.c. of oxygen was sparked for 1¾ hours, the residue was 0·47 c.c., and after removal of oxygen 0·06 c.c. Several repetitions having given similar results, it became clear that the final residue did not depend upon anything that might happen when sparks passed through a greatly reduced volume, *but was in proportion to the amount of air operated upon.*

No satisfactory examination of the residue which refused to be oxidised could be made without the accumulation of a larger quantity. This, however, was difficult of attainment at the time in question. It was thought that the cause probably lay in the solubility of the gas in water, a suspicion since confirmed. At length, however, a sufficiency was collected to allow of sparking in a specially constructed tube, when a comparison with the air spectrum, taken under similar conditions, proved that, at any rate, the gas was not nitrogen. At first scarcely a trace of the principal nitrogen lines could be seen, but after standing over water for an hour or two these lines became apparent.

V. *Early Experments on Withdrawal of Nitrogen from Air by means of Red-hot Magnesium.*

A preliminary experiment carried out by Mr. Percy Williams on the absorption of atmospheric nitrogen, freed from oxygen by means of red-hot copper, in which the gas was not passed over, but simply allowed to remain in contact with the metal, gave a residue of density 14·88. This result, although not conclusive, was encouraging; and an attempt was made, on a larger scale, by passing atmospheric nitrogen backwards and forwards over red-hot magnesium from one large gas-holder to another to obtain a considerable quantity of the heavier gas. In the course of ten days, about 1500 c.c. were collected and transferred gradually to a mercury gas-holder, from which the gas was passed over soda-lime, phosphoric anhydride, magnesium at a red-heat, copper oxide, soda-lime, and phosphoric anhydride into a second mercury gas-holder. After some days the gas was reduced in volume to about 200 c.c., and its density was found to be 16·1. After further absorption, in which the volume was still further reduced, the density of the residue was increased to 19·09.

On passing sparks for several hours through a mixture of a small quantity of this gas with oxygen, its volume was still further reduced. Assuming that this reduction was due to the further elimination of nitrogen, the density of the remaining gas was calculated to be 20·0.

The spectrum of the gas of density 19·09, though showing nitrogen bands, showed many other lines which were not recognisable as belonging to any known element.

VI. *Proof of the Presence of Argon in Air by means of Atmolysis.*

It has already (§ II.) been suggested that if "atmospheric nitrogen" contains two gases of different densities, it should be possible to obtain direct evidence of the fact by the method of atmolysis. The present section contains an account of carefully conducted experiments directed to this end.

The atmolyser was prepared (after Graham) by combining a number of "churchwarden" tobacco pipes. At first twelve pipes were used in three groups, each group including four pipes connected in series. The three groups were then connected in parallel, and placed in a large glass tube closed in such a way that a partial vacuum could be maintained in the space outside the pipes by a water pump. One end of the combination of pipes was open to the atmosphere; the other end was connected to a bottle aspirator, initially full of water, and so arranged as to draw about 2 per cent. of the air which entered the other end of the pipes. The gas collected was thus a very small proportion of that which leaked through the pores of the pipes, and should be relatively rich in the heavier constituents of the atmosphere. The flow of water from the aspirator could not be maintained very constant, but the rate of 2 per cent. was never much exceeded.

The air thus obtained was treated exactly as ordinary air had been treated in determinations of the density of atmospheric nitrogen. Oxygen was removed by red-hot copper, followed by cupric oxide, ammonia by sulphuric acid, moisture and carbonic acid by potash and phosphoric anhydride.

In a total weight of approximately 2·3 grams the excess of weight of the diffused nitrogen over ordinary atmospheric nitrogen was in four experiments, 0·0049, 0·0014, 0·0027, 0·0015.

The mean excess of the four determinations is 0·00262 gram, or, if we omit the first, which depended upon a vacuum weighing of two months old, 0·00187 gram.

The gas from prepared air was thus in every case denser than from unprepared air, and to an extent much beyond the possible errors of experiment. The excess was, however, less than had been expected, and it was thought that the arrangement of the pipes could be improved. The final delivery of gas from each of the groups in parallel being so small in comparison with the whole streams concerned, it seemed possible that each group was not contributing its proper share, and even that there might be a flow in the wrong direction at the delivery end of one or two of them. To meet this objection, the arrangement in parallel had to be abandoned, and for the remaining experiments eight pipes were connected in simple series. The porous surface in operation was thus reduced, but this was partly compensated for by an improved vacuum. Two experiments were made under the new conditions, in which the excess was I., 0·0037; II., 0·0033.

The excess being larger than before is doubtless due to the greater efficiency of the atmolysing apparatus. It should be mentioned that the above recorded experiments include all that have been tried, and the conclusion seems inevitable that "atmospheric nitrogen" is a mixture, and not a simple body.

It was hoped that the concentration of the heavier constituent would be sufficient to facilitate its preparation in a pure state by the use of prepared air in substitution for ordinary air in the oxygen apparatus. The advance of 3½ milligrams on the 11 milligrams, by which atmospheric nitrogen is heavier than chemical nitrogen, is indeed not to be despised, and the use of prepared air would be convenient if the diffusion apparatus could be set up on a large scale and be made thoroughly self-acting.

VII. *Negative Experiments to prove that Argon is not derived from Nitrogen from Chemical Sources.*

Although the evidence of the existence of argon in the atmosphere, derived from the comparison of densities of atmospheric and chemical nitrogen and from the diffusion experiments (§ VI.), appeared overwhelming, we have thought it undesirable to shrink from any labour that would tend to complete the verification. With this object in view, an experiment was undertaken and carried to a conclusion on November 13, in which 3 litres of chemical nitrogen, prepared from ammonium nitrite, were treated with oxygen in precisely the manner in which atmospheric nitrogen had been found to yield a residue of argon. The gas remaining at the close of the large scale operations was worked up as usual with battery and coil until the spectrum showed only slight traces of the nitrogen lines. When cold, the residue measured 4 c.c. This was transferred, and after treatment with alkaline pyrogallate to remove oxygen, measured 3·3 c.c. If atmospheric nitrogen had been employed, the final residue should have been about 30 c.c. Of the 3·3 c.c. actually left, a part is accounted for by an accident, and the result of the experiment is to show that argon is not formed by sparking a mixture of oxygen and chemical nitrogen.

In a second experiment of the same kind 5660 c.c. of nitrogen, from ammonium nitrite was treated with oxygen. The final residue was 3·5 c.c., and was found to consist mainly of argon.

The source of the residual argon is to be sought in the water used for the manipulation of the large quantities of gas (5 litres of nitrogen and 11 litres of oxygen) employed. When carbonic acid was collected in a similar manner and subsequently absorbed by potash, it was found to have acquired a contamination consistent with this explanation.

Negative experiments were also carried out, absorbing nitrogen by means of magnesium. In one instance 3 litres of nitrogen prepared from ammonium chloride and bleaching-powder was reduced in volume to 4·5 c.c., and on sparking with oxygen its volume was further reduced to about 3 c.c. The residue appeared to consist of argon. Another experiment, in which 15 litres of nitrogen from ammonium nitrite was absorbed, gave a final residue of 3·5 c.c. Atmospheric nitrogen, in the latter case, would have yielded 150 c.c., hence less than $\frac{1}{40}$th of the normal quantity was obtained. It should be mentioned that leakage occurred at one stage, by which perhaps 200 c.c. of air entered the apparatus; and besides, the nitrogen was collected over water from which it doubtless acquired some argon. Quantitative negative experiments of this nature are exceedingly difficult, and require a long time to carry them to a successful conclusion.

VIII. *Separation of Argon on a Large Scale.*

To prepare argon on a large scale, air is freed from oxygen by means of red-hot copper. The residue is then passed from a gas-holder through a combustion tube, heated in a furnace, and containing copper, in order to remove all traces of oxygen; the issuing gas is then dried by passage over soda-lime and phosphorus pentoxide, after passage through a small U tube containing sulphuric acid, to indicate the rate of flow. It then enters a combustion-tube packed tightly with magnesium turnings, and heated to redness in a second furnace. From this tube it passes through a second index-tube, and enters a small gas-holder capable of containing 3 or 4 litres. A single tube of magnesium will absorb from 7 to 8 litres of nitrogen. The temperature must be nearly that of the fusion of the glass, and the current of gas must be carefully regulated, else the heat developed by the union of the magnesium with nitrogen will fuse the tube.

Having collected the residue from 100 or 150 litres of atmospheric nitrogen, which may amount to 4 or 5 litres, it is transferred to a small gas-holder connected with an apparatus, whereby, by means of a species of a self-acting Sprengel's pump, the gas is caused to circulate through a tube half filled with copper and half with copper oxide; it then traverses a tube half filled with soda-lime and half with phosphorus pentoxide; it then passes a reservoir of about 300 c.c. capacity, from which, by raising a mercury reservoir, it can be expelled into a small gas-holder. Next it passes through a tube containing magnesium turnings heated to bright redness. The gas is thus freed from any possible contamination with oxygen, hydrogen, or hydrocarbons, and nitrogen is gradually absorbed. As the amount of gas in the tubes and reservoir diminishes in volume, it draws supplies from the gas-holder, and finally, the circulating system is full of argon in a pure state. The circulating system of tubes is connected with a mercury pump, so that, in changing the magnesium tube, no gas may be lost. Before ceasing to heat the magnesium tube the system is pumped empty, and the collected gas is restored to the gas-holder; finally, all the argon is transferred from the mercury reservoir to the second small gas-holder, which should preferably be filled with water saturated with argon, so as to prevent contamination from oxygen or nitrogen; or, if preferred, a mercury gas-holder may be employed. The complete removal of nitrogen from argon is very slow towards the end, but circulation for a couple of days usually effects it.

The principal objection to the oxygen method of isolating argon, as hitherto described, is the extreme slowness of the operation. In extending the scale we had the great advantage of the advice of Mr. Crookes, who not long since called attention to the flame rising from platinum terminals, which convey a high tension alternating electric discharge, and pointed out its dependence upon combustion of the nitrogen and oxygen of the air.[1] The plant consists of a De Meritens alternator, actuated by a gas engine, and the currents are transformed to a high potential by means of a Ruhmkorff or other suitable induction coil. The highest rate of absorption of the mixed gases yet attained is 3 litres per hour, about 3000 times that of Cavendish. It is necessary to keep the apparatus cool, and from this and other causes a good many difficulties have been encountered.

In one experiment of this kind, the total air led in after seven days' working, amounted to 7925 c.c., and of oxygen (prepared from chlorate of potash), 9137 c.c. On the eighth and ninth days oxygen alone was added, of which about 500 c.c. was consumed, while there remained about 700 c.c. in the flask. Hence the proportion in which the air and oxygen combined was as 79 : 96. The progress of the removal of the nitrogen was examined from time to time with the spectroscope, and became ultimately very slow. At last the yellow line disappeared, the contraction having apparently stopped for two hours. It is worthy of notice that, with the removal of the nitrogen, the arc discharge changes greatly in appearance, becoming narrower and blue rather than greenish in colour.

The final treatment of the residual 700 c.c. of gas was on the model of the small scale operations already described. Oxygen or hydrogen could be supplied at pleasure from an electrolytic apparatus, but in no way could the volume be reduced below 65 c.c. This residue refused oxidation, and showed no trace of the yellow line of nitrogen, even under favourable conditions.

[1] *Chemical News*, vol. lxv. p. 301, 1892.

When the gas stood for some days over water, the nitrogen line reasserted itself in the spectrum, and many hours' sparking with a little oxygen was required again to get rid of it. Intentional additions of air to gas free from nitrogen showed that about 1½ per cent. was clearly, and about 3 per cent. was conspicuously, visible. About the same numbers apply to the visibility of nitrogen in oxygen when sparked under these conditions, that is, at atmospheric pressure, and with a jar connected to the secondary terminals.

IX. *Density of Argon prepared by means of Oxygen.*

A first estimate of the density of argon prepared by the oxygen method was founded upon the data already recorded respecting the volume present in air, on the assumption that the accurately known densities of atmospheric and of chemical nitrogen differ on account of the presence of argon in the former, and that during the treatment with oxygen nothing is oxidised except nitrogen. Thus, if

D = density of chemical nitrogen,
D' = ,, atmospheric nitrogen,
d = ,, argon,
α = proportional volume of argon in atmospheric nitrogen,

the law of mixtures give

$$\alpha d + (1 - \alpha)D = D',$$

or

$$d = D + (D' - D)/\alpha.$$

In this formula $D' - D$ and α are both small, but they are known with fair accuracy. From the data already given

$$\alpha = \frac{65}{0{\cdot}79 \times 7925},$$

whence if (on an arbitrary scale of reckoning) $D = 2{\cdot}2990$, $D' = 2{\cdot}3102$, we find $d = 3{\cdot}378$. Thus if N_2 be 14, or O_2 be 16, the density of argon is 20·6.

A direct determination by weighing is desirable, but hitherto it has not been feasible to collect by this means sufficient to fill the large globe employed for other gases. A *mixture* of about 400 c.c. of argon with pure oxygen, however, gave the weight 2·7315, 0·1045 in excess of the weight of oxygen, viz. 2·6270. Thus, if α be the ratio of the volume of argon to the whole volume, the number for argon will be

$$2{\cdot}6270 + 0{\cdot}1045/\alpha.$$

The value of α, being involved only in the excess of weight above that of oxygen, does not require to be known very accurately. Sufficiently concordant analyses by two methods gave $\alpha = 0{\cdot}1845$; whence for the weight of the gas we get 3·193, so that, if $O_2 = 16$, the density of the gas would be 19·45. An allowance for residual nitrogen, still visible in the gas before admixture of oxygen, raises this number to 19·7, which may be taken as the density of pure argon resulting from this determination.

X. *Density of Argon prepared by means of Magnesium.*

The density of the original sample of argon prepared has already been mentioned. It was 19·09; and, after sparking with oxygen, it was calculated to be 20·0. The most reliable results of a number of determinations give it as 19·90. The difficulty in accurately determining the density is to make sure that all nitrogen has been removed. The sample of density 19·90 showed no spectrum of nitrogen when examined in a vacuum tube. It is right, however, to remark that the highest density registered was 20·38. But there is some reason here to distrust the weighing of the vacuous globe.

XI. *Spectrum of Argon.*

The spectrum of argon, seen in a vacuum tube of about 3 mm. pressure, consists of a great number of lines, distributed over almost the whole visible field. Two lines are specially characteristic; they are less refrangible than the red lines of hydrogen or lithium, and serve well to identify the gas, when examined in this way. Mr. Crookes, who will give a full account of the spectrum in a separate communication, has kindly furnished us with the accurate wave-lengths of these lines, as well as of some others next to be described; they are respectively 696·56 and 705·64, 10^{-6} mm.

Besides these red lines, a bright yellow line, more refrangible than the sodium line, occurs at 603·84. A group of five bright green lines occurs next, besides a number of less intensity. Of the group of five, the second, which is perhaps the most brilliant, has the wave-length 561·00. There is next a blue or blue violet line of wave-length 470·2; and last, in the less easily visible part of the spectrum, there are five strong violet lines, of which the fourth, which is the most brilliant, has the wave-length of 420·0.

Unfortunately, the red lines, which are not to be mistaken for those of any other substance, are not easily seen when a jar discharge is passed through argon at atmospheric pressure. The spectrum seen under these conditions has been examined by Prof. Schuster. The most characteristic lines are perhaps those in the neighbourhood of F, and are very easily seen if there be not too much nitrogen, in spite of the presence of some oxygen and water vapour. The approximate wave-lengths are—

487·91	Strong.
[486 07]	F.
484·71	Not quite so strong.
480 52	Strong.
476·50	Fairly strong characteristic triplet.
473·53	
472 56	

It is necessary to anticipate Mr. Crookes' communication, and to state that when the current is passed from the induction coil in one direction, that end of the capillary tube next the positive pole appears of a redder, and that next the negative pole of a bluer hue. There are, in effect, two spectra, which Mr. Crookes has succeeded in separating to a considerable extent. Mr. E. C. Baly, who has noticed a similar phenomenon,[1] attributes it to the presence of two gases. The conclusion would follow that what we have termed "argon" is in reality a mixture of two gases which have as yet not been separated. This conclusion, if true, is of great importance, and experiments are now in progress to test it by the use of other physical methods. The full bearing of this possibility will appear later.

The presence of a small quantity of nitrogen interferes greatly with the argon spectrum. But we have found that in a tube with platinum electrodes, after the discharge has been passed for four hours, the spectrum of nitrogen disappears, and the argon spectrum manifests itself in full purity. A specially constructed tube with magnesium electrodes, which we hoped would yield good results, removed all traces of nitrogen, it is true; but hydrogen was evolved from the magnesium, and showed its characteristic lines very strongly. However, these are easily identified. The gas evolved on heating magnesium *in vacuo*, as proved by a separate experiment, consists entirely of hydrogen.

Mr. Crookes has proved the identity of the chief lines of the spectrum of gas separated from air-nitrogen by aid of magnesium with that remaining after sparking the air-nitrogen with oxygen in presence of caustic soda solution.

Prof. Schuster also has found the principal lines identical in the spectra of the two gases, as observed by the jar discharge at atmospheric pressure.

XII. *Solubility of Argon in Water.*

Determinations of the solubility in water of argon, prepared by sparking, gave 3·94 volumes per 100 of water at 12°. The solubility of gas prepared by means of magnesium was found to be 4·05 volumes per 100 at 13·9°. The gas is therefore about 2½ times as soluble as nitrogen, and possesses approximately the same solubility as oxygen.

The fact that argon is more soluble than nitrogen would lead us to expect it in increased proportion in the dissolved gases of rain water. Experiment has confirmed this anticipation. "Nitrogen" prepared from the dissolved gases of water supplied from a rain-water cistern was weighed upon two occasions. The weights, corresponding to those recorded in § I., were 2·3221 and 2·3227, showing an excess of 24 milligrams above the weight of true nitrogen. Since the corresponding excess for "atmospheric nitrogen" is 11 milligrams, we conclude that the water "nitrogen" is relatively more than twice as rich in argon.

On the other hand, gas evolved from the hot spring at Bath, and collected for us by Dr. A. Richardson, gave a residue after removal of oxygen and carbonic acid, whose weight was only about midway between that of true and atmospheric nitrogen.

XIII. *Behaviour at Low Temperatures.*[1]

Preliminary experiments, carried out to liquefy argon at a pressure of about 100 atmospheres, and at a temperature of − 90°, failed. No appearance of liquefaction could be observed.

Prof. Charles Olszewski, of Cracow, the well-known authority on the constants of liquefied gases at low temperatures, kindly offered to make experiments on the liquefaction of argon. His results are embodied in a separate communication, but it is allowable to state here that the gas has a lower critical temperature (− 121°) and a lower boiling point (− 187°) than oxygen, and that he has succeeded in solidifying argon to white crystals, melting at − 189·6°. The density of the liquid is approximately 1·5, that of oxygen being 1·124, and of nitrogen 0·885. The sample of gas he experimented with was exceptionally pure, and had been prepared by help of magnesium. It showed no trace of nitrogen when examined in a vacuum tube.

XIV. *Ratio of Specific Heats.*

In order to decide regarding the elementary or compound nature of argon, experiments were made on the velocity of sound in it. It will be remembered that, from the velocity of sound in a gas, the ratio of specific heat at constant pressure to that at constant volume can be deduced by means of the equation

$$n\lambda = v = \sqrt{\left\{\frac{e}{d}(1+at)\frac{C_p}{C_v}\right\}},$$

when n is the frequency, λ the wave-length of sound, v its velocity, e the isothermal elasticity, d the density, $(1 + at)$ the temperature correction, C_p the specific heat at constant pressure, and C_v that at constant volume. In comparing two gases at the same temperature, each of which obeys Boyle's law with sufficient approximation, and in using the same sound, many of these terms disappear, and the ratio of specific heats of one gas may be deduced from that of the other, if known, by means of the proportion

$$\lambda^2 d : \lambda'^2 d' :: 1{\cdot}41 : x,$$

where, for example, λ and d refer to air, of which the ratio is 1·41, according to observations by Röntgen, Wüllner, Kayser, and Jamin and Richard.

Two completely different series of observations, one in a tube of about 2 mm. diameter, and one in one of 8 mm., made with entirely different samples of gas, gave, the first, 1·65 as the ratio, and, the second, 1·61.

Experiments made with the first tube, to test the accuracy of its working, gave for carbon dioxide the ratio 1·276, instead of 1·288, the mean of all previous determinations; and the half wave-length of sound in hydrogen was found to be 73·6, instead of 74 5, the mean of those previously found. The ratio of the specific heats of hydrogen found was 1·39, instead of 1·402.

There can be no doubt, therefore, that argon gives practically the ratio of specific heats, viz. 1·66, proper to a gas in which all the energy is translational. The only other gas which has been found to behave similarly is mercury gas, at a high temperature.

XV. *Attempts to induce Chemical Combination.*

Many attempts to induce argon to combine will be described in full in the complete paper. Suffice it to say here, that all such attempts have as yet proved abortive. Argon does not combine with oxygen in presence of alkali under the influence of the electric discharge, nor with hydrogen in presence of acid or alkali also when sparked; nor with chlorine, dry or moist, when sparked; nor with phosphorus at a bright-red heat, nor with sulphur at bright redness. Tellurium may be distilled in a current of the gas; so may sodium and potassium, their metallic lustre remaining unchanged. It is unabsorbed by passing it over fused red-hot caustic soda, or soda-lime heated to bright redness; it passes unaffected over fused and bright red-hot potassium nitrate; and red-hot sodium peroxide does not combine with it. Persulphides of sodium and calcium

[1] *Proc. Phys. Soc.*, 1893, p. 147. He says:—"When an electric current is passed through a mixture of two gases, one is separated from the other and appears in the negative glow."

[1] The arrangements for the experiments upon this branch of the subject were left entirely in Prof. Ramsay's hands.

[2] Kundt and Warburg, *Pogg. Ann.* vol. cxxxv. pp. 337 and 527.

are also without action at a red heat. Platinum black does not absorb it, nor does platinum sponge, and wet oxidising and chlorinating agents, such as nitro-hydrochloric acid, bromine water, bromine and alkali, and hydrochloric acid and potassium permanganate, are entirely without action. Experiments with fluorine are in contemplation, but the difficulty is great; and an attempt will be made to produce a carbon arc in the gas. Mixtures of sodium and silica and of sodium and boracic anhydride are also without action, hence it appears to resist attack by nascent silicon and by nascent boron.

XVI. *General Conclusions.*

It remains, finally, to discuss the probable nature of the gas, or mixture of gases, which we have succeeded in separating from atmospheric air, and which we provisionally name *argon.*

The presence of argon in the atmosphere is proved by many lines of evidence. The high density of "atmospheric nitrogen," the lower density of nitrogen from chemical sources, and the uniformity in the density of samples of chemical nitrogen prepared from different compounds, lead to the conclusion that the cause of the anomaly is the presence of a heavy gas in air. If that gas possess the density 20 compared with hydrogen, "atmospheric" nitrogen should contain of it approximately 1 per cent. This is, in fact, found to be the case. Moreover, as nitrogen is removed from air by means of red-hot magnesium, the density of the remaining gas rises proportionately to the concentration of the heavier constituent.

Second. This gas has been concentrated in the atmosphere by diffusion. It is true that it has not been freed from oxygen and nitrogen by diffusion, but the process of diffusion increases, relatively to nitrogen, the amount of argon in that portion which does not pass through the porous walls. This has been proved by its increase in density.

Third. As the solubility of argon in water is relatively high, it is to be expected that the density of the mixture of argon and nitrogen, pumped out of water along with oxygen, should, after the removal of the oxygen, be higher than that of "atmospheric" nitrogen. Experiment has shown that the density is considerably increased.

Fourth. It is in the highest degree improbable that two processes, so different from each other, should manufacture the same product. The explanation is simple if it be granted that these processes merely eliminate nitrogen from an "atmospheric" mixture. Moreover, as argon is an element, or a mixture of elements, its manufacture would mean its separation from one of the substances employed. The gas which can be removed from red-hot magnesium in a vacuum has been found to be wholly hydrogen. Nitrogen from chemical sources has been practically all absorbed by magnesium, and also when sparked in presence of oxygen; hence argon cannot have resulted from the decomposition of nitrogen. That it is not produced from oxygen is sufficiently borne out by its preparation by means of magnesium.

Other arguments could be adduced, but the above are sufficient to justify the conclusion that argon is present in the atmosphere.

The identity of the leading lines in the spectrum, the similar solubility and the similar density, appear to prove the identity of the argon prepared by both processes.

Argon is an element, or a mixture of elements, for Clausius has shown that if K be the energy of translatory motion of the molecules of a gas, and H their whole kinetic energy, then

$$\frac{K}{H} = \frac{3(C_p - C_v)}{2C_v},$$

C_p and C_v denoting as usual the specific heat at constant pressure and at constant volume respectively. Hence if, as for mercury vapour and for argon (§ XIV.), the ratio of specific heats $C_p : C_v$ be $1\frac{2}{3}$, it follows that $K = H$, or that the whole kinetic energy of the gas is accounted for by the translatory motion of its molecules. In the case of mercury the absence of interatomic energy is regarded as proof of the monatomic character of the vapour, and the conclusion holds equally good for argon.

The only alternative is to suppose that if argon molecules are di- or polyatomic, the atoms acquire no relative motion, even of rotation, a conclusion exceedingly improbable in itself and one postulating the sphericity of such complex groups of atoms.

Now a monatomic gas can be only an element, or a mixture of elements; and hence it follows that argon is not of a compound nature.

From Avogadro's law, the density of a gas is half its molecular weight; and as the density of argon is approximately 20, hence its molecular weight must be 40. But its molecule is identical with its atom; hence its atomic weight, or, if it be a mixture, the mean of the atomic weights of that mixture, taken for the proportion in which they are present, must be 40.

There is evidence both for and against the hypothesis that argon is a mixture: for, owing to Mr. Crookes' observations of the dual character of its spectrum; against, because of Prof. Olszewski's statement that it has a definite melting point, a definite boiling point, and a definite critical temperature and pressure; and because on compressing the gas in presence of its liquid, pressure remains sensibly constant until all gas has condensed to liquid. The latter experiments are the well-known criteria of a pure substance; the former is not known with certainty to be characteristic of a mixture. The conclusions which follow are, however, so startling, that in our future experimental work we shall endeavour to decide the question by other means.

For the present, however, the balance, of evidence seems to point to simplicity. We have therefore to discuss the relations to other elements of an element of atomic weight 40. We inclined for long to the view that argon was possibly one or more than one of the elements which might be expected to follow fluorine in the periodic classification of the elements—elements which should have an atomic weight between 19, that of fluorine, and 23, that of sodium. But this view is completely put out of court by the discovery of the monatomic nature of its molecules.

The series of elements possessing atomic weights near 40 are:—

Chlorine	35·5
Potassium	39·1
Calcium	40·0
Scandium	44·0

There can be no doubt that potassium, calcium, and scandium follow legitimately their predecessors in the vertical columns, lithium, beryllium, and boron, and that they are in almost certain relation with rubidium, strontium, and (but not so certainly) yttrium. If argon be a single element, then there is reason to doubt whether the periodic classification of the elements is complete; whether, in fact, elements may not exist which cannot be fitted among those of which it is composed. On the other hand, if argon be a mixture of two elements, they might find place in the eighth group, one after chlorine and one after bromine. Assuming 37 (the approximate mean between the atomic weights of chlorine and potassium) to be the atomic weight of the lighter element, and 40 the mean atomic weight found, and supposing that the second element has an atomic weight between those of bromine, 80, and rubidium, 85·5, viz. 82, the mixture should consist of 93·3 per cent. of the lighter, and 6·7 per cent of the heavier element. But it appears improbable that such a high percentage as 6·7 of a heavier element should have escaped detection during liquefaction.

If it be supposed that argon belongs to the eighth group, then its properties would fit fairly well with what might be anticipated. For the series, which contains

$$Si^{?\,IV}, \quad P_4^{III\text{ and }V}, \quad S_{8\text{ to }2}^{II\text{ to }VI}, \quad \text{and } Cl^{I\text{ to }VII},$$

might be expected to end with an element of monatomic molecules, of no valency, *i.e.* incapable of forming a compound, or, if forming one, being an octad; and it would form a possible transition to potassium, with its monovalence, on the other hand. Such conceptions are, however, of a speculative nature; yet they may be perhaps excused, if they in any way lead to experiments which tend to throw more light on the anomalies of this curious element.

In conclusion, it need excite no astonishment that argon is so indifferent to reagents. For mercury, although a monatomic element, forms compounds which are by no means stable at a high temperature in the gaseous state; and attempts to produce compounds of argon may be likened to attempts to cause combination between mercury gas at 800° and other elements. As for the physical condition of argon, that of a gas, we possess no knowledge why carbon, with its low atomic weight, should be a solid, while nitrogen is a gas, except in so far as we ascribe molecular complexity to the former and comparative molecular simplicity to the latter. Argon, with its comparatively low density and its molecular simplicity, might well be expected to rank among the gases. And its inertness, which has suggested its name, sufficiently explains why it has not previously been discovered as a constituent of compound bodies.

We would suggest for this element, assuming provisionally that it is not a mixture, the symbol A.

We have to record our thanks to Messrs. Gordon, Kellas, and Matthews, who have materially assisted us in the prosecution of this research.

ON THE SPECTRA OF ARGON.[1]

Through the kindness of Lord Rayleigh and Prof. Ramsay I have been enabled to examine the spectrum of this gas in a very accurate spectroscope, and also to take photographs of its spectra in a spectrograph fitted with a complete quartz train. The results are both interesting and important, and entirely corroborate the conclusions arrived at by the discoverers of argon.

Argon resembles nitrogen in that it gives two distinct spectra according to the strength of the induction current employed. But while the two spectra of nitrogen are different in character, one showed fluted bands and the other sharp lines, the argon spectra both consist of sharp lines. It is, however, very difficult to get argon so free from nitrogen that it will not show the nitrogen flutings superposed on its own special system of lines. I have used argon prepared by Lord Rayleigh, Prof. Ramsay, and myself, and, however free it was supposed to be from nitrogen, I could always detect the nitrogen bands in its spectrum. These, however, soon disappear when the induction spark is passed through the tube for some time, varying from a a few minutes to a few hours.

The pressure of argon giving the greatest luminosity and most brilliant spectrum is 3 mm. (The best pressure for nitrogen is 75 or 80 mm.) At this point the colour of the discharge is an orange-red, and the spectrum is rich in red rays, two being especially prominent at wave-lengths 696 56 and 705·64. On passing the current the traces of nitrogen bands soon disappear, and the argon spectrum is seen in a state of purity.

If the pressure is further reduced, and a Leyden jar intercalated in the circuit, the colour of the luminous discharge changes from red to a rich steel-blue, and the spectrum shows an almost entirely different set of lines. The two spectra, called for brevity red and blue, are shown on the large map, the upper spectrum being that of "blue" argon, and the lower one that of "red" argon. It is not easy to obtain the blue colour and spectrum entirely free from the red. It appears that a low electromotive force (3 cm. spark, or 27,600 volts) is required to bring out the red, and a high E.M.F. and a very hot spark for the blue. The red glow is produced by the positive spark, and the blue by the negative spark.

I have taken photographs of the two spectra of argon partly superposed. In this way their dissimilarity is readily seen.[2] In the spectrum of the blue glow I have counted 119 lines, and in that of the red glow 80 lines, making 199 in all. Of these 26 appear to be common to both spectra.

The disappearance of the red glow and the appearance of the blue glow in argon as the exhaustion increases also resembles the disappearance of the red line of hydrogen when exhaustion is raised to a high point.

I have prepared tubes containing other gases as well as nitrogen at different pressures, and have examined their spectra both by eye observations and by photography. The sharp line spectrum of nitrogen is not nearly so striking in brilliancy, number or sharpness of lines as are those of argon, and the most careful scrutiny fails to show any connection between the spectra. I can detect no lines in common. Between the spectra of argon and the band spectrum of nitrogen there are two or three close approximations of lines, but a projection on the screen of a magnified image of the two spectra partly superposed will show that two at least of these are not really coincidences.

I have found no other spectrum-giving gas or vapour yield spectra at all like those of argon, and the apparent coincidences in some of the lines, which on one or two occasions are noticed, have been very few, and would probably disappear on using a higher dispersion. Having once obtained a tube of argon giving the pure spectra, I can make no alteration in it, other than what I have explained takes place on varying the spark or increasing the exhaustion, when the two spectra change from one to the other. As far, therefore, as spectrum work can decide, the verdict must, I think, be that Lord Rayleigh and Prof. Ramsay have added one, if not two, members to the family of elementary bodies.

The Two Spectra of Argon.

The totals are :—

119 lines in the "blue" spectrum.
80 lines in the "red" spectrum.

199 total lines.
26 lines common to the two spectra.

[1] Abstract of a paper by Mr. William Crookes, F.R.S.

[2] Photographs of the different spectra of argon, and other gaseous spectra for comparison, were projected on the screen.

THE LIQUEFACTION AND SOLIDIFICATION OF ARGON.[1]

Having been furnished, by Prof. Ramsay's kindness, with a sample of the new gas, argon, I have carried out experiments on its behaviour at a low temperature and at high pressures, in order to contribute, at least in part, to the knowledge of the properties of this interesting body.

Four series of experiments in all were carried out, two with the object of determining the critical temperature and pressure of argon, as well as measuring its vapour pressure at several other low temperatures, while two other series served to determine its boiling and freezing points under atmospheric pressure, as well as its density at its boiling point.

A detailed description of these experiments will be given in another place; I shall here give only a short description of the manner in which they were made.

For the first two experiments I made use of a Cailletet's apparatus. Its metallic manometer had been previously compared with the readings of a mercury manometer. As cooling agent I used liquid ethylene, boiling under diminished pressure. The glass tube of Cailletet's apparatus was so arranged that the portion immersed in the liquid ethylene had comparatively thin walls (not exceeding 1 mm.), so as to equalise the external and internal temperature as quickly as possible.

In both the other experiments the argon was contained in a burette, closed at both ends with glass stop-cocks. By connecting the lower end of the burette with a mercury reservoir, the argon was transferred into a narrow glass tube fused at its lower end to the upper end of the burette, and in which the argon was liquefied, and its volume in the liquid state measured. In these two series of experiments liquid oxygen, boiling under atmospheric or under diminished pressure, was employed as a cooling agent. I made use of a hydrogen thermometer in all these experiments to measure low temperatures.

Determination of the Critical Constants of Argon.

As soon as the temperature of liquid ethylene had been lowered to −128°·6, the argon easily condensed to a colourless liquid under a pressure of 38 atmospheres. On slowly raising the temperature of the ethylene, the meniscus of the liquid argon became less and less distinct, and finally vanished.

Seven determinations of the disappearance of the meniscus proved that the critical pressure was 50·6 atmospheres; but determinations of the critical temperature show slight differences.

The mean of the seven estimations of the critical temperature is −121°, and this may be taken as the critical temperature of argon.

The vapour pressures at ten temperatures from −128·6 to 139·1 were also determined.

Determination of the Boiling and Freezing Points.

Two hundred cubic centimetres of liquid oxygen, prepared in my large apparatus,[2] was poured into a glass vessel with quadruple walls, so as to isolate the liquid from external heat. After the liquid oxygen had been thus poured under atmospheric pressure, a great part of it evaporated, but there still remained about 70 c.c. boiling under atmospheric pressure. A calibrated tube, intended to receive the argon to be liquefied, and the hydrogen thermometer were immersed in the boiling oxygen. At this temperature (−182°·7[1]) on admitting argon, no appearance of liquefaction could be noticed, even when compressed by adding a quarter of an atmosphere pressure to that of the atmosphere. This shows that its boiling point lies below that of oxygen. But on diminishing the temperature of the liquid oxygen below −187°, the liquefaction of argon became manifest. When liquefaction had taken place, I carefully equalised the pressure of the argon with that of the atmosphere, and regulated the temperature, so that the state of balance was maintained for a long time. This process gives the boiling point of argon under atmospheric pressure. Four experiments gave the numbers −186°·7, −186°·8, −187°·0, and −187°·3. The mean is −186°·9, which I consider to be the boiling point under atmospheric pressure (740·5 mm.).

The quantity of argon used for these experiments, reduced to normal temperature and pressure, was 99·5 c.c.; the quantity of liquid corresponding to that volume of gas was approximately 0·114 c.c. Hence the density of argon at its boiling point may be taken as approximately 1·5. Two other determinations of the density of liquid argon, for which I employed still smaller quantities of the gas, yielded rather smaller numbers. Owing to the small amount of argon used for these experiments, the numbers given cannot lay claim to great exactness; yet they prove that the density of liquid argon at its boiling point (−187°) is much higher than that of oxygen, which I have found, under similar conditions, to be 1·124.

By lowering the temperature of the oxygen to −191° by slow exhaustion, the argon froze to a crystalline mass, resembling ice; on further lowering temperature it became white and opaque. When the temperature was raised it melted; four observations which I made to determine its melting point gave the numbers: −189°·0, −190°·6, −189°·6, and −189°·4. The mean of these numbers is −189°·6; and this may be accepted as the melting point of argon.

In the following table I have given a comparison of physical constants, in which those of argon are compared with those of other so called permanent gases. The data are from my previous work on the subject.

Name.	Critical temperature.	Critical pressure.	Boiling point.	Freezing point.	Freezing pressure.	Density of gas.	Density of Liquid at boiling point.	Colour of liquid.
	Below.	Atmos.			mm.			
Hydrogen (H_2)	−220·0	20·0	?	?	?	1·0	?	Colourless.
Nitrogen (N_2)	−146·0	35·0	−194·4	214·0	60	14·0	0·885	,,
Carbonic oxide (CO)	−139·5	35·5	−190·0	−207·0	100	14·0	?	,,
Argon (A_1)	−121·0	50·6	−187·0	−189·6	?	19·9	About 1·5	,,
Oxygen (O_2)	−118·8	50·8	−182·7	?	?	16·0	1·124	Bluish.
Nitric oxide (NO)	−93·5	71·2	−153·6	−167·0	138	15·0	?	Colourless.
Methane (CH_4)	−81·8	54·9	−164·0	−185·8	80	8·0	0·415	,,

As can be seen from the foregoing table, argon belongs to the so-called "permanent" gases, and, as regards difficulty in liquefying it, it occupies the fourth place, viz. between carbon monoxide and oxygen. Its behaviour on liquefaction places it nearest to oxygen, but it differs entirely from oxygen in being solidifiable; as is well known, oxygen has not yet been made to assume a solid state.

The high density of argon rendered it probable that its liquefaction would take place at a higher temperature than that

[1] Abstract of a paper by Dr. K. Olszewski, Professor of Chemistry in the University of Cracow.

[2] *Bulletin international de l'Academie de Cracovie*, June 1890; also Wiedemann's *Beiblätter*, vol. 15, p. 29.

[1] I have re-determined the boiling point of oxygen, using large quantities of oxygen, and a hydrogen thermometer of much larger dimensions than previously. The registered temperature is 1°·3 lower than that which I previously recorded.

at which oxygen liquefies. Its unexpectedly low critical temperature and boiling point seem to have some relation to its unexpectedly simple molecular constitution.

After the reading of the three foregoing papers, a discussion followed, of which we give the most important parts.

Dr. H. E. Armstrong said that the case for the existence of the new constituent was undoubtedly a very strong one, and would, no doubt, meet with very considerable criticism throughout the world. But, apart from the facts which were brought forward, there was a portion which was of a wildly speculative character: viz. the portion dealing with the probable nature of this new element. Apparently the authors were not entirely satisfied with the evidence to be adduced from the application of the Clausius method for the determination of the atomicity of the gas. It was quite conceivable that the condition which Prof. Ramsay pointed out as being the only alternative to the one which was apparently accepted by the authors of the communication, is a conceivable condition. It was quite likely that the two atoms existed so firmly locked in each other's embrace, that there was no possibility for them to take notice of anything outside, and that they were perfectly content to roll on together without taking up any of the energy that is put into the molecule. The spectroscopic evidence was not sufficient to justify the conclusion that the new gas was a mixture. The great difficulty in accepting the conclusion that the gas was an element having a molecular weight of 40, and an atomic weight of 40, arose from the difficulty of placing an element of that kind. All these matters, however, would have to be discussed later on more fully: they were matters which could only be discussed very gradually, as more was learned about the new substance.

Prof. A. W. Rücker said that the one certain fact which came out indisputably from the facts described by Prof. Ramsay was, that in spite of the doubt which may have existed on the matter for the last few weeks or months, it was certain that they had now a new constituent of the atmosphere. It seemed to him that one of the most interesting results arrived at from the physical point of view was the fact that the gas was monatomic, arguing from the determined ratio of the specific heats. The experiments carried out by Lord Rayleigh and Prof. Ramsay made it certain that the element had the particular ratio of specific heats mentioned. Well, then the question arose, What followed from this? In order that this ratio might be obtained it was necessary that the atom with which they were dealing should be regarded as spherical. In conclusion, he said that whatever the effect might be upon the great chemical generalisation of Mendeléeff, that was, after all, an empirical law based at present upon no dynamical foundation. If it held its own in this case, it would, of course, strengthen the belief in it, but, on the other hand, the law did not stand on the footing of those great mechanical generalisations which could not be upset without upsetting the whole of our fundamental notions of science.

Prof. Roberts Austen remarked that in the Bessemer process alone some ten tons of iron were put into a vessel called a converter. During the conversion no less than 100.000 cubic feet of air passed through the fluid iron. Therefore 1000 cubic feet of argon went somewhere. He had taken Bessemer-blown metal which had not been treated with ferro-manganese, and pumped out forty times its volume of gas, of which one-twentieth was nitrogen. In that nitrogen he had not been able to detect any argon that could not have come from the water which was necessarily used in the manipulation. It remained to be seen whether the argon found its way into the iron, and if it stayed there, whether certain peculiarities that made Bessemer metal different from other kinds of steel could be traced to some of this 1000 cubic feet of argon, which had either passed into the air or into the iron.

Lord Rayleigh, in the course of his remarks, referred to the argument in favour of the monatomicity of the gas. Of course, what was directly proved by the experiment was that the whole, or nearly the whole, of the energy put into the gas, when it was heated, was devoted to increasing the energy of its translatory motion, and that no margin remained over to be attributed to intermolecular or interatomic motion. At first sight it seemed rather a strange thing that there should be no rotation in the molecules of the gas. That condition was met by the suggestion which had been put forward, and which had also been communicated by Prof. Fitzgerald, in the following words: "The reason why the ratio of specific heats of 1·66 is supposed to prove monatomicity in a gas is because in a monatomic gas there are no internal motions of any consequence. Now, if the atoms in a molecule are so bound together that hardly any internal motions exist, it would, so far as specific heat is concerned, behave like a monatomic element. That the atoms in argon may be very closely connected seems likely from its very great chemical inertness. Hence the conclusion from the ratio of its specific heats may be, not that it is monatomic, but that its atoms are so bound together in its molecule that the molecule behaves as a whole as if it was monatomic." It was difficult to conceive the possibility of such an eccentrically-shaped atom as that to move about without acquiring a considerable energy of rotation. He therefore thought that the only interpretation was that the gas was monatomic.

Lord Kelvin remarked as to the condition under which the ratio of the specific heats could be exactly 1·66, that he did not admit that a spherical atom could fulfil that condition. A spherical atom would not be absolutely smooth. In other words, it must be a Boscovitch point. In fact, the only kind of atom that could be conceived as giving, in the dynamical theory of heat, rigorously the ratio 1·66 for the specific heat, was the ideal Boscovitch mathematical point endowed with the property of inertia, and with the other property of acting upon neighbouring points with a force depending upon distance.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—A meeting was held on Monday last, in the rooms of the Regius Professor of Medicine, at the University Museum, and was attended by all the scientific professors and teachers of the University, with the exception of one or two, who, being unable to be present, expressed their concurrence by letter. It was unanimously resolved that a memorial connecting Sir Henry Acland's name in a permanent manner with the University Museum should be established. Sympathy was generally expressed with the scheme already before the public, but it was felt that a more distinctly personal memorial in the Museum was desirable. The future consideration of the proposal will be the subject of a second meeting to be held shortly.

Mr. A. Trevor Battye delivered a lecture before the Ashmolean Society, on Monday last, entitled "Ice-bound in Kolguev." The lecturer narrated his personal experiences, and gave an account of the manners and customs of the Samoyedi, illustrated by numerous lantern-slides and specimens, and he also described the ornithological features of the island.

The Sibthorpian Professor of Rural Economy, Mr. R. Warington, F.R.S., gave his inaugural lecture to a large audience in the University Museum on Monday afternoon. The subject chosen was "The Present Relations of Agricultural Art and Natural Science." He deplored the want of really good agricultural and horticultural libraries.

CAMBRIDGE.—The election to the Sadleirian Professorship of Pure Mathematics, vacant by the death of Prof. Cayley, will be held on Monday, February 25, at 2.30 p.m. The names and testimonials of candidates are to be sent to the Vice-Chancellor by Monday, February 18. The electors are the Vice-Chancellor (Mr. Austen Leigh), Dr. Phear, Dr. Ferrers, Dr. Taylor, Sir G. G. Stokes, Sir R. S. Ball, and Prof. G. H. Darwin.

The Observatory Syndicate propose the appointment of a Second Assistant Observer, at a stipend of £100 a year. The appointment will be for five years, and will be made by the Director, with the consent of the Vice-Chancellor.

SCIENTIFIC SERIALS.

American Meteorological Journal, January.—Solar magnetism in meteorology, by Prof. F. H. Bigelow. This article contains some general remarks on the present state of the problems arising out of the relations that have been traced by the author's study of solar magnetism and its influences upon meteorological phenomena. Prof. Bigelow endeavours to show that the usually accepted mode of propagation of energy from the sun to the earth is not the only one that exists, and suggests that another possible mode is due to polarised solar magnetic force, such as surrounds a magnet. The progress of the investigation was made in three distinct stages: (1) the detection of the true period of the sun's rotation; (2) the determination of the intensity of the solar magnetic field from meridian to meridian of the sun; (3) the discovery of the inversion of the solar magnetism in certain periods. The author expresses the opinion that the convectional hypothesis of cyclones is untenable, and endeavours to show, from an examination of the American meteorological curves for the years 1878–93, that the three systems—the one at the sun, that of the magnetic field in the northern hemisphere, and that of the American meteorological field—vary together in block from year to year.—Variations in the character of the seasons, by H. Gawthrop. The division of the year into four seasons is traditional, but when measured as phases of weather, it is not possible to fix these periods within definite limits. The author's investigation leads him to conclude that the primal cause for the variations in the character of the seasons must be traced back through all the effects of diurnal and seasonal insolation, and of the cyclonic storms in the lower atmosphere.

Wiedemann's Annalen der Physik und Chemie, No. 1, 1895.—Electromagnetic pulling force, by Max Weber. An iron wire whose length is very great in comparison with its thickness, experiences a pulling force proportional to the field intensity, its magnetisation, and its sectional area, when its end lies in a magnetic field, and its axis is parallel to the lines of force. If the lines of force are perpendicular to the axis of the wire, it also experiences a pulling force along its axis, which is, however, smaller in iron than the former force. The ratio of the pull along the lines of force to that across it is about 100 in moderate fields (such as H = 100), but with increasing strength of field it quickly decreases, and appears to approach unity.—Different forms of multiple resonance, by V. Bjerknes. The conclusion usually drawn from Sarasin and de la Rive's experiments with electric waves propagated along wires, that there are as many stationary wave systems as nodal systems are exhibited by the resonator, is erroneous. These periods are due to the resonator, which resounds to a simple sine oscillation at different points. The only reliable method is to study the wave systems with "indifferent" indicators, such as spark micrometers, electrometers, bolometers, and small thermo-couples. The difference between electric waves and light waves is that the latter are continually maintained, while the former are damped.—Total reflection of light in dense crystalline substances, by R. Camerer. The measurement of the index of refraction of substances of a crystalline structure by total reflection is attended with various difficulties. In some cases, there is no well-defined limit of total reflection, as in the case of paraffin or beeswax planed or cast on mercury. When the same substances are cast or pressed on the surface of the prism, two limits, polarised at right angles to each other, are observed. The author explains this by supposing that in the latter case the substances crystallise in a uniaxial form, with their optical axes perpendicular to the surface, while in the former case they are biaxial.—Elastic behaviour of zinc at different temperatures, by Erich Zimansky. It appears that the suddenness or otherwise of the cooling of cast zinc has no very decided influence upon its brittleness. It is not hardened by rapid cooling to anything like the extent that iron is.

Bulletin de la Société des Naturalistes de Moscou, 1894, No. 2.—On the Mastodons of Russia, and their relations to the Mastodons of other regions, by Mme. Marie Pavlova, being a summing up of her larger work, now ready for print. Its conclusions are: (1) It is the group *Mastodon Zygolophodon*, represented by *M. Borsoni*, *M. ohioticus*, and their varieties, which had a very great spreading in south-west Russia during the Miocene and the Pliocene periods. (2) None of these forms is specific to Russia, all having been widely spread in West Europe and North America. (3) The group of *M. Bunolophodon* is only known till now through a very limited number of specimens of *M. arvernensis*, while this group is widely represented in West Europe, Asia, and America. (4) The close resemblance between the Mastodons of Eurasia and America confirms once more the connection which existed between the two continents during the Tertiary period.—The Post-pliocene mammals of East Russia, by Prof. Stuckenberg (in French). They are: *Rhinoceros tichorhinus*, Fischer, and *Rh. Merckii*, Jaeger; *Elasmotherium Fischeri*, Desmarest, which has never been found in Perm, Ufa, Vyatka, Kazan, Nizhni Novgorod, and Simbirsk, but only further south, *i.e.* in Samara, Penza, and Saratoff; *Equus caballus*, very common—the fossil horses having already been made the subject of special studies by Mme. Pavlova; *Cervus tarandus*, *C. elaphus*, *C. alces* (*Alces palmata*), and *C. megaceros* (*Megaceros hibernicus*), Owen; *Antilope saiga*, Pallas; *Bos priscus*, and *Bos primigenius*, the latter very rare; *Ovibos moschatus*, Blainville (*O. fossilis*, Rütimeyer); *Sus*, sp.; *Elephas primigenius*, very common—some molars offering great divergences from the usual type—and another yet undetermined species of *Elephas*, of which one molar is kept in the museum of Kazan; though like as a whole to a mammoth tooth, it has well-defined peculiarities of structure; *Castor fiber*; *Ursus arctos*; and an undetermined species of *Canis*. All these remains have rarely been found *in situ*, but chiefly in remodelled river deposits.—The second part and conclusions of the work of B. Lwoff, on the embryology of mammals. The current theory of gastrulation is shown not to be supported by direct observation, and a new theory is proposed.—On the use of Bouguer's formula in the study of gravitation anomalies, by Prof. Th. Sloudsky (in French).—On some land shells collected by M. Krishtafowitsch on the Vorobievy Hills, near Moscow, by Dr. Zickendrath. They belong to species now quite common in Middle Europe (*Hyalinia*, *Helix*, *Cionella*, *Pupa*, *Succinea*, &c.), and originate from the period when the Vorobievo plateau was covered with thick marshy forests; they can by no means be considered as belonging to any ice period.—Entomological and botanical notes from Sarepta, by Alex. Becker (in German).

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, January 9.—Dr. Henry Woodward, F.R.S., President, in the chair.—The formation of oolite, by E. B. Wethered. In previous communications the author has described pisolites formed by the growth of *Girvanella*, and some true oolitic granules having a like origin. He had previously expressed the opinion that all oolitic granules are of organic origin, and the facts described in the present paper give support to this view. He described the form of the granules, which frequently exhibit a series of concentric layers of calcium carbonate around a nucleus, and also dark striæ and patches, the former placed more or less at right-angles to the nucleus. The concentric layers often exhibit an irregularity which the author maintained to be incompatible with their chemical origin. Again, granules are found made of calcium carbonate occurring in two forms—a clear crystalline portion representing the organic structural part, and an amorphous portion consisting of ordinary carbonate of lime, which is either infilling or secreted material, possibly both. In discussing the origin of the crusts around the nuclei the author treated of the radial structure which is so marked a feature in the crust of oolitic granules. This structure has the appearance of light and dark striæ when seen by reflected light: the light are tubules which have grown at right-angles to the nucleus, while the dark are secondary formations. He referred to Rothpletz's description of the oolitic granules of the great Salt Lake, which are stated to have originated from the growth of lime-secreting algæ, and thinks it possible that the fossil forms are of like origin, though not necessarily due to organisms allied to algæ, and possibly even lower in the scale of life. In his opinion *Girvanella*—the first type of oolite-forming organism discovered—is simply a tubule. A long discussion followed the reading of the paper. The President thought that the author had placed evidence before the meeting sufficient to prove the organic origin of many of his oolitic granules. Mr. G. F. Harris believed that while most geologists would possibly agree as to the organic nature of the tubules in the pisolites referred to, they would not be unanimous in recognising the tubular structure in many of the oolitic granules shown. Many of the features presented by oolitic granules, and brought forward by the author as evidence of the organic origin of oolite, could be explained by the alteration effected in them since their original formation. Mr. E. T. Newton agreed with the author that the irregular tubules termed *Girvanella*, and seen sometimes within and sometimes on the outside of oolitic granules, were of organic origin, but he thought that the characteristic concentric and radiated structure of oolitic granules was entirely different, and not due to concentric tubules. Dr. G. J. Hinde did not think that the author was right in his interpretation of the concentric layers so common in ordinary oolitic grains as tubular forms of growth. In his (the speaker's) opinion these concentric lines might indicate layers of growth, but they were not in any sense tubules. Mr. A. C. Seward expressed himself in agreement with the main contention in reference to the occurrence of organic tubular structures in the oolitic grains described by the author; but the explanation offered by the author with regard to the radiating structure seen in certain grains he regarded as unsatisfactory, their general appearance being much more suggestive of secondary changes in the oolitic grains, which had no direct connection with the *Girvanella*-tubules. Prof. Judd said that as far back as 1862 the eminent botanist Dr. Ferdinand Cohn had pointed out the important part played by algæ in the formation of the Sprudelstein of Carlsbad and other calcareous rocks. At a later date Bornet, the eminent French algologist, had insisted no less strongly on the work done in perforation and breaking-up calcareous fragments by other plants. The speaker was inclined to regard some of the structures (especially certain of the radial ones) as due to the action of destructive rather than to constructive organisms. Mr. H. B. Woodward referred to the modern formation of oolite-grains in waters charged with bicarbonate of lime, whether in proximity to calcareous springs or coral reefs. He thought that the slides exhibited by the author did not show connection between the *Girvanella* and the concentric and radiate bands of oolite-grains. Prof. Seeley believed that some of the photographs exhibited a structure which, although imperfectly preserved, might be compared with the sections of nullipores which the speaker brought before the British Association at Bath in 1888, as evidence that some grains of oolite are of organic origin. Mr. Rutley said that, with regard to the nuclear portions of some of the sections projected upon the screen, he considered that the author was probably correct in ascribing an organic origin to the interlacing tubular structures; but, so far as the peripheral portion of the oolitic bodies was concerned, he believed that it presented no appreciable difference from that of ordinary calcareous concretions of a purely inorganic origin: similar radiating and concentric structures being also met with in the spherulites frequently present in eruptive rocks. Prof. A. H. Green also spoke; and the author replied.—On the Lias Ironstone around Banbury, by Edwin A. Walford. The ferruginous limestone of the Middle Lias of the Banbury district occurs practically within a ten-mile circle around Banbury. The stone (the Marlstone of the Geological Survey) is an "oolitic" cyprid-limestone with much molluscan and crinoidal débris and some quartz-grains. The author described the lithological characters of the rock, and their variations, as traced laterally and vertically, giving a full description of its local development, with a detailed account of the sections in the principal exposures.—Notes on the geology and mineral resources of Anatolia (Asia Minor), by W. F. Wilkinson. The route traversed from northwards to southwards through the city of Broussa lay through a country composed of sedimentary rocks (largely limestones with some shales and conglomerates). In the mountains metamorphic rocks were met with, and also igneous rocks. The principal igneous rocks noticed are granites and serpentines; in the latter chrome-iron-ore occurs, and is worked.

Physical Society, January 25.—Mr. Medley concluded the reading of a paper, by Prof. Ayrton and himself, on tests of glow-lamps, which was commenced at a former meeting. With the newer lamps employed in these tests, it was found that candle-power, current, and candles per watt, all rose as the lives of the lamps increased. The authors, being surprised at this result, took care to satisfy themselves that the effect observed was due neither to change in the resistance of their manganin potentiometer strip, nor to uncertainty of contact at the sockets of the lamps. Starting again with new lamps, they found that in all cases the light given out was greater after the lamps had been glowing for some time than it was when they were new. In the earlier tests a considerable falling off in candle-power had always taken place after the lamps had been running for some time. Further, while the globes of the earlier lamps were always much blackened, even after a run of a few hundred hours, and so became comparatively useless long before the filament broke, the Edison-Swan lamps now examined showed hardly any blackening, even when the filaments lasted over 1300 hours. The rise in candle-power was always accompanied by a rise in current, which was, however, proportionally much smaller, so that the consumption of power per candle was actually less after the lamp had been running fifty hours than it was at the beginning. Among the conclusions drawn by the authors were the following: (*a*) When a group of Edison-Swan lamps, marked 100–8, are run at 100 volts, and each lamp as its filament breaks is replaced by a new one, it may be expected that the light given out will never subsequently be as small as when all the lamps were new; (*b*) an Edison-Swan lamp, marked 100–8, when run at 100 volts will give an average illumination of about 10 candles, and will absorb on an average power of about 4·3 watts per candle, so that such a lamp must be regarded as a 43-watt lamp, and not a 30-watt lamp, as is frequently stated; (*c*) the maximum rise of light recorded during the life of any lamp was 45 per cent.; (*d*) with lamps of the type examined, there is no point at which it becomes economical to discard a lamp before its filament actually breaks; (*e*) no marked economy can be gained by overrunning such lamps (*i.e.* by using pressures exceeding 100 volts). Prof. Ayrton mentioned that the improvement in glow-lamps after running for some time had been attributed to an improvement in the vacuum. Experiments made on new and used lamps by means of an induction coil showed that the more a lamp was used the better the vacuum became, but he (Prof. Ayrton), though at first inclined to adopt this explanation, had since found that though in all the lamps examined the progressive improvement of the vacuum was equally marked, the increase in candle-power varied between very wide limits, being very considerable in some lamps, and hardly perceptible in others. Prof. Rücker asked if it made any difference to the life of a lamp whether it were kept running continuously until the fibre broke, or were run for periods of a few hours, alternating with intervals of rest. The latter case would more nearly correspond with the conditions obtaining in practice. Prof. Ayrton replied that the lamps were kept running during the night, and were disconnected during the day.—A paper, by Prof. Anderson and Mr. J. A. McClelland, on the temperature of maximum density of water and its coefficient of expansion in the neighbourhood of this temperature, was read by the secretary, Mr. Elder. The dilatometer method was used, but the bulb of the instrument contained a quantity of mercury, determined by experiment, which for the range of temperature concerned was such as to secure the constancy of the remaining internal volume, occupied by water. The observed changes were thus the real, and not the apparent changes. The bulb was furnished with a graduated tube of small bore, bent twice at right angles, which served at the same time the purpose of a ground-glass stopper. (The joint was made water-tight by a little Canada balsam.) To determine the coefficient of expansion of the glass, the bulb and tube were filled with mercury at 0° C., and heated up to about 9°·7 C., the necessary weighings being afterwards performed. The coefficient of expansion of mercury being known, the number of grams of mercury to be kept in the bulb during the experiments on water was calculated. The dilatometer was next filled with (thoroughly boiled) distilled water at about 8° C., the stopper-end of the graduated tube inserted, and the free end dipped under mercury, giving at 4° C. a column of mercury whose changes of level could be observed. A thermometer was placed with its bulb close to the middle part of that of the dilatometer; both being immersed in a water-bath which could be cooled by the addition of ice-cold water, or heated by radiation from surrounding objects. The thermometer used was graduated to tenths of a degree, and was compared with two similarly graduated ones by different makers. The two latter agreed very closely with one another, and one had a Kew certificate showing no error in the readings. Temperatures were written to the fourth decimal place, but accuracy to this extent was not claimed. Three sets of experiments were made, and for each a corresponding curve was drawn. In the first, the water was at atmospheric pressure; in the other two, at 1½ and 2 atmospheres respectively. Corresponding to these three pressures, the temperatures of maximum density found were 4°·1844 C., 4°·1823 C., and 4°·1756 C. The value 4°·1844 C., corresponding to atmospheric pressure, is greater than that generally received. Mr. Rhodes thought that sufficient precaution had not been taken to accurately calibrate the thermometers. He doubted whether temperatures read in the manner described could be relied upon to much less than 0°·1. He did not see that any real advantage was gained by having mercury inside the dilatometer to compensate for the expansion of the glass. Mr. W. Watson thought that the mercury within the vessel would cause further uncertainty by tending to produce distortion of the glass. He pointed out that in the case of water at maximum density, there would be practically no convection currents, so that equalisation of temperature would be very slow. As the bulb used was about 8 cm. in diameter, and all the experiments were made with the temperature rising, he thought that this would account for the high value obtained for the temperature of maximum density. Dr. Burton thought a distinct advantage was gained by compensating for the expansion of the glass. The values obtained in different experiments did not seem to be highly concordant. Prof. Rücker thought that the criticisms which had been passed were, for the most part, just. For such measurements as those recorded, it was not sufficient to know the corrections of the thermometer readings at a few isolated points; the portion of the stem over which the readings were taken must be carefully and minutely calibrated. The Kew certificate not only ignored errors of less than ·05° (as mentioned by the authors), but it only gave corrections for a small number of temperatures, separated by considerable intervals.

Linnean Society, January 17.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. George Murray exhibited lantern slides representing a new part of *Pachytheca*, consisting of a cup-shaped receptacle in which *Pachytheca* was found by Mr. John Storrie, of Cardiff. The walls of the cup are composed of radiating chambers like those of *Acetabularia*, and in the centre there are traces of an axile structure. Mr. Murray considered that this discovery only made the interpretation of the nature of *Pachytheca* more difficult than ever.—Mr. Arthur Lister exhibited and made remarks upon a Landrail (*Crex pratensis*) which had been found, a few days previously, near Axminster, in Devonshire, where it had been killed by coming in contact with telegraph wires. The occurrence in midwinter of a bird which is a summer visitor to this country, seemed to him to be worth notice.—Mr. J. E. Harting exhibited specimens of northern sea-birds which had been driven upon the east coast of England during recent gales; amongst others, the Little Auk (*Mergulus alba*), of which great numbers had come ashore dead, or in an exhausted condition; the Little Gull (*Larus minutus*), obtained at Whitstable on January 5; and an example of Brünnich's Guillemot, *Uria brunnichii*, Sabine (*Trans. Linn. Soc.* xii. p. 538), a species which, though abundant in Greenland, North-East Iceland, and Spitzbergen, is of such extremely rare occurrence on our coasts, that not more than two or three authenticated instances of its appearance here have been recorded. The specimen exhibited had been forwarded by Mr. W. J. Clarke, of Scarborough, near which sea-port it was shot on December 7, 1894.—A paper was then read by Mr. I. H. Burkill, on variations in the number of stamens and carpels. Of *Stellaria media* about 5700 flowers were examined, showing that towards the end of the life of the plant the number of stamens becomes reduced. *Ranunculus Ficaria* (nearly 800 flowers) showed that towards the end of the flowering period both stamens and carpels become reduced in number without their proportion being changed. Smaller numbers were examined of *Caltha palustris*, *Ranunculus arvensis*, *R. bulbosus*, *Thalictum flavum*, *Bocconia cordata*, *Prunus Padus*, *Prunus Lauro-cerasus*, *Cratægus Oxycantha*, *Rosa canina*, *Quercus Ilex*, and *Sagittaria montevidensis*, all of which showed, either in carpels or in stamens, a reduction in number towards the end of the flowering period. Of other influences besides age which affect the number of parts, temperature might be one, but nothing could be safely assumed.—Of a kindred nature was a paper by Mr. A. G. Tansley and Miss E. Dale, on variation in the floral symmetry of *Potentilla Tormentilla*, Necker. This paper, of which Mr. Tansley gave an abstract, was mainly a record of variations tending to alter the normal tetramerous actinomorphic symmetry of this flower. From his observations it appeared that independent variations of the epicalyx is considerable, but is probably mainly due to a tendency of its segments to revert to a primitively double condition. The residual independent variation is small, and roughly equal to that of the calyx and corolla. The number of stamens is more variable, and the carpels extremely so. Correlated variation of all the whorls is frequent, and produces deviating types of symmetry in about 3 per cent. of the flowers examined. The series of groups into which the various deviating types might be said to fall, illustrated the shifting of the centre of variation from the pentamerous type of allied flowers to the tetramerous type of *P. Tormentilla*.—A discussion followed, in which the President, Mr. H. N. Ridley, and others took part, and Mr. Tansley replied to the criticisms offered.

Chemical Society, January 17.—Dr. Armstrong, President, in the chair.—The following papers were read: Octacetylmaltose, by A. R. Ling and J. L. Baker. Herzfeld's description of octacetylmaltose is in many respects erroneous.—Action of diastase on starch, by A. R. Ling and J. L. Baker. The isomaltose obtained by Lintner by the action of diastase on starch is not a pure substance. From the product of hydrolysis of starch paste by diastase, a triosazone was isolated; one of the products of the action is therefore probably a triose $C_{18}H_{32}O_{16}$.—New derivatives from α-dibromocamphor, by M. O. Forster. Fuming nitric acid dissolves α-dibromocamphor with formation of a neutral substance $C_{10}H_{12}Br_2O_2$; this on alkaline reduction yields a monobromo-derivative $C_{10}H_{13}BrO_2$. The latter substance is converted into a nitro-derivative $C_9H_{12}BrNO_4$ by nitric acid.—Acid sulphate of hydroxylamine, by E. Divers. Crystalline hydroxylamine hydrogen sulphate is prepared by acting on hydroxylamine hydrochloride with the calculated quantity of sulphuric acid.—The hypophosphites of mercury and bismuth, by S. Hada. Hypophosphites of the composition HgH_2PO_2, $HgNO_3$, H_2O and $Bi(H_2PO_2)_3$, H_2O have been prepared.—Kamala, part ii., by A. G. Perkin. The three acids previously obtained by the oxidation of rottlerine are now shown to be ortho- and para-nitrocinnamic acids and para-nitrobenzoic acid. From the composition of its metallic derivatives rottlerine would seem to have the composition $C_{32}H_{29}O_7.COOH$; it yields a crystalline substance, rottlerone $C_{29}H_{26}O_6$, when boiled with sodium carbonate.—The action of aqueous potassium cyanide on gold and silver in presence of oxygen, by J. S. Maclaurin. The solution of gold or silver by potassium cyanide solution is dependent on the presence of oxygen, and the rate of solution is proportional to the quantity of oxygen present, and to the coefficient of viscosity of the solution.—The crystalline forms of the two dimethylpimelic acids, by W. J. Pope.—Oxidising action of ammonia solution on some metals, by W. R. Hodgkinson and N. E. Bellairs.—Action of magnesium on some phenylhydrazine compounds, by W. R. Hodgkinson and A. H. Coote. Complicated mixtures of products are obtained on boiling acetyl- or benzoyl-phenylhydrazine with magnesium filings.—Refraction equivalents of the elements and the periodic law, by R. M. Deeley.

PARIS.

Academy of Sciences, January 28.—M. Marey in the chair.—Preparation and properties of boride of iron, by M. Henri Moissan. A boride of iron of the composition FeB is obtained by heating together iron and boron, best in the electric furnace. It forms brilliant grey crystals which remain unaltered in air or dry oxygen. Its density is 7·15 at 18° C. Its chemical behaviour with ordinary reagents is fully described.—On Fourier's problem, by M. E. Le Roy.—On the exact levelling operations recently carried out in Russia, by General Venukoff. In a total of 1090 stations scattered throughout Russia, no altitude was determined greater than 338 metres. The most important result of the survey was the establishment of the identity of level of the Baltic, Black, and Azov Seas.—On the solution of solids in vapours, by M. P. Villard.—Action of an electric current on a number of metallic sulphides in the fused state, by M. Jules Garnier. Sulphur is gradually eliminated from the fused mass out of contact with air, the copper retaining a greater proportion of sulphur than iron and nickel in an ore containing the three sulphides.—On some properties of bismuth sulphide, by M. A. Ditte. The production and properties of crystalline bismuth sulphide, made in the wet way, are described. A remarkable double compound with potassium sulphide, $Bi_2S_3 . 4K_2S . 4H_2O$, is obtained in very sharp and brilliant reddish-yellow, transparent rhombohedra from a solution of Bi_2S_3 in potassium sulphide. The crystals cannot be kept in a moist atmosphere, as water readily blackens them.—Influence of the surrounding medium on the transformation of amorphous zinc sulphide, by M. A. Villiers.—On carbonyl chlorobromide and dibromide, by M. A. Besson. The author obtains the substances $COClBr$ and $COBr_2$ by the interaction of $COCl_2$ and BBr_3. They are both partially decomposed by distillation in air. They are very dilatable by heat, and possess very irritating vapours. In contact with mercury at 100° in sealed tubes they suffer total decomposition, but are only slowly acted on by cold water.—Mixed ether and ammonium derivatives of hexamethyl-triamido-triphenylmethane, by M. A. Rosenstiehl.—On acetic ethers from sugars, by M. C. Tanret. The author shows the various reactions given with different classes of sugars by acetic acid in presence of fused sodium acetate and of zinc chloride respectively. He describes three pentacetyl compounds derived from glucose under the names α, β, and γ pentacetines.—On hexamethylene-amine, by M. Delépine. The molecular weight, determined by the cryoscopic method, requires the formula $C_6H_{12}N_4$. This result is fully confirmed by examination of its reactions and by the character of its nitroso-derivatives.—On the seeds of *Coula* from French Congo, by MM. H. Lecomte and A. Hébert. The oil obtained from these seeds appears to consist wholly of triolein.—New facts relating to the mechanism of hyperglycæmia and hypoglycæmia; influence of the nervous system on glucose formation and histolysis, by M. M. Kaufmann. The conclusions are drawn that: (1) in hyperglycæmia, and hence in diabetes, glucose formation and histolytic resorption are active; (2) in hypoglycæmia, glucose formation and histolysis are diminished; (3) section of the medulla near the brachial enlargement modifies the action of the liver; this organ then supplies the blood with less sugar and more glycogen; nutrition is also generally modified, the storage power of the tissues is augmented and their histolytic resorption diminished.—On some points in connection with spermatogenesis in the *Sélaciens*, by M. ELECTRIC OSCILLATIONS.

Les Oscillations Électriques. Par H. Poincaré, Membre de l'Institut, Redigées par M. Ch. Maurain. (Paris: Georges Carré, 1894)

WE have already noticed at some length M. Poincaré's works on Électricité et Optique, and given an account of his views regarding Maxwell's theories, and his mode of presenting the subject in the light of Hertz's researches. The present work discusses more particularly the subject of Electric Oscillations, and includes comparatively little of the more abstract treatment of electrical theory to be found in the others. We have in it a very instructive and well-timed *résumé* of a good deal of the later work on the subject, with mathematical investigations of many points arising in connection with the various experimental researches referred to, which are of great value.

In a short preliminary statement of the theory underlying the Hertzian experiments, M. Poincaré adopts, to a certain extent, the mode of presentation used by Hertz himself. The two reciprocal sets of equations also made by Heaviside the starting-point of his researches, and called by him the circuital equations, are made by Hertz the basis of everything. Thus if L, M, N, X, Y, Z be the components of the magnetic and electric forces, μ and ϵ the "coefficients of magnetic and electric induction," and A the reciprocal of the velocity of light, the equations are

$$A\mu\left(\frac{\partial L}{\partial t}, \frac{\partial M}{\partial t}, \frac{\partial N}{\partial t}\right)=\left(\frac{\partial Z}{\partial y}-\frac{\partial Y}{\partial z}, \frac{\partial X}{\partial z}-\frac{\partial Z}{\partial x}, \frac{\partial Y}{\partial x}-\frac{\partial X}{\partial y}\right),$$

$$A\left(\epsilon\frac{\partial X}{\partial t}+4\pi u, \text{ \&c.}\right)=\left(\frac{\partial M}{\partial z}-\frac{\partial N}{\partial y}, \text{ \&c.}\right)$$

where u, v, w are the components of conduction current at x, y, z. When $u, v, w=0$, one set of equations can thus be formed from the other set by interchange of L, M, N with X, Y, Z, and μ with $-\epsilon$. The electric energy is $\epsilon(X^2+Y^2+Z^2)/8\pi$, and the magnetic energy $\mu(L^2+M^2+N^2)/8\pi$, each taken per unit of volume of the medium.

The units of force are so chosen that μ and ϵ are both unity for vacuum, that is, for ether. Hence the introduction of A in the equations above. It is required to make the dimensions of both sides alike. We must confess that we much prefer the idea contained, though not clearly expressed, in Maxwell's treatise, of regarding μ and K as quantities dependent on the physical properties of the medium, and such that the velocity of light in the medium is $1/\sqrt{\mu K}$. There can be no question of the enormous advantage of thus proceeding. It avoids the obvious absurdity of giving in a general system of measurement founded on the units of length, mass, and time, two different sets of dimensions to the same quantity according as it is measured electrostatically or electromagnetically. Further, if this were recognised, the serious difficulty which besets students, when they find that what is defined or explained as a mere ratio is unity, or the reciprocal of the square of the velocity of light, according to the system of units adopted, would entirely disappear. The discussion which took place in 1882 regarding the dimensions of magnetic pole in electrostatic units, gave illustrations of the confusion and misconception to which neglect of the dimensional relation between μ and K can give rise in the mind of even a master of physical science.

Let μ_0 K_0, or better, μ_0, κ_0, be the inductive capacities (magnetic and electric) of ether, μ, κ, those of any other substance, then μ/μ_0, κ/κ_0 will be the magnetic and electric permeabilities of the medium, and will be mere ratios. The magnetic permeability will then be as Lord Kelvin originally defined it, the ratio of two magnetic forces, of the magnetic force defined electromagnetically (in a crevasse across the direction of magnetisation) to the magnetic force according to the polar definition (in a narrow cylindrical hollow parallel to the magnetisation), and our ideas will no longer be liable to obfuscation in an important fundamental matter.

M. Poincaré derives the second set of equations stated above from the first set and the principle of conservation of energy, using for the total energy per unit of volume the sum of the expressions quoted above. The theoretical basis consists thus of (1) the experimental fact that the line-integral of electric force round a circuit is equal to the time-rate of variation of the total magnetic induction through the circuit, which gives the first set of equations; (2) the expressions for the magnetic and electric energies; and (3) the theorem that the work spent in heat per unit of volume per unit of time is $Xu+Yv+Zw$. The expressions for the energies are thus taken as fundamental. The result does not, however, depend on any supposition as to exact localisation of the energy; all that is involved is the expression of the energy as an integral extended through the whole field.

This is not the same as the process of Hertz, and it is not clear that it possesses any advantage over that method. In fact, Hertz's foundation is the two sets of reciprocal equations, which are first postulated, then shown to be consistent with observed phenomena. Thus the whole structure rests on the equations, and Hertz is but little, if at all, concerned with the dynamical explanation of electromagnetic phenomena. This, on the other hand, Maxwell is continually; and one of the most remarkable chapters of his book is that in which he applies the method of Lagrange to give a dynamical basis to the theory of induction and electromagnetic action. This was a natural outcome of the other process, which he followed, of establishing his equations as far as possible directly from the experimental facts, and connecting them by a strong web of dynamical theory. It does not seem likely, moreover, that the minds of many of those who are eagerly seeking for some more intimate knowledge of electromagnetic action will be content with anything but a dynamical explanation of electrical phenomena, and one which shall elucidate, in some measure at least, the relation of the ether to ordinary matter, and the reason for the existence of the ponderomotive forces exerted in the electromagnetic field.

In chapter iii. M. Poincaré proceeds to the theoretical study of Hertzian oscillations, and discusses in the first instance the solution of the differential equations for the case of conductors situated in a dielectric. The first part of this does not call for special remark. X is taken in the ordinary way as the real part of $(B - i\,C)e^{ipt}$ where $i = \sqrt{-1}$, and $p = q - i\gamma$. The value of p is here misprinted $\gamma + iq$. The author then proceeds to find solutions for the case of an indefinitely extended dielectric, and throwing the equations into the form

$$L, M, N = \frac{\partial\xi}{\partial y} - \frac{\partial\eta}{\partial z}, \text{ \&c.},$$

that is introducing the vector-potential, he goes on to solve the resulting equations for X, Y, Z. Two solutions are obtained of the form

$$\xi = -A\int\frac{(u)}{r}dxdydz$$

where (u) may have either of the values u', u'', given by $u' = f(x', y', z', t)$, $u'' = f(x', y', z', t - Ar)$. Here u' is the value of the x-component of the current at the point (x', y', z') at time t, u'' the value of the same component at the same point at a time previous by the interval required for the light to travel from (x, y, z) to (x', y', z'), r being the distance between these two points. The latter solution is, of course, adapted to the case of propagation in space with velocity 1/A. It is exemplified by application to the complete solution of Lodge's spherical vibrator. This, in the assumed absence of radiation of energy and frictional damping out of the electrical vibration, may be regarded, for points external to the sphere, as simply a time-periodic electric doublet; for its electrification may be imagined produced by the relative displacement through a small distance of two uniform spherical volume distributions, each of which acts as if its whole charge were situated at its centre. But the existence of radiation very materially affects the result, for if r be the distance of any point from the centre of the vibrator, a the radius of the sphere, ψ a function which gives the electric forces by the equations

$$X = \partial^2\psi/\partial x\partial z,\quad Y = \partial^2\psi/\partial y\partial z,$$
$$Z = -A^2\partial^2\psi/\partial t^2 + \partial^2\psi/\partial z^2,$$

the direction of the axis of the vibrator being that of z then

$$r\psi = Be^{r/2a}e^{-t/2aA}\cos\frac{\sqrt{3}}{2a}\left(r - \frac{t}{A}\right) + Ce^{r/2a}e^{-t/2aA}\sin\frac{\sqrt{3}}{2a}\left(r - \frac{t}{A}\right).$$

This expression is interesting as showing exactly the damping due to radiation in this case; that due to frictional generation of heat is neglected. As 1/A is the velocity of light, it will be seen that the radiation damping is exceedingly rapid. This illustrates the difficulty of "maintaining" electric oscillations; and has an important bearing on the interpretation of results obtained with resonators which are damped slowly as compared with the exciters.

Of course, the damping in complicated cases can be found when the total flow of energy through a spherical surface of large radius, surrounding the vibrator, can be computed by Poynting's theorem. Thus it is possible to construct a more accurate solution for points distant from the vibrator, than that given by the supposition of no damping, by thus calculating approximately the exponential factor, and we can go on by successive approximation if need be.

The results obtained by Hert with regard to the period and the damping out of the vibrations of his exciter were tested, of course, by his resonator; and we have, in chapter iv. of M. Poincaré's work, an excellent account of the mathematics of resonance, so far as here required, and of the propagation of electric waves along wires, illustrated by reference to the experiments of Sarasin and De la Rive, Blondlot, and others. Many of these have reference to the variation of the current with distance from the end of the wire, at which, of course, reflections took place. The theory, for example, of Mr. D. E. Jones' experiments, in which a thermo-electric couple was used to measure the heating effect at different distances from the end of a long wire, is worked out; and the results, when compared with those of the experiments, are found to agree.

Chapters follow on Propagation in Air, and Applications of Theory. In the latter, M. Poincaré refers, among other things, to the results of the very important experiments of Bjerknes, on waves received by resonators of different metals; that is, their different rates of damping, and the depths to which the currents penetrate into the metal as measured by the thickness (to take an example) of copper, which must be deposited on an iron resonator in order that it may behave like one of solid copper.

These three chapters have a very important bearing on the question of multiple resonance, to which M. Poincaré has himself devoted special attention, and form, perhaps, the most valuable part of the work.

Lastly, the book deals with such applications of electrical oscillations as the determination of specific inductive capacities, the reflection and refraction of electric waves, and ends with a study of Hertz's "Memoir on the Fundamental Equations of Electrodynamics for Moving Bodies."

The mathematical discussions are, as we have indicated, throughout lucid and very frequently elegant. The facility with which an apparently intractable problem is taken hold of, and a few more or less elementary considerations made to yield an approximate solution or result, is very remarkable. We could have wished for a somewhat more physical treatment of the subject; but to those whose physical ideas have had some training with regard to these matters, M. Poincaré's treatise cannot but be of great service, as supplying what no doubt was its object, a review of the principal results obtained in this field of research compared with theory, as far as possible by the only sure test, that of calculation.

A. GRAY.

THE BOOK OF THE ROSE.

The Book of the Rose. By the Rev. A. Foster-Melliar, M.A., Rector of Sproughton, Suffolk. Pp. 336. 29 illustrations. (London: Macmillan and Co., 1894.)

MR. MELLIAR is well known among horticulturists as a successful grower and exhibitor of roses, and his book is what he wished it to be—the rose considered as a flower, with full details for its practical culture for amateurs, from the beginning to the end. Art is his text all through. He has very little to say about the botany of the rose, its geographical distribution, the origin of the numerous races of garden roses as distinguished from their wild progenitors, the fourteen chapters of his book being devoted to such matters as soil, manure, planting, pruning, propagating, and exhibiting. For the cultivator the book covers all the ground, and Mr. Melliar's instructions are as clear, as thorough, and as trustworthy as any budding "Rosarian" could desire. There are already plenty of books about the rose, of which as much as this can be said, but there is still room for Mr. Melliar's. He writes mainly for the amateur grower of roses, and strongly recommends his hobby to the country parsons who are, he says, "all so poor, and likely to be poorer still." The delights of the rose-grower are only experienced when he himself does all the work entailed in the production of plants from cuttings, buds or seeds, to the exhibition flowers. The genuineness of Mr. Melliar's love for his hobby is seen in the following extract from his book :—

"But if it was you alone who had found, chosen, and grubbed out the [briar] stock from the hedge, or cut, prepared, planted, and transplanted the briar or manetti cutting if no hand but yours had budded it, cared for it in all stages, and finally cut and shown the Rose—then, when perchance it is declared on all hands to be the finest specimen of the variety ever shown, it must be an additional pleasure to know that it is your Rose indeed, for that, as far as all human aid is concerned, you made it yourself."

If the book has a fault, it is to be found in this treating of the rose solely as a flower to be set on a tray at an exhibition and win a prize. Mr. Melliar has something of the narrowness of view of the old florist, for he sees little beauty in roses which are not likely to win prizes. He devotes thirty pages to instructions on exhibiting the flowers. This chapter is interesting as showing how much care and self-sacrifice are necessary to success in the exhibition tent, the paper covers to protect the buds from rain, wind, and sun, and the precautions necessary even when the flowers are ready to pack in their prepared mossy beds in boxes. In one very dry season, he says, his mossed boxes had been kept in the shade and duly watered, with the result that two huge slugs, each as big as his thumb, concealed themselves in the moss, and during the journey to the Crystal Palace regaled themselves on the roses!

Mr. Melliar speaks of several varieties of rose that show deterioration since they were first introduced, or "sent out," as the raisers express it. These fine varieties of rose are always propagated from grafts or cuttings, and deterioration is therefore unlikely. The same statement has been made with regard to apples, pears, and other fruits, which are multiplied in the same way as roses, but they have never been substantiated.

Until within the last thirty years or so, all the best garden roses were raised by continental growers, the belief being that they could not be produced in England. The same belief prevailed until recently with regard to chrysanthemums. It is therefore a pleasant surprise to see that of the 144 varieties of the Hybrid Perpetual section of roses, selected by Mr. Melliar as the choicest and best, no less than sixty of them were raised in England, and that the two best H.P. roses known, viz. "Her Majesty" and "Mrs. J. Laing," were raised by the ate Mr. Bennett in Surrey. To these I would add a third, namely, "Grace Darling," also raised by Mr. Bennett, and which, although not an exhibition rose, is yet one of the most beautiful of all in the garden. Its only rival is "Gloire de Dijon," raised in France forty years ago, and of which Dean Hole, prince of rosarians said, "Were I condemned to have but one rose for the rest of my life, I should ask, before leaving the dock, to be presented with a strong plant of 'Gloire de Dijon.'"

A book which deals chiefly with exhibition roses can scarcely be considered to justify its title, "The Book of the Rose," because to all but a very small section of gardeners the rose appeals with greatest force when seen as a naturally grown bush in the garden. The close pruning and other rigorous methods of the grower-exhibitor are suggestive of ear-cropping for dogs, and comb-cutting for cocks, disfiguring, for a special purpose, otherwise beautiful objects. Mr. Melliar has very little to say for the many beautiful single-flowered roses which are now coming rapidly into favour with gardeners, and whose flowers are often as lovely as the highest floral art could wish. Many of the perfect exhibition roses are just about as attractive in form and colour as a red-cabbage. The hybrids raised by Lord Penzance from the sweetbriar crossed with garden roses, are exceedingly beautiful, so too are the forms of the Japanese *Rosa rugosa*, *R. multiflora*, *R. bracteata*, *R. indica*, &c.

It is becoming a too common practice amongst professional gardeners to set about crossing beautiful species of plants, roses included, with a view to doubling or otherwise altering the form, or "improving" the colour of the flowers, to satisfy some absurd ideal, the consequence often being a considerable loss from the point of view of true art. We owe the garden roses of the present time to the breeders of florists' flowers, and are duly thankful. At the same time we would prefer to keep the best of the single-flowered roses just as they are. Mr. Melliar does not agree with those who look upon the rose as a decorative plant for the garden, but only as a means whereby he may obtain glorious roses. For me, the best tray of exhibition roses ever produced has infinitely less charm than a bed of yellow Banksian roses, or even a tangled mass of sweetbriar when covered with flowers. However, Mr. Melliar's book will teach any one how to grow good rose flowers, and there are thousands who would find pleasure in rose-growing by reading and following his directions. W.

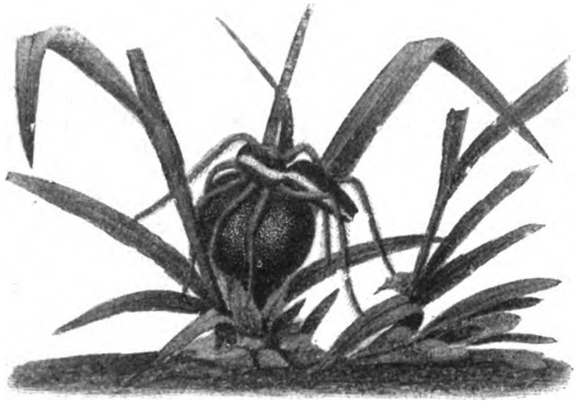
OUR BOOK SHELF.

L'Industrie des Araneina. By Woldemar Wagner. (St. Pétersbourg : L'Académie Impériale des Sciences, 1894.)

THIS work may be divided into two sections: (1) the descriptions of the cocoons, nests, &c., of the commoner kinds of Russian spiders; and (2) the conclusions respecting the evolution of instincts and the classification of the species, to be drawn from the data thus established.

Wagner recognises four kinds of silken structures—namely, the snare, the retreat, the nest, and the cocoon. About the first of these but little is said. The remaining three, however, are discussed in considerable detail, and to the question as to whether these structures are of great taxonomic value, M. Wagner gives an unhesitating and most positive affirmative reply. It is unfortunately impossible within the limits of a short notice to criticise closely his arguments; but that they are worthy of the deepest attention, will be realised by all arachnologists who are acquainted with M. Wagner's previous works.

Perhaps the highest praise that can be bestowed upon this work, is to say that, even when stripped of its theories, it quite reaches the high standard of excellence attained by M. Wagner's previous papers, and that the great value of the theoretical part lies in the fact that



the key to all problems is sought in the hypothesis of evolution by means of Natural Selection.

The memoir is admirably illustrated with ten lithographed plates, of which eight are coloured, and, in addition, with two hundred and fifty-two diagrams in the text. The figure we here select for reproduction, to give an indication of the nature of the rest, represents the female of *Ocyale mirabilis* carrying her cocoon.

R. I. P.

Elementary Practical Chemistry, Inorganic and Organic. By J. T. Hewitt, M.A., D Sc., Ph.D., F.C.S., and F. G. Pope. Pp. 42. (London: Whittaker and Co.)

ALTHOUGH the authors of this small book have confined themselves to such parts of elementary qualitative analysis as find a place in Stage I. of the Science and Art Department Syllabus, neither in general plan nor in details of treatment does the book possess any educational advantage over its many competitors. A mere recital of reactions cannot be considered as "Elementary Practical Chemistry." Surely it is possible to present even the array of facts utilised in analysis in such a manner as to comply with the fundamental requirements necessary to be fulfilled by all educational works designed for young students of science. The production of compilations of the present type will probably cease to exist when the new regulations for Organised Science Schools come into force. We may then, perhaps, look for the production of really philosophical text-books arranged on sound educational lines, and yet calculated to minimise the very real difficulties encountered by the beginner. Putting aside these fundamental considerations, it is only just to say that the authors have brought together a strictly limited set of reactions with few positive inaccuracies.

How to Live in Tropical Africa. By J. Murray, M.D. Pp. 252. (London: George Philip and Son, 1895.)

SO far as literary merit is concerned, this is a poor book. The text is disjointed, it is too full of unnecessary quotations, and there is too much tautology. But if only the subject-matter is considered, the verdict is that the book is a trustworthy guide to tropical hygiene, and a useful manual on the cause, prevention, and cure of malarial fevers. The importance of such a handy volume to emigrants and visitors to Africa can hardly be overstated. And as the book is the outcome of medical experience, it possesses exceptional value.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Liquefaction of Gases.

PROF. OLSZEWSKI's letter in NATURE of January 10 is a more serious matter than *a claim for priority*. The letter charges Prof. Dewar with allowing the impression to go abroad that he has carried out much original research into the methods of liquefying the more permanent gases, and the properties of the liquids produced; whereas, according to Prof. Olszewski, most of Prof. Dewar's experiments have been merely repetitions of work done by others.

In his brief communication to NATURE (January 10), Prof. Dewar has been too modest either to defend himself or to meet his opponent. Fortunately, he makes one definite statement:—"A reference to the *Proceedings* of the Royal Institution between the years 1878 and 1893 will be sufficient to remove the suggestion that the apparatus I use has been copied from the *Cracovie Bulletin* of 1890."

I have followed Prof. Dewar's recommendation, and made references to the *Proceedings* of the Royal Institution. In his lecture at the Royal Institution on June 13, 1884 (*Proc. R. I.*, xi. 148), Prof. Dewar refers to Messrs. Olszewski and Wroblewski as having "recently made such a splendid success in the production and maintenance of low temperature." He describes and figures an apparatus which is a slightly modified form of that of the Polish professors, which in turn was derived from the apparatus of Cailletet; and he says: "Provided a supply of liquid ethylene can be had, there is no difficulty in repeating all the experiments of the Russian observers." No claim is made here to originality in the essentials of the apparatus, nor in the experiments performed. The apparatus referred to by Prof. Dewar in his lecture of June, 1884, was used by Prof. Olszewski in 1883, and was improved by him in 1884; in 1887 the apparatus was made capable of liquefying oxygen and other gases in considerable quantities at the ordinary atmospheric pressure (see Olszewski, *Phil. Mag.* February 1895, 189–190). In 1890 the apparatus was so improved that from 30 to 100 c.c. of liquid oxygen could be produced by it (see Olszewski, *Phil. Mag.* February 1895 192–193). Prof. Olszewski states (NATURE, January 10) that a description of this improved apparatus was sent to Prof. Dewar. A year after this, on June 26, 1891, Prof. Dewar delivered a discourse on Faraday's work at the Royal Institution. The published abstract of his lecture (*Proc. R. I.* xiii. 481) contains a photograph of the pump and engines used in the laboratory of the Royal Institution, and a photograph of the arrangement of the apparatus on the lecture table; but it is impossible to make out the details of the apparatus from these photographs. So far as can be judged from the *Proceedings* of the Royal Institution, Prof. Dewar did not show large quantities of liquid oxygen, nitrogen, or air in his lectures until June 10, 1892, when he placed before his audience a pint of liquid oxygen. Two years before this Prof. Olszewski had obtained 100 c.c of liquid oxygen, and he tells us in his letter to NATURE (January 10) that 200 c.c. of this liquid were prepared and exhibited by him in July 1891. A pint is undoubtedly more than 200 c.c., but unless one does something with the larger quantity which cannot be done equally well with the smaller, nothing is gained by conducting the manufacture on the large scale.

I can find no other mention of the apparatus used at the Royal Institution for liquefying large quantities of gases. There is indeed no accurate description in the *Proceedings* of that Institution of the apparatus used by Prof. Dewar. If Prof. Dewar has made marked improvements in any essential parts of Prof. Olszewski's apparatus, why has he not published an accurate description of these improvements in some recognised scientific journal?

A reference to the *Proceedings* of the Royal Institution is then sufficient, not to remove, but to strengthen, "the suggestion that the apparatus I [Prof. Dewar] use, has been copied from the *Cracovie Bulletin* of 1890," or at least that it has been borrowed from descriptions of apparatus devised by Prof. Olszewski.

Every one must admire and praise the skill which fashioned, the vacuum receivers for storing and experimenting with comparatively large quantities of liquid oxygen and air, which Prof. Dewar used in public for the first time on January 20, 1893, so far as can be gathered from the *Proceedings* of the Royal Institution (see *Proc. R. I.* xiv. 1.) The following sentences occur in the published abstract of Prof. Dewar's lecture on that date: "The prosecution of research at temperatures approaching the zero of absolute temperature is attended with difficulties and dangers of no ordinary kind. *Having no recorded experience to guide us in conducting such investigations*, the best instruments and methods of working have to be discovered." (The italics are mine.) (*Proc. R. I.* xiv. 1.) Now, in June 1890, that is two and a half years before Prof. Dewar made the statement I have quoted, Prof. Olszewski was able to say: "My new apparatus excludes the inconveniences of the former one, and renders it possible to preserve the liquid oxygen a longer time under the ordinary atmospheric pressure." And again: "Thus was solved the problem of liquefying considerable quantities of oxygen without the slightest danger." (See Olszewski, *Phil. Mag.* February 1895, 193–3.) Every reader of Prof. Olszewski's paper will agree that these statements are justified. Moreover, in October 1891, that is, fifteen months before Prof. Dewar declared there was "no recorded experience to guide us in conducting such investigations," Prof. Olszewski (in conjunction with M. Witkowski) described a method for not only storing but also experimenting with, considerable quantities of liquid oxygen (*Cracovie Bulletin*, October 1891). So far back as 1887 he published, in *Wiedemann's Annalen* (xxxi. 58), a full account of methods for determining the densities of liquid oxygen, nitrogen, and marsh gas. In 1887, also, he determined the boiling point of liquid ozone, and he began his measurements of the absorption spectra of liquid oxygen and air (*Wiedemann's Annalen*, xxxiii. 570); and in 1891 he published further measurements of the absorption spectrum, and the refractive index, of liquid oxygen (*ibid.* xlii. 663; see also *Phil. Mag.* February 1895, 197–9, and 206–8.)

It is just these properties, namely, the optical properties, of liquid oxygen which had been elaborately studied by Prof. Olszewski from 1887 to 1891 that are largely dwelt on by Prof. Dewar in his discourse of January 1893; and it is the illustration of these properties that is prefaced by the remark, there is "no recorded experience to guide us in conducting such investigations."

On January 20, 1893 (*Proc. R. I.* xiv. 10) Prof. Dewar said that liquid oxygen is "the most convenient substance to use for the production of temperatures about −200° C. Liquid nitrogen, carbonic oxide, or air can conveniently be made at the ordinary atmospheric pressure, provided they are brought into a vessel cooled by liquid oxygen boiling under the pressure of about half an inch of mercury." It is interesting to compare with this Prof. Olszewski's words published in June 1890 (*Crac. Bull.*; I quote from the translation in *Phil. Mag* February 1895, 192): "I proved long ago [*Compt. rend.* c. 350 (1885)] that liquid oxygen is the best cooling agent; for it easily gives the temperature of −211°·5 C. if the pressure is lowered 9 mm. of mercury, and it does not freeze even at the pressure of 4 mm." It may be said that the similarity between these statements is merely a coincidence. Perhaps it is. Nevertheless, Prof. Dewar's statement conveys the impression that he was the first experimenter to employ liquid oxygen for obtaining, and maintaining, very low temperatures. Another of Prof. Dewar's statements which imply more than they express, occurs in his lecture of June 10, 1892 (*Proc. R. I.*, xiii. 695): "He hoped that evening to go several steps further, and to show liquid air, and to render visible some of its more extraordinary properties." Remembering that air had been liquefied by Prof. Olszewski at least eight years before the lecture wherein this statement occurs was delivered, one must regret that Prof. Dewar did not choose words which should have made it impossible for the English public to suppose "that the liquefaction of oxygen and other so-called permanent gases was achieved for the first time by [him]." (See Prof. Olszewski's letter in NATURE of January 10).

Not only does Prof. Olszewski claim to have devised the methods, and constructed the apparatus, for liquefying considerable quantities of the more permanent gases, but he also asserts that most of the experiments on the properties of these liquefied gases which have been performed by Prof. Dewar are only repetitions, on a larger scale, of work done by others. What, then, are these experiments?

Measurements of the refractive index of liquid oxygen, for the sodium light, and also of the absorption spectrum of liquid oxygen, were published by Profs. Liveing and Dewar in August 1892 (*Phil. Mag.* (5) xxxiv. 205; see also Dewar in *Proc. R. I.*, June 10, 1892; and Liveing and Dewar in *Phil. Mag.* for August 1894). The refractive index of liquid oxygen had been measured, and determinations of the absorption spectrum had been made, by Olszewski and Witkowski in October 1891, and these measurements were the complement of work begun, and published, by Prof. Olszewski in 1887 (*Wiedemann's Annalen*, xxxiii. 570. See Olszewski in *Phil. Mag.*, February 1895, 197–9). It is true that preliminary experiments on the absorption spectrum of liquid oxygen had been made by Profs. Liveing and Dewar in 1889. In their paper in *Proc. R. S.*, June 6, 1889, they say:—"We have observed repeatedly the absorption of liquid oxygen in thicknesses of 8 and 12 mm. Our observations confirm those of Olszewski."

On December 10, 1891, Prof. Dewar announced, in a note to the President of the Royal Society, that liquid oxygen is attracted by the poles of a magnet. This note was followed by another, on December 17, 1891, saying that liquid ozone was also attracted by the poles of a magnet. These detached, but interesting, experiments, which followed up work done by Faraday many years ago, must be placed to the credit of the Fullerian Professor at the Royal Institution.

A paper published in *Phil. Mag.* (5) xxxiv. 326 (1892) by Dewar and Fleming, on the electrical resistances of metals and other bodies at very low temperatures, contains the only piece of exact investigation to which Prof. Dewar's name is attached wherein liquid oxygen or air is used as an instrument of research, with the exception of the measurements of the optical properties of liquid oxygen, which have been shown to be mainly repetitions of the work of Olszewski and Witkowski. This research carries on and supplements earlier work done by Cailletet and Bouty, and by Wroblewski (*Comptes rendus*, ci. 161 (1885).

A few observations have been made by Prof. Dewar on the phosphorescence of various substances at the temperature of boiling oxygen, and on the cessation of chemical action, and the continuance of photographic action, at the same temperature (see *Proc. R.I.* June 26, 1891 and June 10, 1892, also January 20, 1893; also *Proc. Royal Soc.* April 19, 1894, and *Proc. Chem. Soc.* June 28, 1894). The subject of chemical action at very low temperatures was investigated by Pictet in May and November 1892 (*Comptes rendus*, cxiv. 1245; cxv. 814) in a much more exhaustive way than has been done by Dewar, who has only touched the fringe of the matter (compare also Olszewski, *Phil. Mag.* February 1895, 208–9). The observations on the sensitiveness of the Eastman film at very low temperatures are interesting; but, so far as it has been published, the work is too slight to present material for detailed criticisms; and the same may justly be said of the lecture illustrations of phosphorescence at low temperatures. It may be remarked that Prof. Dewar's paper on photographic action at low temperatures has appeared only in the *Proceedings*, not in the *Transactions*, of the Chemical Society.

Prof Olszewski's work on the properties of liquefied gases was begun, and accounts of his accurate experiments were published in recognised scientific journals, long before Prof. Dewar's experiments were heard of. The work of the Polish Professor is being continued in the same exact, modest, and scientific manner (see his paper on the optical dispersion of liquid oxygen in *Cracovie Bulletin*, July 1894, noticed in *Phil. Mag.*, February 1895, 208; and his determinations of the boiling and freezing points, and other constants, of argon communicated to the Royal Society, January 31, 1895).

It seems to me that Prof. Olszewski has established a case which demands the instant and serious consideration of those who are truly interested in the advance of science, and are jealous of the good name of the scientific men of this country.

Cambridge, February 7. M. M. PATTISON MUIR.

THE object of the communications on the liquefaction of gases, which have recently appeared in NATURE and the *Philosophical Magazine*, is to depreciate the work of Cailletet and Pictet, to smother away the first-class work of the deceased

Wroblewski; to annihilate myself, and thereby to magnify the claims for originality of Prof. Olszewski. In spite of the mistakes inevitable to pioneers, the work of Cailletet and Pictet must always be credited with originating research in this department. To show my appreciation of such investigation, and to give it a wide publicity in the year 1878, a Friday evening address was devoted to the work of Cailletet and Pictet, during the course of which I showed for the first time in this country the working of the Cailletet apparatus. Similarly, in the year 1884, an address was given on the work of Wroblewski and Olszewski, in the course of which I illustrated for the first time in public the liquefaction of oxygen and air, showing the boiling point, &c., by means of a simple form of apparatus which did not involve the use of the Cailletet pump as employed by these experimenters. To deliver a lecture on the work of other people is generally considered a mark of honour, and as usefully diffusing a knowledge of the same. The critic has for some object omitted half the opening sentence of this address, which runs as follows:—

"The two Russian chemists, MM. Wroblewski and Olszewski, who have recently made such a splendid success in the production and maintenance of low temperature, have used in their researches an enlarged form of the well-known Cailletet apparatus; but for the purpose of lecture demonstration, which necessarily involves the projection on a screen of the actions taking place, the apparatus represented in the annexed woodcut is more readily and quickly handled, and enables comparatively large quantities of liquid oxygen to be produced."

The same tactics have been adopted of taking half a sentence from another part of the address, and leaving out the context. The sentence to which I refer ran thus:—

"*Provided a supply of liquid ethylene can be had, there is no difficulty in repeating all the experiments of the Russian observers;* but as this gas is troublesome to make in quantity, and cannot be bought like carbonic acid or nitrous oxide, such experiments necessitate a considerable sacrifice of time. It was therefore with considerable satisfaction that I observed the production of liquid oxygen by the use of solid carbonic acid, or, preferably, liquid nitrous oxide."

Then follows a full description of how to use nitrous oxide with the apparatus in order to get liquid oxygen. Note the disingenuous comment of the critic: "No claim is made here to originality in the essentials of the apparatus, nor in the experiments performed." It has never been the custom to make public claims for originality, either in apparatus or experiment, in the course of an address given at the Royal Institution. He proceeds to allege, "the apparatus referred to by Prof. Dewar in his lecture of June, 1884, was used by Prof. Olszewski in 1883." On turning to the reference given, I find the following statement by Olszewski: "In 1883, and for several years following, I liquefied the gases in a strong glass tube." According to this distortion of fact, the apparatus of Andrews, Cailletet, Wroblewski, and Dewar are all the same, because gas was liquefied in a glass tube. I challenge the production of a reference to an apparatus antecedent to the date of this lecture in which liquid nitrous oxide had been used for the production of liquid oxygen. But all this is ancient history; the real charge begins with the year 1890. Assuming that I had been the thief of Prof. Olszewski's apparatus of 1890, which is alleged to be the type used in the Faraday Commemoration Lecture of 1891, *what explanation is forthcoming of the delay of four years in ventilating the question of priority and personal grievance? What has occurred at the present juncture to precipitate a crisis?* Can any one avoid coming to the conclusion that Prof. Olszewski's contact with "Argon" explains the sudden assault upon my labours in the same field of investigation. . . .

If the critic had been a trustworthy person even to examine into the published facts, he could have found a reference in the *Proceedings* of the Royal Institution, between the years 1878 and 1893, that would have enlightened his ignorance, and thereby prevented his reiterating Prof. Olszewski's suggestion that my large apparatus of 1891, which produced pints of liquid oxygen, was copied or borrowed from a description in the *Cracovie Bulletin* for 1890. . . .

Let us see what Prof. Olszewski said in that paper, entitled "Transvasement de l'oxygene liquide," June 1890:—

"A flask of wrought iron, five litres in capacity (such as is used to hold liquid carbon dioxide), containing oxygen under a pressure of 80 atm., is joined by a narrow copper tube to the upper end of a steel cylinder tested at a pressure of 200 atm. This cylinder having a capacity of 30–100 cub. centim., according to the quantity of oxygen which we wish to liquefy at a time, is immersed in liquid ethylene, of which the temperature may easily be lowered to 140 c. by means of an air-pump. The lower end of the cylinder is joined by a narrow copper tube to a little stopcock, through which the oxygen, liquefied in the cylinder, can be poured down into an open glass vessel, kept cool by the surrounding air."

In other words, replace the glass tube in my apparatus of 1884 by a small steel cylinder, and attach to its lower end a narrow copper tube with a stopcock, and the Olszewski apparatus of 1890 is produced (as a matter of fact, Pictet had used the same principle in the year 1878). Now, on June 11, 1886, I delivered a lecture on "Recent Researches on Meteorites," and the report in the *Proceedings* of the Royal Institution contains a sectional drawing of an apparatus solely constructed of copper, together with a valve for drawing off liquid oxygen, entirely different in type from the crude plan Olszewski adopted in 1890. I may mention that the plan of the apparatus was reproduced immediately after the delivery of the lecture, both in England and America. The section is confined to the refrigerator, all the accessories of liquefied and compressed gas bottles, compression and exhaust gauges, &c., having been omitted. From this plan of the refrigerator, any person so desiring could increase its capacity so as to work on a larger scale. The drawing shows the apparatus arranged for the special experiment of ejecting liquid oxygen into a vacuum chamber, but it is clear the apparatus discharged as easily into an open vessel. It is not any isolated experiment that is in dispute, but the new form of apparatus. The special object for which liquid oxygen was in use in this lecture, was to cool a piece of meteorite before insertion into an electric furnace. The following extract from the lecture will explain how the subject was introduced:—

"Meteorites, no doubt, have an exceedingly low temperature before they enter the earth's atmosphere, and the question had been raised as to what chemical reactions could take place under such conditions. It resulted from Prof. Dewar's investigations that at a temperature of about 130° C., liquid oxygen had no chemical action upon hydrogen, potassium, sodium, phosphorus, hydriodic acid or sulphydric acid. It would appear, therefore, that as the absolute zero is approached, even the strongest chemical affinities are inactive.

"The lecturer exhibited at work the apparatus by which he had recently succeeded in solidifying oxygen. The apparatus is illustrated in the accompanying diagram, where a copper tube is seen passing through a vessel kept constantly full of ether and solid carbonic acid; ethylene is sent through this tube, and is liquefied by the intense cold; it is then conveyed by the tube, through an india-rubber stopper, into the lower vessel; the outer one is filled with ether and solid carbonic acid. A continuous copper tube, about 45 feet long, conveying oxygen, passes through the outer vessel, and then through that containing the liquid ethylene; the latter evaporates through the space between the two vessels, and thus intense cold is produced, whereby oxygen is liquefied in the tube to the extent occasionally of 22 cubic centimetres at one time. The temperature at which this is effected is about − 130° C., at a pressure of 75 atmospheres; but less pressure will suffice. When the oxygen is known to be liquid, by means of a gauge near the oxygen inlet, the valve A is opened, and the liquid oxygen rushes into a vacuum in the central glass tube below; some liquid ethylene at the bottom of the next tube outwards is also caused to evaporate into a vacuum at the same moment, and instantly some of the liquid oxygen in the central tube becomes solid, owing to the intense cold of the double evaporation. The outer glass vessel serves to keep moisture from settling on the sides of the ethylene tube. By means of the electric lantern and a lens, an image of this part of the apparatus was projected upon the screen, this being the first time that the experiment had been shown on a large scale in public.

"Performing this experiment, the temperature reached was a little below 200° C., that is, only 50° or 70° above the absolute zero of temperature, and in the experiment about 5 lbs. of liquid ethylene were employed."

This I declare to be the first apparatus made wholly of metal, being an arrangement of copper coils, in which liquid oxygen was made and decarted or transferred from the vessel in which t was liquefied to another by means of a valve, and thereby rendered capable of use as a cooling agent. In support of this assertion, I call as witness Prof. Charles Olszewski himself, who states in the *Philosophical Magazine*, February 1895, p. 189: "In 1883, and for several years following, I liquefied the gases in a strong glass tube." There is no suggestion made that a steel cylinder and valve was used by Olszewski till the year 1890. Whereas four years in advance I had used a much safer and better form of apparatus, practically identical in principle with that used in Cracow in the year 1890. Have I ever suggested that Prof. Olszewski was anticipated, or attempted to raise any question of priority? Perhaps the critic will have the audacity to say, in reply, this is no publication, the *Proceedings* of the Royal Institution, English and American science periodicals, not being amongst the class of recognised scientific journals. Well, if I am pleased to throw my bread upon the waters, adopting the view that every truthfully recorded experiment which appears in any journal associated with my name is publication, surely I should simply be conducting myself in the "too modest" way my critic commends.

As a specimen of the distortion of facts to prove another case of priority that is claimed, I find that MM. Charles Olszewski and Auguste Witkowski, Membres Correspondants, presenting their memoir "Propriétés optique de l'oxygene liquide," on October 3, 1892, and, on referring to the paper, it is dated July 15, 1892, and the following footnote is added:

"Avant la publication de notre communication, MM. Liveing et Dewar ont fait connaitre (*Phil. Mag.* Aout 1892), les resultats de leurs recherches sur la refraction des gaz liquéfiés."

Yet the critic says our experiments were "mainly repetitions of the work of Olszewski and Witkowski." The garbled extracts selected to make it appear that I have been guilty of misrepresentation are all of the same kind. . . . Thus I am taken to task for using the expression in the lecture on liquid air, of 1893: "Having no recorded experience to guide us in conducting such investigations, the best instruments and methods of working have to be discovered." The next sentence runs as follows: "The necessity of devising some new kind of vessel for storing and manipulating exceedingly volatile fluids like liquid oxygen and liquid air, became apparent when the optical properties of the bodies came under examination. Apart altogether from the rapid ebullition interfering with the experimental work, the fact that it did take place involved a great additional cost in the conduct of experiments on the properties of matter under such exceptional conditions of temperature." What can be said in defence of such glaring misrepresentation of the meaning of my words? Mr. M. M. Pattison Muir's demand for "*instant and serious consideration*" of his client's "*case*" has been quickly met. I trust the result will . . . . fit in with his brief. JAMES DEWAR.

Royal Institution, February 12.

[A few personal remarks in Prof. Dewar's letter have been omitted, as they do not affect the points at issue.—Ed. NATURE.]

Vertebrate Segmentation.

MR. H. G. WELLS, in a recent number of NATURE, honours my little book by making it an example of a contravention of what he regards as a principle of education. With that I have no quarrel. But I must object to the instance he has chosen. The sentences from which he quotes refer to the phenomena of segmentation common to cœlomate tissues, and not to the derivation of vertebrates from any invertebrate group. So far from giving "the impression almost in so many words—'cut and dried,' and ready to be cast into the oven—that the vertebrate type is merely a concentrated derivative (concertina fashion) of the chætopod type," I devote the chapter (xv.) from which he has taken his quotations, to showing that the earthworm and the vertebrates merely belong to two out of the many isolated groups; and at the end of the chapter (though not in spaced type, as I did not consider the question of vertebrate descent congruous with the aims of an elementary text-book) I state that "the type common to the lowest members of the groups of which the earthworm on the one hand, and the vertebrates on the other, form the highest examples, is a simple unsegmented cœlomate animal."

P. CHALMERS MITCHELL.

The Black veined White Butterfly.

MR. KIRBY, on p. 340 of your last issue, says (in criticism of Mr. Furneaux) that this insect "would not frequent open ground at a distance from trees." I suppose there are not now many Englishmen who have taken it in this country; and it may be worth while to record that the common on which my brother and I used to find it tolerably abundant in the years 1857–1859, was quite an open place, with no adjacent wood, and very little hedge timber. This common is about a mile and a half to the west of Cardiff; I passed it in the train a few weeks ago, and noted that it is being encroached on by suburbs. We had many a hot chase there over gorse and briar, and always considered this butterfly the most difficult of all to catch. I have never seen it in England since 1859 or 1860.

Oxford, February 11.

W. WARDE FOWLER.

Parrots in the Philippine Islands.

PRAY allow me space to acknowledge a bad mistake which I first made in the ninth edition of the "Encyclopædia Britannica" (xviii. p. 322), and have lately repeated in the "Dictionary of Birds" (p. 687), by asserting that parrots are "wanting in the Philippine Islands." Seeing that the article was written more than ten years ago, it is quite out of my power to account for the misstatement: my only wonder is that it has not been before challenged, since there is, and has been for some centuries, abundance of evidence to show that there are plenty of parrots in that group of islands, which, indeed, is as well furnished with them (as remarked by my friend Mr. L. W. Wiglesworth, who has kindly drawn my attention to my error) as is the island of Celebes, and I had already (p. 93) noticed the Philippine species of Cockatoo.

Cambridge, February 9.

ALFRED NEWTON.

TWENTY-FIVE YEARS OF GEOLOGICAL PROGRESS IN BRITAIN.

LOOKING back across the fourth part of a century in the progress of any branch of science, we naturally turn first to the list of names of those to whose labours that progress has been due, and though many of these names may happily still be counted among the living, we note many a blank where the hand of death has thinned the ranks. Perhaps in this country no department of natural knowledge can boast a more illustrious bead-roll than that of Geology. The story of the earth had hardly begun to be scientifically studied until the first decades of the present century, and some of the early fathers of geology lived on until well within the life-time of the present generation. A curious transition has thus been going on during the last five-and-twenty years. On the one hand, there have been moving amongst us geological magnates who achieved their fame in the old days when it was still possible for a man to possess a tolerably full personal knowledge of almost every department of the science. On the other hand, around these few living memorials of the heroic age, grew up hosts of younger men, who, finding the main lines already traced for them, have become in large measure specialists, devoting themselves with enthusiasm, but with more restricted vision, to one formation, or one group of rocks, or one tribe of fossils. The days of broad outlines and rapid generalisation have gone. No new systems remain to be added to the geological record of these islands. No new assemblages of extinct types of life now reward the sedulous collector. We have entered upon the era of minute detail and patient elaboration. The field-glass has given way to the microscope. The advance of the science must now be based on laborious research, less brilliant no doubt in its immediate effect, but probably not less lasting in its influence and its results.

Among the great leaders who have passed away within the last twenty-five years are some who have largely helped to mould the whole fabric of geological science. In the philosophy of geology, when will men cease to venerate the names of Lyell and Darwin? In laying down the broad lines of stratigraphy, Sedgwick and Murchison, Phillips, Griffith, Logan, Ramsay and Jukes have left behind them imperishable monuments of their genius. In the palæontological domain, among many other illustrious men, Owen, Lonsdale, Salter, Davidson, Morris, Wright and Egerton have left us. In other departments of the science, our losses have been likewise heavy—the gentle Scrope, pioneer of volcanic geology; Robert Chambers, who, after Agassiz, led the way here in the study of ancient glaciers; David Forbes, who did so much to revive the study of rocks in Britain; as well as men like Page and Ansted, who by their popular writings helped to spread abroad an interest in geology.

Passing from the workers to the work accomplished, we may note a few of the more prominent features in the progress of geology in Britain during the last quarter of a century. Space will not permit the survey to be extended to the history of the science on the continent of Europe and in North America. And first as to the general recognition of the science as an important department of a liberal education. No previous generation has seen so many proofs of this recognition. Many new chairs of Geology have been founded in our universities and colleges. Text-books, class-books, hand-books, manuals and primers of the science have been issued in edition after edition, and new publications are constantly appearing. Field-clubs, and other local associations, have started abundantly into existence, and field-geology is one of their most attractive features. At no time of its comparatively short history has geology been more popular, in the best sense of the word, than it is at the present time.

If one were asked to specify the feature which above all others has marked the progress of geology in Britain during the last five-and-twenty years, one would reply with little hesitation—the enlarged attention given to the study of rocks, or what is termed the petrographical department of the science. For many years in this country that study was almost entirely neglected. The attractions of fossils and of stratigraphy drove minerals and rocks out of the field. As David Forbes used sarcastically to complain, geologists had forgotten that their father was a mineralogist. They allowed the petrography of the British Isles to lapse into a condition of dire confusion, without system, without accurate determinations, and without reference to what had been done in the subject abroad. The first important step in the way of reform was taken by one who is happily still among us, Mr. H. C. Sorby. Reviving the method of making thin slices for microscopical examination, devised by William Nicol, of Edinburgh, he applied it to the study of rocks, and showed how fruitful it might be made in investigating their history. Though his first paper appeared in 1856, it was long in awakening geologists in this country to the value of the new implement of research thus placed in their hands. It attracted notice sooner in Germany, and its applicability as demonstrated there, led ultimately to its adoption in the land of its birth. But only within the last twenty years has it been acknowledged to be absolutely indispensable in the investigation of the origin and history of rocks.

The introduction of the microscope as an adjunct in research has entirely revolutionised the study of petrography. And nowhere has the change been so marked as in Britain. The former chaos has been in large measure reduced to order. The rocks of this country, instead of being neglected, are a foremost object of study, and this branch of British geology has been brought abreast of the petrography of the continent.

It is perhaps inevitable that in such a complete transformation of methods, the new should be apt to be regarded as completely replacing the old way. The microscope has done so much, that its potency may not unnaturally be exaggerated, and a tendency so to magnify it may sometimes be observed. But, after all, the great field-relations of the rocks must in the first place claim our attention and guide our reasoning. The minute structures revealed by the microscope may be made admirably serviceable in controlling that reasoning, and in supplementing the field-evidence by a new body of data otherwise unattainable. Yet the microscope must remain the servant, not the master, in the applications of petrography to the larger questions of geological theory.

If now we turn to the stratigraphical domain of geology, perhaps the first remark that will occur to a reflective observer is that a much closer attention than ever before has been given in Britain to the investigation of the most ancient accessible parts of the earth's crust. The fundamental platform on which the oldest fossiliferous rocks repose, has been searched for with enthusiasm, and though this enthusiasm has led to mistakes, it has undoubtedly been successful in detecting that platform in several places where it was not before supposed to exist. The rocks of the platform have been laboriously investigated, and have been found to include both aqueous and igneous materials. Not only so, but a succession has been observed among them, vast sedimentary masses lying ununiformably on still more ancient gneisses. In these sedimentary accumulations no certain trace of organic forms has yet been detected. Nevertheless the search has not been abandoned. If it should eventually be successful, it would reveal evidence of a fauna or flora older than the oldest relic of life yet discovered in Britain.

In the region where the most ancient gneisses are typically developed, foliated representatives of almost all the well-known plutonic rocks have been recognised, and perhaps also, though dimly, traces of a group of primæval sediments, into which igneous masses have made their way. We have thus been able to take several distinct steps backward into the abyss of time. We know more clearly than before the general outlines of two or more great geological periods anterior to the earliest relics of animal life. And as a band of zealous investigators is busy in the exploration of these dim records, it is perhaps not too much to anticipate a rich harvest of discovery from their labours.

Among the applications of palæontology to the stratigraphical side of geology, unquestionably the most important in recent times has been the recognition of life-zones among the stratified formations, and the adoption of these as a clue to the interpretation of the sequence of strata, and even of tectonic structure. It is long since the ammonite zones of the Lias, first worked out in Germany, were traced in this country. Subsequently the palæontological platforms in the Chalk, so well developed in France, were found to hold good also in England. Still more recently the vertical distribution of graptolites has been shown by Prof Lapworth to be so restricted that these organisms may be used to mark definite zones in the Silurian system. Nor is it in the animal kingdom only that such restriction has been asserted. The members of an extinct flora have been found to show a more or less marked sequence of genera and species, so that, alike in France and in England, the Carboniferous system has been subdivided into more or less distinct plant-zones.

The value of this palæontological aid in the investigation of stratigraphical succession can hardly be overestimated. Among the undisturbed Secondary rocks of England, indeed, it is not indispensable, for the sequence of their formations and their subdivisions can be accurately determined there from other evidence. Nevertheless stratigraphical arrangement gains much in precision, as well as in scientific interest, when changes in lithological characters are found to be accompanied by changes in organic forms; or, on the other hand, when the succession of animal or vegetable types is found to be repeated in distant localities irrespective of local variations in lithology. But where the rocks have been so folded and broken that from mere mineral characters their true order cannot be made out, the presence in them of determinable life zones, elsewhere well established, may enable their complicated structure to be unravelled. How this task can be successfully accomplished, has been well shown by Messrs. Lapworth, Peach, and Horne, in regard to the excessively convoluted structure of the Silurian uplands of the South of Scotland

There is, however, some risk of error in the application of this valuable aid in tectonic investigation. Obviously the existence of a life-zone, which will be of general utility, must be determined upon a basis of evidence sufficiently wide to eliminate mere local peculiarities. It should rest not on the presence of a single species, but on a group of species or genera, for the narrower its palæontological range the greater will be the risk of elevating accidental into general characters. We cannot suppose that a given species began and ended everywhere at the same time or on the same platform. In some areas the conditions would be favourable for its earlier appearance or longer continuance, so that we may expect the zones not to be very sharply defined, but to blend into each other, and in such a way that if we were to define them by single species we should find them to present exceedingly variable limits. In a restricted region, where the sequence of life-zones has been accurately ascertained, these platforms are of great value in working out questions of geological structure. But as we recede from that region the necessity of caution increases. The broad features of biological sequence will no doubt remain, and we shall be able to say where the upper or the lower members of a sedimentary series lie, but we may be led into mistakes by trying too rigidly to make the palæontological zones of one country agree with those of another.

In the department of geotectonics, one of the most interesting features has been the increased attention bestowed upon the nature and results of the great movements that have affected the crust of the earth. The early experiments of Hall, showing that the stratified rocks have undergone enormous lateral compression, have been repeated and extended, and many of the remarkable structures of mountain-ranges have been successfully imitated. More detailed investigation has been bestowed upon plicated and disrupted rocks, especially in Switzerland, Saxony and Scotland. The effects of mechanical deformation in producing foliated structures, even in what were originally massive rocks, have been copiously illustrated. The study of these questions has led to a better appreciation of the enormous plications, inversions, and dislocations which mountain-chains, modern as well as ancient, have undergone. In the Alps and in the Scottish Highlands, the subject has been pursued with great ardour, and these regions will henceforth be classical examples of some of the great features of geotectonic geology.

Another distinguishing characteristic of the last quarter of a century of geological progress has been the increased interest taken in the history of the earth's surface. It is strange that while, generation after generation, men laboured zealously to investigate the history of the planet as recorded in the rocks of the terrestrial crust, they neglected to take account of the superficial topography. They did not realise that every land-surface is a kind of palimpsest, on which the chronicles of a long series of ages may be more or less distinctly traced, and thus that every landscape has, as it were, two histories: first, that of the rocks which form its framework, and, secondly, that of the configuration into which these rocks have been carved. It was in Britain that this fascinating branch of geological inquiry first took definite form in the early days of Hutton and Playfair, and it is here that, after long neglect, it has within the last twenty or thirty years been renewed and pursued with most success. The varied geological structure of these islands, their changeable climate, their mountainous groups, and long lines of sea-beaten coast, make them exceptionally suitable for the prosecution of this inquiry. But this branch of geology is now receiving even more attention in the United States than among ourselves, and in many respects the geological structure of North America offers peculiar advantages for its cultivation.

It is impossible within the limits of this article to do more than present in brief outline a retrospect of a few of the departments of so wide a science as geology. Let me, in conclusion, make reference to but one more subject which has greatly exercised the minds of geologists during the last quarter of a century. It is more than thirty years since Lord Kelvin pointed out that there must be an ascertainable limit to the antiquity of the earth, and that from the data at that time available the limit could not be fixed at less than twenty, or more than 400, millions of years ago. He based this calculation on the thermal conductivity of the globe. Afterwards returning to the subject, he placed the limit within 100 millions of years; and still more recently, reviewing the question in the light of the arguments from tidal retardation and the age of the sun's heat, he has brought down the period of the earth's antiquity to about twenty millions of years.

Geologists have not been slow to admit that they were in error in assuming that they had an eternity of past time for the evolution of the earth's history. They have frankly acknowledged the validity of the physical arguments which go to place more or less definite limits to the antiquity of the earth. They were, on the whole, disposed to acquiesce in the allowance of 100 millions of years granted to them by Lord Kelvin, for the transaction of the whole of the long cycles of geological history. But the physicists have been insatiable and inexorable. As remorseless as Lear's daughters, they have cut down their grant of years by successive slices, until some of them have brought the number to something less than ten millions.

In vain have the geologists protested that there must somewhere be a flaw in a line of argument which tends to results so entirely at variance with the strong evidence for a higher antiquity, furnished not only by the geological record, but by the existing races of plants and animals. They have insisted that this evidence is not mere theory or imagination, but is drawn from a multitude of facts which become hopelessly unintelligible unless sufficient time is admitted for the evolution of geological history. They have not been able to disprove the arguments of the physicists, but they have contended that the physicists have simply ignored the geological arguments as of no account in the discussion.

So here the matter has rested for some years, neither side giving way, and with no prospect of agreement. Within the last few weeks, however, as readers of NATURE will have observed, the question has been taken up anew from the physical side.[1] Prof. Perry, feeling that, after all, the united testimony of geologists and biologists was so decidedly against the latest reductions of time, that it was desirable to reconsider the physical arguments, has gone over them once more. He now finds that on the assumption that the earth is not homogeneous, as postulated by Lord Kelvin, but possesses a much

[1] NATURE, January 3 and February 7, 1895, pp. 224–341.

higher conductivity and thermal capacity in its interior than in its crust, its age may be enormously greater than previous calculations have allowed.

The question being *sub judice*, we must wait until it is settled. But there seems at present every prospect that the physicists will concede not merely the 100 millions of years with which the geologists would be quite content, but a very much greater extent of time.

ARCH. GEIKIE.

NOTES.

THE second of the special meetings of the Royal Society is announced for the 28th inst., when Prof. Weldon will bring forward as a subject for discussion, "Variation in Animals and Plants."

A SUM of 12,000 francs (£480) was voted to the Mont Blanc Observatory by the French Chamber on Tuesday.

PROF. HENRY A. ROWLAND has recently been elected a Foreign Member of the Reale Accademia dei Lincei of Rome, in the section of Physics.

THE death is announced of the Marquis de Saporta, the eminent botanist, at Aix. He was a Correspondent of the Section of Botany of the Paris Academy of Sciences.

MR. REGINALD STUART POOLE, late Keeper of Coins at the British Museum, died on Friday last, in his sixty-third year. Few men have done so much as he to extend the study of Egyptology and antiquities, or have added more to these branches of knowledge. Before he was seventeen years of age he wrote a series of articles on Egyptian chronology, which afterwards appeared in book form under the title "Horæ Ægyptiacæ." He began very early to lecture on Egyptology and numismatics, and in May 1864 made his first appearance in a Friday evening lecture at the Royal Institution. In 1877 he became Keeper of Coins, and during his twenty-two years' tenure of that post he saw through the press thirty-five most valuable catalogues of the collections under his charge. He was the author of the "Cities of Egypt," and of the articles on "Egypt," "Hieroglyphics," and "Numismatics," in the "Encyclopædia Britannica." With Miss Amelia B. Edwards, he was one of the founders of the Egypt Exploration Fund, of which he remained the honorary secretary to his death.

A NEW scientific society, composed chiefly of the professors and assistants in the Paris Natural History Museum, has just been founded. The society owes its existence to Prof. Milne-Edwards, the eminent director of the museum. It is proposed to hold monthly meetings, and to issue a *Bulletin des Naturalistes*, dealing with natural history matters.

THE Manchester Literary and Philosophical Society is fortunate in having Mr. Henry Wilde, F.R.S., for its president. Always one of the best of provincial societies, its usefulness is likely to increase, for Mr. Wilde has intimated his intention to endow the Society with the sum of eight thousand pounds, the annual income from which is to be devoted to various purposes in connection with its work.

THE history of the Museum of the Corporation of London, in the Guildhall, has never been written, although the collections housed therein are of very considerable interest and value. Taking occasion of the visit of the Essex Field Club on Saturday next, Mr. C. Welch, the Curator, will read a paper on the "Origin and Progress of the Guildhall Museum," to remedy this defect. The museum deserves to be better known and better housed than it is at present. A museum fully illustrating the ancient history of London might easily arise from the present collections, and would be a worthy object for achievement for the richest Corporation in the world.

THE Société Technique de l'Industrie du Gaz en France offers several prizes in connection with the Congress to be held during the present year. The *Journal* of the Society of Arts says that the prizes open to all include one of 10,000 francs (£400) offered to the inventor of an incandescent gas-burner showing marked superiority, to be handed in to the Society before April 1 in the present year, unless the committee exercise their power of extending the period for another year. The sum of 8000 francs (£320) will be devoted to various prizes to be awarded to the authors of the best papers on some subject connected with the gas industry, such as the mechanical *manutention* (handling) of coals, cokes, and the various substances used in gasworks, a study of water-gas, and the substitution of hydro-carbons for cannel coal. The papers must be written in French, and not bear the name of the author; but they must contain at the commencement a motto, which must be reproduced on a sealed envelope containing a declaration, signed by the author, that his work is unpublished, and that he will not make any other publication on the same subject within a year. The manuscripts, with sealed envelope, must be sent to the Society, 65 Rue de Provence, Paris, at least forty days before the period fixed for the Congress.

DURING the past week the severe frost has continued over the whole of these islands, and heavy falls of snow have occurred in all three countries. The distribution of pressure has been generally anticyclonic, biting easterly winds, and gales on our coasts. The following are a few of the lowest shade minima published in the *Daily Weather Report* of the Meteorological Office, since we last went to press:—

February	7	8	9	10	11	12	13
	°	°	°	°	°	°	°
Nairn	0	6	5	4	3	18	5
Loughborough	2	−5	−4	−1	1	4	2
London	12	10	11	13	20	14	15
Cambridge	6	6	7	7	13	15	15

In the neighbourhood of the metropolis some very low readings were recorded on the 8th instant: Wallington 2°·1, Croydon 5°·5, Tulse Hill 6°, Greenwich 6°·9; and in other parts of the country the following minima have been observed: −12° at Braemar, −8° at Stamford on the 8th, −5° at Glenlee on the 9th, and a still lower reading, viz. −17°, is said to have been observed at Braemar on the 11th instant. The reading of 6°·9 at Greenwich is the lowest but one in the last 50 years, a temperature of 6°·6 having been recorded on January 5, 1860. There had been no reading there lower than 10° in February during the same period, until the present frost, in which lower temperatures have occurred on two successive nights. In London such low temperatures rarely occur; a minimum of −5° was observed by Luke Howard on February 9, 1816. Another feature of the present frost has been the low daily maxima. On the 9th instant it did not exceed 20° at Tulse Hill. At Greenwich the maximum temperature on January 5, 1894, was 19°, which was then the lowest maximum observed there since 1841.

IN a paper read before the British Medical Association in 1889, Dr. A. C. Miller pointed out that, under certain circumstances, advantage might be derived from high level residence in the treatment of tuberculous conditions. A note, which has a bearing upon this view, is contributed by him to the *British Medical Journal*. The observers at the meteorological station on the summit of Ben Nevis are changed every three months or so. While on duty at the observatory, they are, as a matter of course, exposed to the rigours and inclemencies of the climate on the top of the mountain, and are thus subject to conditions that, *prima facie*, might be expected to favour the occurrence of catarrhs and inflammations. But experience shows quite a different result. The observatory staff while in actual residence on the summit has been remarkably free from all kinds of ailments during the eleven years that have elapsed since the opening. The subsequent residence at low level, however, renders the members of the staff peculiarly liable to an affection which closely resembles, in most of its features, what is usually recognised as an influenzal catarrh. There seems little room for doubt that this condition is due to germ influences in the lower atmosphere. At the summit of the mountain organisms do not exist, or if they do exist, only in innocuous numbers. At the low level they relatively thrive, and, seizing upon the "virgin soil" of a renewed and susceptible mucous surface, they set up the phenomena described.

IN the January and February numbers of the *Geological Magazine*, Mr. E. P. Culverwell criticises severely the astronomical theory of the Ice Age. He concludes that the change in the distribution of the solar heat received by the earth during a period of maximum eccentricity, would not cause a shifting of the isotherms as great as the displacements to which the course of existing isotherms is subject from purely geographical causes. If this is correct, the eccentricity theory of the Ice Age must be abandoned. As a possible alternative theory, Mr. Culverwell suggests a variation in atmospheric pressure through interchange of gases during the earth's passage through space.

SOME interesting additions to Palæobotany are being made by Japanese geologists. In a recent paper (*Journ. Coll. Sci., Imp. Univ., Japan*, vol. vii. part iii. 1894), Prof. Yokoyama gives the results of his study of the fossil plants from several localities on the outer or convex side of that remarkable island. Unlike the plant-bearing beds of the inner, concave side, which, so far as is known, are all Middle Jurassic, the strata from which the flora in question comes appear to be comparable in age to the Wealden of our own country. In the same number, Mr. Nishiwada records the occurrence in Japan of a Tertiary (probably Miocene) limestone with abundant remains of the peculiar calcareous alga or "nullipore," *Lithothamnion*.

PROF. A. ISSEL and Dr. G. Agamennone, who were deputed by the Italian Government to investigate the Zante earthquakes of 1893, have recently issued a valuable report of more than two hundred quarto pages (*Ann. dell' Uff. Cent. di Met. e Geod.* vol. xv. part i. : Rome, 1894). Dr. Agamennone contributes a catalogue of the earthquakes felt in Zante from the earliest times until 1893, and some general remarks on the same, as well as chapters on the relation between the shocks of 1893 and the contemporaneous geodynamic phenomena in Italy, and on the velocity of propagation of the principal shocks. Prof. Issel describes the geology of the island, relates in some detail the features of the recent earthquakes, and concludes the work with a chapter of theoretical considerations.

IN a former note (p. 232), a brief description was given of a remarkable group of earthquake-pulsations recorded at several Italian observatories, and at Nicolaiew on October 27, 1894. It was supposed that these might have proceeded from the great earthquake which occurred on the same day in Chili and the Argentine Republic. The doubt which formerly existed about the time of the shock is now removed by the receipt of detailed accounts. The first pulsations were registered at Rome at 9h. 7m. 35s. p.m., Greenwich mean time, while the shock was recorded at the observatory of Santiago (Chili) at 8h. 50m. 26s., *i.e.* 17m. 9s. earlier. There can thus be little doubt as to the origin of the pulsations, which probably travelled with a velocity of nearly 11 k.m. per second.

A SIMPLIFIED process for silvering glass is described by MM. Auguste and Louis Lumière in the *Journal de Physique*. Take 100 parts by volume of a 10 per cent. solution of nitrate of silver, and add, drop by drop, a quantity of ammonia, just sufficient to dissolve the precipitate formed, avoiding any excess of ammonia. Make up the volume of the solution to ten times the amount by adding distilled water. The reducing solution used is the formaldehyde of commerce. The 40 per cent. solution is diluted to a 1 per cent. solution. The glass to be silvered is polished with chamois leather, and the bath is made up immediately before use, by mixing two parts by volume of the silver solution with one of formaldehyde. The solution must be poured right over the surface without stopping. After about five or ten minutes, at a temperature between 15° and 19° C., all the silver in the solution is deposited on the glass in a bright layer, which is then washed in running water. It is then varnished if the glass side is to be used, or polished if the free surface is required for reflection. This method does not require the scrupulous care necessary with other methods, but Brashear's process, for instance, gives mirrors which do not require polishing.

THE Government of Cape Colony has recently instituted inquiries in various quarters with a view to gain suggestions as to the best methods of developing the neglected sea-fisheries of the colony. The Minister of Agriculture has received a number of replies upon the subject, which have been published in the *Agricultural Journal* of Cape Colony. The first desideratum in a matter of this important nature is clearly that the Government should possess some trustworthy and responsible source of information upon matters connected with its sea-fisheries; and on this account Dr. Trimen, the Curator of the South African Museum, strongly recommends the Government to obtain the services of a competent naturalist, accustomed to the study of marine animals and, if possible, experienced in the work of English or American Fishery Departments, who would devote himself to a thorough study of South African Fisheries. The appointment of skilled naturalists as Fishery Advisers to Governments has been attended with excellent results in Holland and other countries, and we heartily endorse all that Dr. Trimen has to say in favour of the adoption of a similar course in the present instance.

MESSRS. LAWS AND ANDREWES have not finished their vindication of the innocuous nature of sewer air. We thought that from the microbic point of view this question had been disposed of; but the London County Council evidently think differently, and another report is to hand, telling us that the microbes present in sewage are not present in sewer air, and that there is no microbic relationship, either in quantity or quality, between the two. These investigators claim to have found a bacillus resembling the typhoid bacillus in a drain from the typhoid block of a fever hospital in which no disinfection had been carried out for two days previously. This is hardly "an important fact," and perhaps not an unexpected discovery; but it is interesting to note that when typhoid germs are placed in sterile sewage, they are said to succumb rapidly, whilst the closely allied *B. coli communis* multiplies extensively. Details are given as to how the sewage was sterilised; but whether culture material was introduced along with the respective organisms, is not mentioned. We fail to understand why the colon bacillus is described as "harmless"; it has been shown to possess very distinct pathogenic properties. Experiments were conducted to ascertain what effect certain sewage microbes would have on the vitality of the typhoid bacillus in sterile sewage, whether the demise of the latter would be hastened or retarded by their presence. In these investigations we are informed that the respective microbes were inoculated into the sewage *direct from broth cultures*, so that we cannot accept the results obtained as representative. It has been repeatedly shown what an effect the presence of even minute traces of culture material has on the vitality of particular microbes in water, &c., and what confusing and conflicting results have been obtained by different observers working with the same microbe through neglect of this simple precaution. It is to be hoped that if any further experiments in this direction are contemplated, Messrs. Laws and Andrewes will bear this fact in mind.

THE inaugural lecture "On the Present Relations of Agricultural Art and Science," delivered by Prof. R. Warington, F.R.S., in the University Museum, Oxford, on the 4th inst., has been published by Mr. Henry Frowde. By a few statements of fact, the Sibthorpian Professor shows that the agricultural industry can only be placed upon a sound basis by the full adoption of scientific methods and the recognition of research. It is very well known that the provision for agricultural investigations in England is at present wholly inadequate. We have the important experiment station at Rothamsted, and the Royal Agricultural's Society's station at Woburn. Experiments are also carried on at some of our agricultural colleges; but this represents practically all that is being done here for the elucidation of agricultural problems. Compare this with the provision made in other countries. "In the German Empire alone there are fifty-four agricultural experiment stations, besides numerous public laboratories for the analysis of manures, and seed testing. The experiment stations are supported by aid from the State. The whole number of experiment stations on the continent of Europe is about 190. There are besides these, about 120 public laboratories devoted to special kinds of agricultural work. In the United States, a great effort has recently been made to provide the whole country with experiment stations. Every State in the Union has now at least one station, supported, since the year 1887, with an annual income of about £3000 paid to it by the nation. The total number of experiment stations in the United States is at present fifty-five . . . the practical working out of agricultural problems can only be accomplished by the establishment among us of a considerable number of experiment stations; only in this way can science be brought into touch with practices, and the teachings of science reduced to that concrete form in which they can be put to profitable use by the farmer. Why should not our County Councils found and maintain an agricultural experiment station in each county? Such a station would become a centre of light and teaching to a large district."

THE *Proceedings* of the eleventh annual convention of the Association of Official Agricultural Chemists, just distributed by the U.S. Department of Agriculture, enforces the remarks referred to above. The volume is literally full of facts relating to agricultural chemistry. It contains many original articles, abstracts of papers, analyses of fertilisers, foods, soils, and farm products, and numerous reports. Unfortunately, the results of such investigations in the United States are not fully applicable to British agriculture. What is wanted, as Prof. Warington points out, is a central agricultural laboratory in England, having as one of its duties the preparation of chemical agricultural statistics. When this has been established for a few years, agriculturists will not have to confess that they know more about the composition and properties of German and American produce than they do of similar products in our own country.

THE tenth of the Alembic Club Reprints, published by Mr. W. F. Clay, Edinburgh, contains Graham's most valuable contribution to pure chemistry, viz., the paper read before the Royal Society in 1833, entitled "Researches on the Arseniates, Phosphates, and Modifications of Phosphoric Acid."

ALL that is readable about comets is to be found in Mr. Thynne Lynn's "Remarkable Comets" (Edward Stanford), the third edition of which has just been published. Though but a slender brochure of less than fifty pages, this little treatise comprises most of the interesting facts in the history of cometary discovery.

THE new illustrated catalogue of electrical and other apparatus, just published by Messrs Elliott Brothers, is capable of giving the student of elementary science a liberal education in scientific instruments. Almost every important piece of apparatus used in electricity is illustrated in the catalogue, as well as the tools of research and education in other branches of physical science.

THE Calendar of the Department of Science and Art, for 1895, has been issued. For the benefit of those unfamiliar with this publication, it may be worth mention that the Calendar comprises a history and general description of the whole Department, with a summary of the rules, and a list of the Science and Art Schools and Classes, containing the number of students in each school and in each subject.

IN the *Bulletin* of the College of Agriculture of the Imperial University of Japan (vol ii. No. 3), Prof. Sasaki gives a full description of the scale insect of mulberry trees (*Diaspis patelliformis*, n. sp.) and of the principal features of its life-history. A great deal of damage seems to be done by this insect pest; and it would be well if tree-owners in Japan would make use of the simple remedial measures recommended by Prof. Sasaki. The *Bulletin* also includes a paper on the spermatogenesis of the silkworm by K. Toyama.

IN 1881, the first edition of "Elementary Lessons in Electricity and Magnetism" (Macmillan), by Prof. S. P. Thompson, F.R.S., was published. Since then the book has been reprinted, with alterations and additions, many times, and an entirely new edition has now been issued. We are reminded in the preface that during the fourteen years which have elapsed since the book first appeared, electrical science and the science of magnetism have been greatly advanced. Striking progress has been made in theory and in practice, and the expansion of knowledge has necessitated an expansion of the book. Whoso seeks a class-book on electricity and magnetism, containing an elementary exposition of recent work, will find their want supplied by Prof. Thompson's Lessons.

In *Science Progress* for February, Dr. C. S. Sherrington F.R.S., describes the varieties of leucocytes. Mr. A. C. Seward concludes his second contribution on the structure and formation of coal, with a paragraph which expresses his conviction that "the weight of evidence seems to tip the balance of opinion very materially towards the theory of drifting and subaqueous sedimentation, for the majority of the Palæozoic coal seams." An account of the researches on the methods of digestion in Cœlenterates, is given by Prof. S. J. Hickson; Dr. W. F. Hume reviews works on geological folds and faulting; and Mr. Philip Lake adds to the literature of tectonic geology, a paper on Neozoic—that is, Mesozoic and Cainozoic—geology in Europe.

AT present the English Arboricultural Society hardly justifies its name, for it is more or less limited to the North of England. There is every prospect, however, of its extension southwards in the future, both on account of the attention now being given to forestry, and because the Society is making efforts to increase its membership by going further afield. The *Transactions* of the Society, of which we have received a recent issue (vol. iii part iv.), should materially assist towards this end; for the instructive papers contained therein appeal to all foresters. In the Part received by us, there is an essay on "How Trees Grow," by Mr. J. Maughan; an essay on "Thinning Mixed Plantations," by Mr. W. Forbes; and a paper on "The Distribution of Trees in a Wood," by Prof. W. Somerville. These are all useful contributions, but even more important is the publication of the results of an inquiry, conducted by the Society, into the disease of the Larch, a subject about which much has been written and said. The information which Prof. Somerville has brought together, forms a valuable summary of the present position of knowledge in regard to the Larch disease, and shows the various conditions and cultural methods which hold out some prospect of securing comparative immunity from attack. With a larger membership, the Society would be able to carry out, and publish, the results of many similar investigations.

PROF. SCHIFF and Dr. Tarugi describe, in a communication to the *Berichte*, an admirable substitute for the disagreeable sulphuretted hydrogen in qualitative analysis. The new reagent is the ammonium salt of thio-acetic acid, $CH_3 . COSNH_4$. Ammonium thio-acetate is decomposed by hot dilute hydrochloric acid, liberating sulphuretted hydrogen without any precipitation of sulphur. No objectionable bye-products are formed in the reaction, only sal-ammoniac and acetic acid being produced. When a feebly ammoniacal solution of ammonium thio-acetate is added to a hydrochloric acid solution of the metals of the second group, and the liquid is heated to near boiling, the metals are at once precipitated as sulphides, while only the faintest odour of sulphuretted hydrogen is perceptible. After cooling and filtering, the filtrate is found to contain no trace of the metals, not even of arsenic if an arseniate had been originally present. The completeness and rapidity of the reaction, particularly in the case of arsenic, which is usually so troublesome to precipitate from arseniates, is one of its strongest recommendations, and is described by Prof. Schiff as being perfectly surprising. A couple of cubic centimetres of a 30 per cent. solution of ammonium thio-acetate is usually ample for a gram of the substance to be analysed. The reagent has been employed for some time by Prof. Schiff in the Pisa laboratory, and is much appreciated by his students, sulphuretted hydrogen being completely excluded from the laboratory, doubtless to the material advantage of all concerned, both as regards comfort and health. Thio-acetic acid is readily prepared by acting upon glacial acetic acid with phosphorus pentasulphide. It boils at 95°, and is but slightly soluble in water. When the acid is dissolved in a slight excess of dilute ammonia, a yellow solution is obtained, which is then diluted to three times the volume of the acid originally taken—that is, 10 cubic centimetres of the acid furnish 30 cubic centimetres of the reagent. Prof. Schiff serves the reagent out to his students in small bottles closed by a cork, through which a small pipette, holding 2 cubic centimetres, is inserted, by means of which the convenient quantity of the reagent can at once be added to the hydrochloric solution of their test substance. It is scarcely necessary to add that zinc, manganese, nickel, and cobalt are not precipitated in the presence of hydrochloric acid by the new reagent, any more than by sulphuretted hydrogen itself. The sulphides of these metals are at once precipitated, however, upon rendering the solution alkaline; but as ammonium sulphide acts quite as well for this purpose, Prof. Schiff confines the use of ammonium thio-acetate to the precipitation of the metals of the second group.

THE additions to the Zoological Society's Gardens during the past week include a Lion (*Felis leo*, ♂) from India, presented by H.R.H. the Duke of Connaught; a Cape Bucephalus (*Bucephalus capensis*) from South Africa, presented by Mr. J. E. Matcham.

OUR ASTRONOMICAL COLUMN.

THE MASS OF THE ASTEROIDS.—A preliminary note on the probable mass of the asteroids was contributed by Mr. B. M. Roszel to the *Johns Hopkins University Circular* in May 1894, and summarised in these columns (NATURE, vol. l. p. 87.) In that paper Mr. Roszel limited himself to determining the mass from a study of 216 minor planets; he has now extended the computations to 311 asteroids, the orbits of which are given in the *Berliner Astronomisches Jahrbuch* for 1894 (*University Circular*, January 1895). His chief object was to find a probable limiting value for the mass, rather than an accurate determination of the mass itself. Using the photometric determinations of the diameter of Vesta, by Pickering and Müller, and the direct measures of the diameters of Ceres, Pallas, and Vesta by Barnard, Mr. Roszel has reduced the volumes of all the asteroids to the volume of Vesta, except when Barnard's measures were the basis, in which case he computed the volumes of Ceres and Pallas separately, and added them to the combined volume of the remaining 309. Assuming the albedo constant and a constant density equal to the density of Mars, he obtained the following numbers:

Combined volume of 311 asteroids .	5·185 vol. of Vesta.
,, ,, omitting Ceres and Pallas. . .	2·684 ,, ,,
Volume of Vesta, in terms of volume of Mars:	
(1) From Pickering's estimate of the diameter of Vesta, assuming the albedo = albedo of Mars	= 0·00022
(2) From Müller's estimate, assuming (*a*) the albedo = albedo of Mars . . .	= 0·00065
(3) From Müller's estimate, assuming (*b*) the albedo = albedo of Mercury . . .	= 0·00129
(4) From Barnard's estimate of the diameter of Vesta	= 0·00018
Combined mass of 311 asteroids, in terms of mass of Mars:	
From Pickering's estimate, as above . .	= 0·00112
,, Müller's estimate, as above (*a*) . .	= 0·00336
,, ,, ,, ,, (*b*) . .	= 0·00666
,, Barnard's measures	= 0·00273

The mean diameter of Mars was taken as 4230 miles. It appears from the above numbers that the combined mass of the asteriods is about ·026 of the mass of the moon.

THE APPARENT DIAMETERS OF MERCURY.—During the transits of Mercury on May 9, 1891, and November 10, 1894, Prof. Barnard gave special attention to measurements of the planet's apparent diameter. (*Ast Jour.* No. 335.) In both cases the diameter in R.A. was found to be slightly greater than that in declination, and if this be not a mere accidental coincidence, as Prof. Barnard seems rather inclined to believe, it would indicate a small polar compression. The measures at the two transits respectively indicate a polar compression of 1/134 and 1/98, or a mean of 1/116. Though by no means insisting on the reality of the difference in the diameters, Prof. Barnard points out that "the results may be of great importance in the future, as bearing upon the rotation of the planet on its axis in a reasonably short period." Expressed in angular measure, reduced to unit distance, the two diameters as measured in 1894 were 6″·241 for the "equatorial," and 6″·178 for the "polar" diameter. It is incidentally mentioned that "though Mercury cannot be seen at transits with the naked eye alone, it only requires a power of 2½ diameters to make it easily visible."

THE VARIATION OF LATITUDE.—The results obtained by Mr. Chandler in his investigations of variation of latitude seem to be confirmed by M. Ivanof's recent discussion of the older series of observations made with the great vertical circle at Pulkowa. (*Ast. Jour.* No. 335). "There is no doubt that two periods subsist; one equal to 428 days, the other to a year. Also, the semi-amplitudes of both terms are variable beyond any doubt."

THE SUN'S PLACE IN NATURE.[1]

I.

WHEN, in 1886, it became my duty to give a course of lectures here, I thought it advisable to deal with the sun and stars, not with reference specially to solar physics, but in order to give a general idea of two important lines of work which were running then nearly parallel to each other, and promised soon to meet, with the greatest benefit to science. Only a very little was said in those lectures touching the relation of stars to nebulæ, and the various views which have been held time out of mind with regard to the special nature of both these classes of celestial bodies. Such questions, however, have always had the greatest interest for mankind, for those at all events among us who like to know something about the universe in which our lot is cast. No dividends, unfortunately or fortunately, depend upon the discussion or even the application of any branches of inquiry which are necessary in order to make progress along the lines of thought thus opened up; scant attention is paid to them by educational bodies, for they lead to no profession; but in spite of that, some of the noblest triumphs of the human mind have been made in that region where man finds himself face to face with the mysteries of the distant heavens.

To consider completely the Sun's Place in Nature, which is the subject I have chosen for this present course of lectures, the relation of these two apparently different classes of celestial bodies to which I have referred, must be gone into. Thanks to the advance of modern science, I shall be able by-and-by to throw upon the screen pictures of clusters of stars, and of nebulæ, in which you will see those bodies very much better than you could do if to-night you were in one of the best equipped observatories in the world, for it so happens that the enormous progress which has recently been made in the application of photography to astronomical work enables us to get permanent records of parts of them which are so dim that they never have been and never will be directly revealed to the eye of mortals.

When we compare these two great groups of celestial bodies we find that, at all events in appearance, there is an enormous difference between them; that a nebula is certainly unlike a star, or even an ordinary star cluster. This is so obvious that even those who first observed those very few nebulæ which are visible to the naked eye (such a one, for instance, as that which is now beautifully visible to us in the early night in the nebula of Orion, or the other in Andromeda, which we can see almost throughout the year), the greatest wonderment was caused by their strange appearance.

Let us go back 150 years. I have here a book ("Les Hypothèses Cosmogoniques"), recently written by a distinguished French astronomer, M. Wolf, which contains a reference to what the French philosopher Maupertuis said about them in the year 1745. "The first phenomenon is that of those brilliant patches in the sky which are named nebulæ, and have been considered as masses or groups of small stars; but our astronomers, with the aid of better telescopes, have only seen them as great oval areas, luminous and with a light brighter than the rest of the heavens. Huygens first discovered one in the constellation of Orion; Halley, in the *Philosophical Transactions*, pointed out six, the first in the Sword of Orion, the second in the constellation of Sagittarius, the third in the Centaur, the fourth before the right foot of Antinoüs, the fifth in Hercules, and the sixth in Andromeda. Five of these spots having been observed with a reflector of 8 ft., only one of them, the fourth, could be taken for a group of stars; the others seem to be great shining areas, and do not differ among themselves, except that some are more round and others more oval in shape. It seems also that in the first the little stars which one discovers with the telescope are not capable of causing this brightness. Halley was much struck with these phenomena, which he believes capable of explaining a thing which seemed difficult to understand in the Book of Genesis, viz. that light was created before the sun. Durham regards them as holes through which one discovers an immense region of light, and finally the empyrean heaven itself. He professes to have been able to distinguish that the stars which are seen in some of them are very much less distant from us than the spots of light themselves."[2]

I need not follow the quotation any further, but you see that 150 years ago some of our keenest intellects were struggling with the questions involved in mystery which had been started by the discovery of these nebulous bodies in space. That was in the year 1745. Soon after this, in the year 1755, Kant, who was a German, though he was by direct descent a Scotchman, brought out an hypothesis in which he attempted to show that there was the closest possible connection between stars and the clusters and nebulæ of which Maupertuis spoke. He held distinctly that the stars were produced by some action brought about in nebulæ; in other words, that the nebulæ represented a first stage out of which stars, representing a later stage, were produced by certain processes of evolution.

From 1755 we pass to 1796, at which date we find a great Frenchman (Laplace) practically rediscovering and reasserting the same thing. It is believed that he knew nothing of Kant's prior work, and therefore we have the advantage of dealing with the results of the thoughts of two great minds. Laplace came to the same conclusion as Kant, so far as it went, but he went further than Kant did, because he held that the nebulæ really represent enormous masses of elastic gas at high temperature, and that therefore the stars, which he conceived, as Kant had conceived, to be produced by evolutionary processes from these nebulæ, were really produced from incandescent masses of gas.

Now, seeing that our sun is a star, it is perfectly clear from this that both Kant and Laplace agreed that the sun, representing a star, had originally been produced from a nebula. That is my first point.

About the time of Laplace, *i.e.* about 1796, Sir William Herschel was making England famous by the discoveries rendered possible by that wonderful telescope which he had erected at Slough. There, for the first time, the possible similarities and the possible differences of these two great groups of celestial bodies were subjected to the most minute and laborious scrutiny. Well, he came absolutely to the same conclusion as his predecessors had done, and for Sir William Herschel there was no doubt whatever that from the most irregular nebula to the densest star there was a gradual process of change; that there was no radical difference, but that the star represented simply the result of certain evolutionary changes. This view thus strengthened held the field for some years; then a larger telescope was made by Lord Rosse, a 6-foot mirror was now available instead of the 4-foot one which had been erected by Herschel at Slough. Lord Rosse—you will find the whole story admirably told in Prof. Nichol's book, "The Architecture of the Heavens"—came to the conclusion that when he observed a so-called nebula on the finest possible nights, when the air was stillest, and the magnifying power which he could use was greater than usual, he could see what he called the possibility of a resolvability in it. That is to say, nebulæ might after all really be star clusters, only immensely remote, so that the light of all the stars was, as it were, so welded together as to give that appearance of a candle seen through horn, which Maupertuis and his predecessors had observed.

Next we come to the year 1862, and we find a new instrument brought to bear, which at once drove into thin air all the statements which had been made ón what had turned out to be a line of inquiry which was incapable of giving a final verdict. It so happened that in that year there was a very powerful combination formed by a distinguished chemist and philosopher, Dr. William Allen Miller, the Treasurer of the Royal Society, who had already done most admirable spectroscopic work, and a neighbour of his, Mr. Huggins, who had mounted a powerful telescope in 1856. The spectroscope, which was then practically a new instrument, was applied to the telescope.

I need not say much about the spectroscope, as I have already had an opportunity of describing it to some of you, but I may in a few words show exactly the function of this new instrument of enormous power, which has in a very few years perfectly changed the aspect of astronomic science. If we pass a ray of white light through a piece of glass called a prism, we find that after the light has so passed through, it is changed into a beautiful band, showing all the colours of the rainbow. This prism then is the fundamental part of the instrument which is called the spectroscope, and the most complicated spectroscope which we can imagine simply utilises the part which this piece of triangular glass plays in breaking a beam of light of any colour

[1] Revised from shorthand notes of a course of lectures to working men at the Museum of Practical Geology during November and December, 1894.

[2] "Discours sur les différentes figures des Astres," chap. vi. pp. 104-14.

into its constituent parts from the red to the violet; between these colours we get that string of orange yellow, green, and blue which you are familiar with in the rainbow. For sixpence any of you may make for yourselves an instrument which will serve many of the purposes of demonstrating some of the more beautiful fields of knowledge which have been opened up

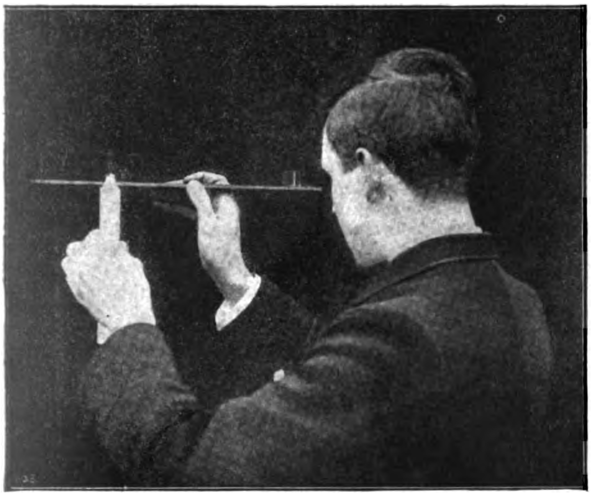


FIG. 1.—A simple form of spectroscope.

to us by its use. From an optician you can get a tiny prism for sixpence; glue it at one end of a piece of wood about $12 \times 1 \times \frac{1}{2}$ inch, so that you can see through it a coloured image of a needle stuck in at the other end of the piece of wood (Fig. 1). This you must do by looking sideways through it. Allow your needle to be illuminated by a candle or a gas

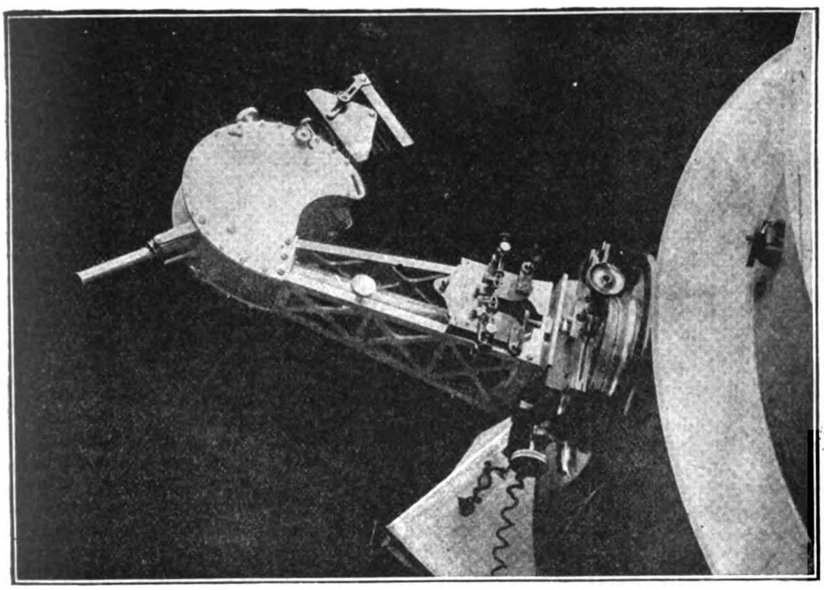

FIG. 2.—Star spectroscope, arranged for photographing, attached to eye-end of reflecting telescope.

flame, taking care that the direct light from the candle does not fall upon the face of the prism; you will then get a complete band of colour from red to blue. If you go into the sunlight—taking care again to protect the prism itself from the entrance of any foreign light—and allow the sunbeam to illuminate your needle, you get a spectrum of a different kind, full of black lines.

By such experiments as that, certain spectroscopic axioms have been formulated: three of them are very important.

First, when solid or liquid or densely gaseous bodies are incandescent, they give out continuous spectra.

Second, when a solid or liquid body reduced to a state of gas, or any gas itself, is giving light, the spectrum consists of bright lines, and these lines are different for different substances.

Third, when light from a solid or liquid body passes through gas at a lower temperature, the gas absorbs those particular rays of light of which its own spectrum consists.

We will next suppose, then, a spectroscope placed at the eye-end of a telescope (Fig. 2). The question put to the combined instruments is: What is starlight like? It was found that the stars give a spectrum very much like the spectrum of the sun, in most cases at all events, and that this spectrum could be defined in the light of the third axiom, that certain of the light was absorbed, there were dark lines in the spectrum (Fig. 3); and thus we knew that light had been absorbed by an atmosphere surrounding something which was very much hotter than itself, and in that way the science of solar and stellar physics was founded.

Suppose another question put to this instrument: What is the light of the nebulæ like?

I have already told you that Laplace held that in these bodies we were dealing with gas at a high temperature. From the time of Tycho Brahe downwards, people had an idea that the nebulæ were "fiery." What should we expect to get in our instrument? The second axiom tells us that, if we are dealing with matter in a state of gas, or anything vapourous at very high temperature, we shall get bright lines only. The question as to the nebulæ was put in 1864, and, curiously enough, when the observation was made, Dr. Huggins remarked: "I suspected some derangement of the instrument had taken place, for no spectrum was seen, but only a line." "Only a line" was exactly what I suppose Laplace would have given all he possessed to see, if spectrum analysis had been invented in his day. That line settled the question. There was certainly a tremendous spectroscopic difference between stars and nebulæ, and this difference has been emphasised by subsequent researches. (See Fig. 3.) It is evident, therefore, that Lord Rosse's suspicion that the nebulæ might, after all, be found to be resolvable into star clusters when greater optical power was used, was proved to be erroneous.

Now we come to the second point. I indicated in the previous course of lectures that there were differences among the stars, depending possibly upon chemical constitution, or temperature, or even upon their ages, and that the stars had been classified by several very diligent inquirers. Also, that in all the classifications that had been attempted, it was universally taken for granted, for some reason or other—possibly in view of the idea of Laplace—that all the stars in the heavens began in the condition of highest temperature, and that all that the stars did after that was to spend their millions and billions of years of life in getting colder; so that, if we could at the present moment find out which was the very hottest star in the heavens, we might be perfectly certain that every star in its beginning resembled exactly in spectrum, and therefore in physical constitution, that particular star which we suppose to be the hottest. It so happened that in that very course of lectures I pointed out, for the first time, I think, in reference to the separation of stars into classes, that such an idea as that would never do; for if we form any conception of nebulæ changing into stars, we begin by knowing that the stars are very much denser than the nebulæ—taking the sun as an instance, the star practically close to us—and that as the stars are denser than the nebulæ, they must be hotter than the nebulæ, instead of being colder.

This depended absolutely upon the application of thermodynamics, and had been pointed out by Helmholtz in the year 1845. Sir William Thomson, now Lord Kelvin, also pointed out quite distinctly that the hypothesis of fiery nebulous matter —by that meaning nebulous matter hotter than the stars— was invented before the discovery of thermo-dynamics; otherwise, he said, the nebulæ would certainly never have been conceived to have been fiery, *i.e.* something hotter than the average star.

I then went on to show that Lord Kelvin told us how he could imagine a condition of nebulæ which might ultimately condense into stars without violating the laws of thermodynamics, which were completely traversed by Laplace's view; and he referred to a suggestion that had been made by Prof. Tait, who supposed that the luminosity of nebulæ, and even the spectroscopic appearances which have been observed, might be explained by supposing that we were dealing with gaseous exhalations proceeding from the collisions of meteoric stones; and he also pointed out that possibly that would not only explain the luminosity of nebulæ, but the luminosity of comets as well. By the kindness of the Director of this Museum, I have some specimens of these meteoric stones on the table. I would remind you that the few specimens which I have here have been selected from the magnificent collection upstairs; if you have a few minutes to spare after this lecture, you cannot do better than go and have a look at them, and you will see how very various both to the eye and in chemical and physical constitution they are. Let me also recommend you to get a little pamphlet (price 2*d.*) containing a description of the meteorite collection in the Natural History Museum, which is one of the finest in the world.

We thus arrived at the idea that these wonderful nebulæ may be explained, apart from any fiery gas; that we have simply to look to a meteoritic origin to explain both the appearances and the spectrum.

After that point had been made, I went on to make another. I had already referred to the classification of stars, and I remarked that if one looked at the different groups of spectra, it seemed as if a classification of them, based on these ideas, did fit the facts better, the existing ones depending on the unphilosophic one of Laplace. It is possible, I said, that the great differences which had been observed in the spectra of comets and of nebulæ, although the origin of the light of both was ascribed to the clashing together of stones in different parts of space, might be explained by the fact that, in consequence of the collisions between these bodies occurring under different conditions and at different velocities, there would be very considerable differences in the temperatures produced in the two cases. Similar conditions might hold for stars in different degrees of condensation. It was also suggested that this new idea might explain the phenomena of variable and new stars, which have always been accounted to be the most extraordinary and mysterious in the whole domain of astronomy; and, finally, I said the subject was well worthy of study, because it seemed as if many phenomena on the nearest star to us, our own sun, might be really phenomena produced by the fall of meteoric bodies upon that surface which we see, and which we call the photosphere. It is now many years ago since Balfour Stewart and others threw out the idea that the phenomena connected with the formation of sun-spots were really produced by the fall of bodies upon that surface. Other philosophers have preferred the idea that we have to do with eruptions from the interior of the sun; nothing can be more divergent than the opinions which have been brought forward as explanations of these appearances.

But you at once see that, if we assume that this meteoritic action may take place in the solar atmosphere, it need not necessarily be a meteoritic action coming from without. Taking our own case, we live in a damp climate, and sometimes the air is dampest when there are no clouds. Clouds are condensations of the moisture in the air, and we know that it is not really a question of clouds only; we may have snow, rain, or hail, and all these represent different condensations of the damp—or, as we call it, the aqueous—vapour which is ever present in our air. Apply that to the sun. What is the air of the sun composed of? Well, certainly one important constituent of it is the incandescent vapour of iron; we are no longer dealing with a low temperature and the vapour of water, but with an atmosphere in the hotter parts of which iron is not solid or liquid, but in which the temperature is high enough to keep it in a state of gas, probably thousands of degrees higher than is arrived at in the Bessemer process.

We will assume, then, that that temperature and that condition of atmosphere prevails for 20,000 (it is probably nearer 50,000) miles above the photosphere of the sun. As we get further from the sun, the atmosphere is of course getting cooler, and at a certain distance above the photosphere the temperature will be so reduced that the iron vapour might play the part of our aqueous vapour; then it condenses and turns into iron snow

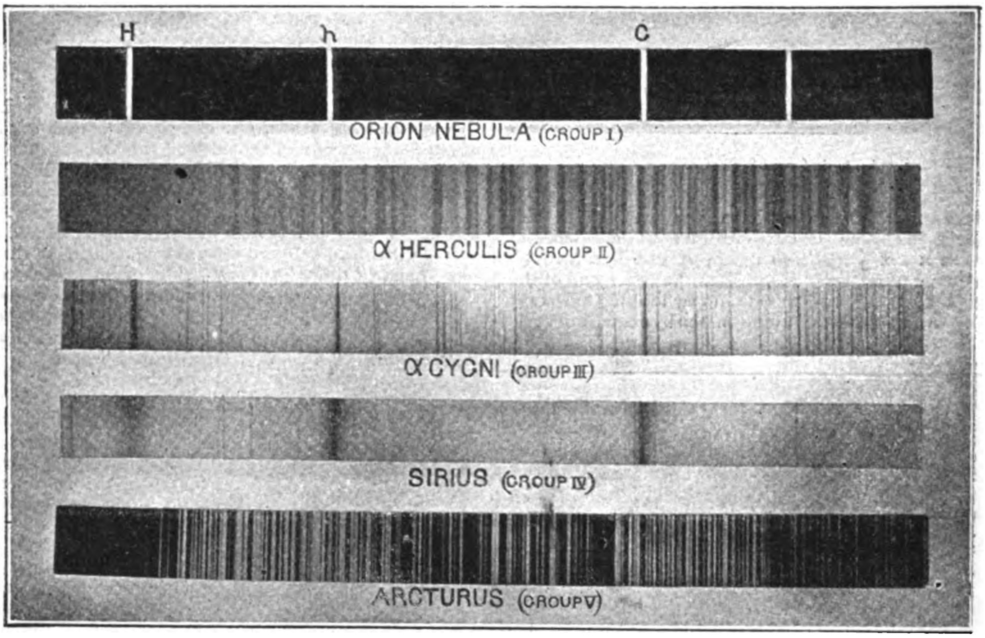

FIG. 3.—The photographed spectrum of a nebula, contrasted with the spectra of stars.

nd iron hail and iron rain, and so on, falling upon the photosphere as the rain falls on the earth. There is thus a possibility in the sun of home-made meteoritic action.

So far as my last course of lectures was concerned, I there nded that part of the subject. But so many points had been aised in trying to give a connected view of these two very lowly converging lines of research to which I referred, that, after he lectures were over, I determined to discuss the various oints which had been raised. I determined to take up Prof. Tait's suggestion, and see how all the spectroscopic observations which had been made up to the time of my lectures in 886, bore out that suggestion which had been made in 1871, efore there was very much spectroscopic evidence to go upon. The result was that my assistants and myself spent something ike three years in gathering together, we believe, every available observation; at all events, if not every available observation, there were between thirty and forty thousand of them, and we found that a very considerable number. I not only determined to collect them, but also to discuss them, and make any xperiments or observations which might be suggested by the iscussion. The result of this was that, as a fruit of that course f lectures, several papers, some of them very long—it is not or me to say anything as to their value—were sent in to the Royal Society, and eventually brought together in a book.

Now, what I found was that when we discussed the meteoritic view in the light of all the observations we could get ogether, and in relation to stars as well as nebulæ and comets, t seemed to explain many things, and threw a perfectly new ight upon the visible universe; there were, moreover, several oints raised of intense novelty and freshness, each of which could be discussed separately, cast aside if it were false, and held on to if it were true. I give a table of some of these new points of view.

New points of view in the Meteoritic Hypothesis.

(1) There is the closest possible connection between nebulæ and stars.

(2) The first stage in the development of cosmical bodies is not a mass of hot gas, but a swarm of cold meteorites.

(3) Many bodies in space which look like stars are really centres of nebulæ; that is, of meteoritic swarms.

(4) Stars with bright-line spectra must be associated with nebulæ.

(5) Some of the heavenly bodies are increasing their temperatures; others are decreasing their temperatures.

(6) Double swarms, in any stages of condensation, may give rise to the phenomena of variability.

(7) New stars are produced by the clash of meteor swarms. They are closely related to nebulæ and bright-line stars.

(8) Cosmical space is a meteoritic plenum.

(9) A new classification of the heavenly bodies, based on the varying states of condensation of the meteoritic swarms.

(10) The sun is one of those stars the temperature of which is rapidly decreasing.

(11) Many of the changing phenomena of the sun are due to the fall of meteoritic matter upon the photosphere.

We ultimately arrived at the conclusion that the sun is one of the stars, the temperature of which is gradually decreasing, and that many of the phenomena of the sun are due to the fall of meteoritic matter on the photosphere.

The doing of a large piece of work like that—and I say it is large because I am glad to have the opportunity here of expressing my gratitude to my assistants, who stood by me for three years—brings one out pretty well into the open, and renders one liable to a brisk fire of criticisms, some very valuable, some quite unworthy of the critics.

You will see that the work was undertaken with a view of determining the sun's place among the stars.

J. NORMAN LOCKYER.

(*To be continued.*)

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual general meeting of the Institution of Mechanical Engineers was held on Thursday and Friday evenings, the 31st ult. and the 1st inst. Prof. A. B. W. Kennedy, F.R.S., occupied the chair. There were two papers set down for reading and discussion:

"The Determination of the Dryness of Steam." By Prof. W. Cawthorne Unwin, F.R.S.

"Comparison between Governing by Throttling and by Variable Expansion." By Captain H. Riall Sankey.

Prof. Unwin, in his interesting paper, gave descriptions of the best known methods of determining the mean of moisture in steam up to now introduced. Most of the apparatus described was exhibited on the table of the theatre, whilst diagrams illustrative of them were hung on the wall. The author pointed out that the earliest attempts to determine the amount of moisture in steam, of which records have been found were made during some boiler trials carried out by a committee of the Société Industrielle of Mulhouse in 1859. This committee tried three different methods—a method of separation, a condensing method suggested by Hirn, and a chemical method. In these early trials the condensing method only, in which the total heat of a sample of the steam was measured, appeared to give satisfactory results. But although the committee did not place full reliance on any of their methods, these have all been used by various experimenters down to the present time.

The origin of water entrained in steam, Prof. Unwin said, was to be attributed to three causes:

(1) Water projected into the boiler's steam space during ebullition. The extent to which wetness occurs depends on the activity of the ebullition, the area of the water surface, the volume of the steam space, the position of the steam valve, the density of the steam, and, probably more than anything else, on the quality of the water and its liability to produce foam. The author referred to the experiments of Mr. Thornycroft, who constructed a boiler with glass ends, through which the process of boiling could be seen. The result of observations on this boiler showed[1] that waters which cause priming produce foam on boiling. Water which is very bad produces bubbles so durable as to remain a considerable time without breaking; and by them the steam space of a boiler may be entirely filled. So soon as this takes place, instead of simply steam leaving the boiler, the discharge consists of foam, which becomes broken up in its rapid passage through the steam-pipe. With pure water, steam retains no film of liquid long enough to be seen.

(2) Water may be produced in steam from the expansions to which it is subjected. Fluctuations of pressure arise from the intermittent demand for steam, and from the steam passing from places of higher to places of lower pressure. Prof. Unwin considered it difficult to believe that any great amount of wetness arises in this way in ordinary cases.

(3) The steam in the boiler, and the steam-pipes, loses heat by radiation. Probably in some cases considerable wetness is produced in this way. The wetness of the steam, so far as it is due to this cause, will increase as the demand for steam diminishes.

The author next went on to deal with the various methods of determining the wetness of steam, referring first to the weighing method, by which a known volume is weighed, when any excess of weight above that of a corresponding volume of dry saturated steam must be due to the water present. This method is obviously one of excessive difficulty.

The superheating method was next referred to in the paper, the experiments of Barrus and Carpenter being quoted. The Carpenter calorimeter consists of a vessel about 12 inches high by 5 inches diameter, consisting of an inner chamber and a jacket. The steam from the steam-pipe passes first to the inner chamber, where the moisture is separated, and then into the outer chamber. The separating chamber is therefore perfectly protected from radiation. As the water accumulates in the inner chamber, its level is shown by a gauge glass, and the amount in hundredths of a pound can be read off on a scale. A very small orifice at the bottom of the outer chamber regulates the amount of steam discharged. The escaping steam passes through a flexible tube to a simple form of condenser. The increase of weight in any given time in the condenser is noted, and the amount accumulated in the same time in the separator.

The condensing method was next described. This is founded on the condensation of a known weight of steam and the determination of its total heat by the rise of temperature in the condensing water. By comparing the total heat per pound of a sample of steam with that of a pound of dry saturated steam according to Regnault's tables, the amount of moisture in the steam can be determined. This method was first suggested by Hirn, and the apparatus which he designed is perhaps the most

[1] "Circulation in the Thornycroft Water-Tube Boiler." *Transactions* of the Institution of Naval Architects, 1894.

convenient form of apparatus for determinations by this method. It consists of an iron vessel about a foot in diameter, furnished with a loose cover; this forms the condenser. A small pipe and cock in the steam-pipe deliver steam through a small orifice near the steam-pipe into another pipe, through which it passes into the condensing water. An agitator and a sensitive thermometer are provided in the condenser. For weighing the amount of steam condensed, the whole condenser is suspended from a hydrostat, which permits extremely accurate determination of any change of weight. The hydrostat is balanced by weights till the pointer is at a fixed mark before and after condensing the steam. The condensing method, the author said, is strictly accurate in principle, but difficult to carry out in a satisfactory manner. In order to overcome these difficulties a method of continuous condensation has been introduced. By this steam and cold water are both supplied at a constant rate, and the condenser acquires a steady temperature, which can be very accurately observed. A diagram of a continuous injection condenser was shown on the wall of the theatre. Steam passes from the steam-pipe to a small injector. The condensing water is drawn from a tank, and the mixed water and condensed steam are discharged into another tank. The two tanks are placed on platform weighing machines. Two thermometers give the temperature of the condensing water (the water used for condensing the steam), and of the mixture of condensed steam and condensing water. The difference of the total weight in the two tanks, after any interval of time, is the steam condensed in that time.

A superheating method, which was introduced about the year 1890, by Mr. G. Barrus, was next referred to by the author. The steam to be tested is passed through an inner chamber jacketed by superheated steam. The sample of steam to be tested was thus dried and superheated at the expense of heat borrowed from the jacket. To avoid measuring the steam, an attempt was made to secure that equal weights of steam passed through the inner chamber and through the jacket. In that case the wetness of the steam can be calculated from observation of the temperatures only. The method, the author said, is accurate in principle, but appears to be difficult to carry out satisfactorily.

The wire drawing calorimeter was next described. This and the separating method the author considers most nearly fulfilled the necessary conditions requisite for measuring the quantity of moisture contained in steam. This calorimeter consists of two chambers, steam passing from the first to the second through an aperture $\frac{1}{16}$ inch in diameter. The full steam pressure is in the first chamber, and the pressure in the second differs little from atmospheric pressure. Thermometers give the temperatures in the chambers (which are protected from radiation), and in this way the quantity of water present in the steam is estimated. The steam is allowed to flow through the apparatus for twenty minutes or more, when the temperatures become nearly steady. No weighing is required, and temperatures only have to be observed. The observations can be continued as long as desired, so as to obtain a mean value for the dryness fraction from a considerable quantity of steam. If the steam is very wet, the temperature in the second chamber falls to about 212°, showing that wire-drawing to atmospheric pressure is insufficient to dry the steam. Practically the instrument cannot be used if the wetness exceeds the values given in the following table, the pressures being in lbs. per square inch, and the atmospheric pressure being assumed at 14·7 lbs.

Initial pressure (absolute).	Initial pressure (gauge).	Initial temperature F.	Initial wetness per cent.
29·9	15·2	250°	0·80
67·2	52·5	300°	2·44
135·1	123·4	350°	4·21
247·7	233·0	400°	6·13

Two conditions are necessary for accuracy in using this method. The second chamber must be large enough for the eddies to die out before the steam leaves the chamber. Radiation must be so far prevented that the steam in the chamber is not sensibly cooled. A calorimeter by which the separating and wire-drawing methods were combined was also explained by the author. This is the globe calorimeter which is a well-arranged apparatus.

The Cummins superheating method was also described. A vessel is filled with the steam to be tested, and then heated by a jacket. As it is heated, the rise of pressure in the inner vessel is observed, the volume being constant. So long as the steam is moist, the pressure will rise with the temperature according to the law for saturated steam. The moment all the moisture is evaporated, the rate of rise of pressure with temperature will become much slower.

The well-known salt test was next alluded to by the author. This, however, he pronounced to be inconvenient and untrustworthy, excepting perhaps in the case of a boiler subject to marked priming action.

The general conclusion drawn by the author was that the wire-drawing calorimeter without separator is the most convenient and accurate for steam with less than about 2 per cent. of moisture. For steam containing more moisture, the separating calorimeter without wire-drawing apparatus is accurate enough and convenient. The use of the separator and wire-drawing calorimeter combined is more troublesome, especially if, as is desirable, a condenser is also used to determine the amount of steam passing through the separator. In cases where there is much priming, it would seem best to take the whole of the steam through an ordinary steam-separator, measuring the amount of water trapped, and then to test by a wire-drawing or separating calorimeter the dryness of the steam after passing the separator. With priming much of the water probably flows along the bottom of the pipe, and it appears impossible that a sample can be obtained containing an average proportion of steam and water. It is recommended by Prof. Carpenter that the sample of steam to be tested should always be taken from a vertical, not from a horizontal steam-pipe. No doubt there is rather more tendency for water to flow along the bottom of a horizontal pipe than down the sides of a vertical pipe; but merely taking steam from a vertical pipe does not ensure freedom from error, especially if the amount of moisture in the steam is considerable. Variations in tests for wetness are doubtless often due to the difficulty of getting a true average sample of steam; and it would seem that errors are generally in the direction of under-estimating the amount of moisture.

A long and interesting discussion, which was adjourned from the Thursday until the Friday evening, was held on Prof. Unwin's paper. The chief point touched upon was the method to be adopted in getting a true sample of steam for analysis. This undoubtedly is the great difficulty that has to be overcome before a satisfactory method of determining the amount of moisture in steam can be arrived at. The majority of speakers were of opinion that water entrained in the steam would hang to the sides of the pipe, and a good many suggestions were made with a view to shifting the collecting nozzle over the whole area of the cross-section of the pipe, or else to give such an orifice to the nozzle as would cover a large part of the pipe area.

In his reply to the discussion, Prof. Unwin explained that this did not seem to him the true light in which the problem should be regarded. With steam rushing through a pipe at high speed, eddies would be set up which would be sufficient to thoroughly mix the steam and water so that there would be a fairly homogeneous mixture. The true difficulty arose from the checking of the velocity of the steam at the collecting orifice, an action which resulted in water accumulating so that an excess of moisture was shown in the sample drawn off. In order to overcome this, he had devised a collecting nozzle consisting of a bent-over tapered pipe, the orifice of which was at the small end, and was pointed towards the flow of steam. By adopting the necessary dimensions for the collecting nozzle, the steam collected would not be checked in velocity at the collecting orifice, and therefore moisture would not be deposited at that point.

Captain Sankey's paper was one of considerable length, and although dealing with one point only of engine design, was of great interest to engineers. It was illustrated by a large number of diagrams hung on the wall of the theatre. Without these it would be extremely difficult to give a fair idea of the course of reasoning followed by the author in discussing the merits of the two systems of governing engines. The paper, as the author said, was an elaboration of one section of a paper contributed to the Institution of Civil Engineers by the late Mr. Willans.

Speaking broadly, it may be said that the author's opinion was that the popular verdict in favour of variable expansion governing may for many purposes be accepted, yet its advantages were commonly much overrated, and in some cases it had no advantage at all.

It would be impossible within the limits of our report to trace out the respective merits of the use of the throttle valve and utomatic expansion gear, under the many conditions of work-ng which the author supposes; and as the discussion on the aper was adjourned until the next meeting, we may leave the ubject for the present.

The summer meeting of this Institution will be held in Glas-ow this year, commencing Tuesday, July 30, and concluding n the following Friday.

THE ADVANCE OF TECHNICAL EDUCATION.

THE present state of technical education in England is, on the whole, satisfactory from the scientific point of view. The authorities having the funds arising from the Customs and Excise Act under their control, are beginning to see that in-truction in the principles of science is by far the most mportant of the requirements. They are also coming o recognise that immediate results cannot be expected from heir work—that they are laying a foundation rather than erect-ng a complex edifice. The Technical Instruction Committees who have not sufficiently realised this, will find that they will have to materially modify their at present too ambitious schemes, postponing much of the instruction in subjects of echnology until a more thorough acquaintance with the funda-mental principles of science underlying all such purely technical education has been provided, for it is only by such means that the stability of their educational superstructure can be ensured.

There are no grounds, therefore, for taking a pessimistic view of the future of technical instruction. One of the most gratify-ing signs of development is the large number of scholarships now awarded, and the increase in the number of competitors for them. The current number of the *Record* of Technical and Secondary Education sets forth in detail a statement as to the scholarships and exhibitions actually awarded, during the year 1893–4, by County and County Borough Councils. This most valuable Return shows the number of scholarships and exhibi-tions awarded; the value and length of tenure of the awards; where held; conditions to be fulfilled by the candidates; the examining body, and the subjects of examination. Subjoined is a summary of the information.

Scholarships and Exhibitions tenable at	No. of Councils.	Scholarships and Exhibitions. Number awarded.	Total yearly value.
			£
(1) Technical, and Science and Art Schools ...	36 ...	3456 ...	10,620
(2) Secondary Schools ...	37 ...	1789 ...	20,409
(3) Universities or Institutions of University rank	28 ...	362 ...	6,783
(4) Short courses of instruction	25 ...	561 ...	3,825
		6168	41,637

Sixty individual counties and county boroughs are represented in the above summary. Two others, Derby and Sheffield, allocate respectively £325 and £1000 annually to scholarships, and taking these into consideration, it appears that the total sum expended for the promotion of technical and secondary education by scholarships, during the year ending March 1894, was, in round numbers, £43,000. But this by no means represents the limits of expenditure under the scholarship head. It does not take the renewal of scholarships into account, and there are still seven local authorities whose scholarship schemes have not come into operation. Also, the scholarship schemes will undoubtedly be further developed as the work goes on; in fact, it is estimated that before very long as much as £30,000 will be spent annually on scholarships by the London Technical Education Board alone. Truly, these are halcyon days for the promising young student, however humble his state of life may be.

As to the values of the scholarships, they vary from a few shillings, as a fee for a short course of instruction, to £60 a year tenable for three years. The lower limit of age is usually thirteen, and the higher, twenty-five, though we see no reason why such a maximum age should be made absolute. In some cases, the income of the parents of competitors must not exceed £400 a year, but in others—London is the most notable instance—the parents of competitors for junior scholar-ships must not be in receipt of more than £150 a year.

Another important statement in the current *Record* shows the plans for promoting technical and secondary education in each of the counties and county boroughs of England. From this it appears that, of the 110 local authorities in England, 96 are giving the whole, and 13 part of their grants to educational purposes. Preston is the remaining authority, and it devotes the whole of the grant available—about £1600 per year—to the relief of the borough rate. But it should be stated at once, that Preston possesses a well-endowed "Harris Institute," where technical education has been carried on for years. The total amount available by local authorities is about £744,000, of which about £144,000 is diverted to the relief of the rates, leaving £600,000 for expendi-ture on education. We are sanguine enough to believe that, before long, most of the £144,000 at present devoted to general county purposes will be expended in advancing technical educa-tion. London alone is responsible for £114,000 of this mis-applied balance, but as its educational scheme matures, it will doubtless absorb the whole amount available. It is to be hoped that the authorities applying the remaining £30,000 to rates, will soon see how detrimental their action is to their own interests.

In this connection it is necessary to condemn the application to rates of any unexpended balance of the grant available. In every county and county borough there are persons who utterly fail to realise that the interests of science are the interests of industry. To them, immediate advantages in the shape of a minute reduction of the rates, appeals far more than prospective developments of our national industries. Had such people the control of affairs, technical instruction would indeed be curtailed within narrow limits. Fortunately, they represent but a small minority in the County Councils; nevertheless, their influence is occasionally manifest. Ever since the Technical Education Acts came into force, attempts have been made here and there to use for general county purposes the funds available and neces-sary for education. But if the work is to be successfully carried out, it is essential that the Technical Instruction Committees should have entire control of the grants allocated to technical education. There is far too much uncertainty about the grants even now, and the County Councils which are inclined to exer-cise a veto as to the destination of the surplus funds of their Technical Education Committees, will soon find that self-respecting members of the Committees will retire from the work. Recently, however, one or two Councils have shown their incapacity to understand the magnitude of the problem before them, by voting the unexpended balance of their grants to the relief of rates. This action is tantamount to declaring that the funds at the disposal of the Committee are in excess of what is required; whereas, it is hardly too much to say that additional secondary schools are needed in almost every county and county borough in England, only to mention one way in which the money might be expended. For the balance to be diverted from education is bad enough, but no great foresight is needed to see that, once the action has been taken, there is no knowing where or when it will stop. Perhaps the county of Hampshire is the most notable instance in which a County Council has crippled the work of its Technical Instruction Committee. In November last, according to the *Southampton Times*, the Council resolved to appropriate, for general purposes, £6000 from the surplus funds which had been accumulated by the Technical Instruction Committee with the idea of eventually using it in educational developments. Without taking the views of the Committee into consideration, the Council appears to have calmly confiscated the balance resulting from economical administration, and by so doing not only discouraged careful expenditure, but in one fell swoop rendered the Committee powerless to deal in the future with matters which alone could be met by exceptional means. Surely it is not too much to expect a Council to have confidence in the ability of the Technical Instruction Committee, and to allow it to know its own needs. At any rate, a Committee whose opinion is disregarded must soon lose confidence in itself. It is a matter for congratulation that County Councils generally have not treated their Committees in the same way as the elect of the county of Hampshire.

One of the most refreshing reports we have seen for some time has recently been issued by the Derbyshire County Council. The report is satisfactory, not so much on account of work accomplished, but because it affords evidence that the Committee seems to have been brought to a good understanding as to what technical instruction should mean. One of the chief difficultie met with in most parts of the country arises from the suspicion with which the spoilt "practical man" regards the whole scheme of education designed to benefit him. No class harbours this prejudice more than farmers and their labourers. Almost every local authority complains of the apathy, or the opposition, of agriculturists to the extension of knowledge in the scientific principles of agriculture. When the Derbyshire Committee approached this branch of their work, they hesitated to establish agriculture classes under the auspices of the Department of Science and Art, because such classes are open to undesirable objections from this section of the community. In the first place, there is an appearance of attempting to teach "farming" in the lecture-room, and secondly, the teachers who are qualified to give most of the information contained in the Science and Art syllabus, are usually not actually engaged in the agricultural industry itself. Both these difficulties have been cleverly met by the Committee in this way:—"In place of the 'Agriculture' Classes of the Science and Art Department, the Committee are anxious that the students in rural evening schools shall go through a course of elementary science, which shall be of a very simple but thoroughly scientific nature. It is intended that the student shall be taught by actual experiment, and shall thus come to appreciate that the results of science are not fanciful, but are conclusions drawn from a study of actual facts. The phenomena studied in this course of lessons are of a general character, but are also largely chosen from the domain of agriculture, so that without any suspicion that the schoolmaster is attempting to teach 'farming,' the student learns a number of principles which cannot fail to affect him in practice.

"The great merits of this scheme of teaching elementary science in rural evening schools in place of starting Science and Art Department 'Agriculture' Classes are that the students are kept together year after year, studying other subjects which go to make up the curriculum, the Elementary Science course extending over two or three years, so that a first set of pupils is ready when the older ones have passed through; and further, there is no suspicion of teaching what can only be learned on the farm."

The scheme is very attractive, and good results may be expected from its application in Derbyshire. It enforces the fact that a knowledge of the elementary principles of science is the only sound basis upon which to build courses of technology.

The county of Derby is more dependent upon the mining industry than on any other; therefore its organisation of instruction in mining deserves a word of remark. It attempted to provide the instruction by means of courses of lectures delivered in a certain number of pit villages, but the results were hardly successful. The teaching was afterwards given by local men who had practical knowledge of mining, and some acquaintance with collateral branches of science, and this scheme was more satisfactory than the former. The point to be borne in mind in all such cases is that chemistry, steam, geology, some branches of physics, and mechanical drawing should form a part of the education of every mining student. With reference to local teachers, a word may be necessary. There is, of course, a tendency in many districts to patronise local ability, but it should always be borne in mind that the local man is not of necessity the man who will do best. In the expenditure of public money, it ought to be a guiding principle that the best teachers available by advertisement and good salaries should always be selected.

The evergreen complaint of Technical Education Committees finds expression in the report from Derbyshire. In connection with the subject of evening continuation schools, we read: "The Committee have found that one of the great difficulties which the ordinary student experiences in receiving instruction in every kind of technical subject is the lack of sufficient preliminary knowledge. His elementary school education has very largely leaked away, instead of having been continued to the point giving easy comprehension of scientific principles and problems. This implies that the national expenditure on elementary education is very largely wasted without some supplementary scheme by which the instruction given shall be conserved and continued until the student is old enough to grasp its importance." This puts the whole matter in a nutshell. When the average boy leaves the elementary school, at about fourteen years of age, he regards his education as completed, with the result that he has no interest whatever in schools or classes of any educational value. Committees must not hope to attract the majority of working lads into evening continuation schools, however diversified their prospectuses may be. Only here and there can pupils be found who have begun to see the depths of their ignorance, but these are the minds to nurture, and for their benefit systems of evening-classes should be constructed.

Before the era of the County Councils, the principal means for the spread of instruction in elementary science was undoubtedly the classes of the Science and Art Department. Testimony is borne to this in the report referred to. We read:

"It has been the custom in many educational quarters to criticise and condemn the methods of that Department, and to create an impression that but little good has been accomplished. The contrary of this is undoubtedly the case. In all manufacturing centres it will be found that there are numbers of persons applying to every kind of industry scientific principles and knowledge gained at Science and Art Classes, and which could not have been gained anywhere else during the last thirty-five years." The Department is very well able to take care of itself, but this statement of fact may be profitably considered by those who disparage its usefulness.

If there is one thing our educational system lacks more than another, it is proper facilities for secondary education. Recognising that a good education in a secondary school is the only means by which the highest branches of technical instruction could be approached, the Derbyshire Committee offered for competition sixty scholarships tenable at secondary schools. After the awards had been made, it was found that only six out of the sixty successful candidates chose schools in the county, and that there was only one school in the administrative county available for the girls who had won scholarships. An inspection of the Grammar Schools, and similar institutions in the county, with a view to determining their educational conditions and needs, revealed a general want of proper equipment; indeed, only one out of nine secondary schools had a chemical laboratory. Derbyshire is certainly not alone in this deplorable state of things, which it will take some years to improve. The fact that the defects in our educational system are being exposed, and that attempts are being made to meet them fairly, is a clear promise of progress. If the Technical Instruction Committees had done no more than reveal the inefficiency and insufficiency of scientific instruction in the counties of England, they would have furthered the interests of science. But as they have also helped to organise and increase the facilities for such instruction, they have worked in no mean way for the extension of natural knowledge. Encouragement and friendly guidance is all that is required to render the work even more valuable in the future than it has been in the past.

R. A. GREGORY.

SCIENCE IN THE MAGAZINES.

FIRST in importance among the contributions to the February magazines is a collection of opinions on forest preservation, published in the *Century*. In response to a request from the editor of that magazine, a number of persons interested in arboriculture sent their views as to the general need of a thorough, scientific, and permanent system of forest management in the United States, and specifically as to the plan suggested by Prof. C. S. Sargent, which comprised the following features:—

(1) Forestry instruction at West Point; the establishment of a chair of Forestry at the United States Military Academy, to be supplemented by practical study in the woods and by personal inspection of foreign systems of forestry.

(2) An experimental forest reservation; the purchase on the Highlands near West Point, or elsewhere, of a small territory for the use of the proposed new branch of instruction.

(3) Control by educated officers; the assignment of the best educated of these officers to the supervision of the forest reservations.

(4) The enlistment of a forest guard; a body of local foresters, to be specially enlisted for the purpose of carrying out the principles of forestry thus taught.

The experts consulted agree in the opinion that the United States needs a thoroughly scientific and permanent system of forest management in the interests of the people of to-day, and of future generations. But the general feeling seems to be that the management of the forests should not be placed under any military organisation. As to the suggestion to increase the curriculum of the U.S. Military Academy so as to cover instruction in forestry, it is rightly pointed out that a course in forestry which is merely an adjunct to a military education must fail to produce the highest efficiency as foresters in the officers who take it. "Adequate training in so large a subject," is remarked by one of the correspondents, "can be reached only by long and undivided attention." And further, as Prof. Cleveland Abbe says, "the arts of warfare are a special application of the arts of peace, and it is a perversion of the military school to make it a rival of the civilian schools of engineering, chemistry, forestry, &c." The general opinion appears to be that for the preservation and management of forest reservations, a permanent body of foresters is required, but it should be composed of practical woodmen who have devoted some years to the study of forestry. If we may express an opinion upon the matter, to us this seems the only view which can have any support from scientific men. To make forestry a subsidiary branch of a military education, would be to establish scant provision for the science. If merely the protection of forest reservation be aimed at, Prof. Sargent's plan probably offers the easiest way of obtaining it; but if the forests are to be developed, a forest school, where foresters can be scientifically trained, becomes essential.

Another contribution to the *Century* is the sad story of the death of Emin Pasha, told by Mr. R. Dorsey Mohun, the United States agent in the Congo Free State. In April of last year, Mr. Mohun arrested and took the confessions of the two Arab slaves, named Ismailia and Mamba, who had killed Emin. The following is a brief statement of the melancholy facts:—In the Unyoro country, to the west of the Victoria River, Emin came upon an Arab camp, under the command of Said ben Abedi. He expressed his intention of making his way to Kibonge, about eighty miles south of Stanley Falls, and it was arranged that his force, numbering about 150 people, and Said's, should travel together. On October 5, 1892, Emin and Said arrived at the small village of Kinena, which lies 150 miles to the north-east of Kibonge. Said then went on to inform the Kibonge chief that the white man was coming, Ismailia and Mamba going with him. About twenty days later, Mamba returned with a letter to Emin, saying that safe conduct to Kibonge should be given; but the Kibonge chief sent another letter to the Kinena chief by Ismailia, containing instructions to kill Emin. The Pasha was induced to send his men into the plantations on a pretext, and while they were away he was murdered, and his head sent to Kibonge. This appears to have occurred on the morning of October 28, 1892. Emin's head was sent by Kibonge to Munie-Mohara at Nyangwe, the reason being, Mr. Mohun thinks, that Kibonge wished to show that he could kill a white man as well as Munie-Mohara, who had ordered the destruction of Hodister's expedition five months previously. "Not the slightest suspicion," says Mr. Mohun, "attaches to Said ben Abedi of having had any connection with Emin Pasha's death, which is regarded by the Arabs with whom I have talked as a stupid error on the part of Kibonge, who committed the crime simply to place himself on the same level as Munie-Mohara, who had killed Hodister. I do not believe, either, that Tippoo Tib had any hand in the crime, which must have been as great a surprise to him and to his son, Sefu, and his nephew, Rachid, who was the Governor of Stanley Falls, as it was to us." An article on "New Weapons of the United States Army," also in the *Century*, and the eighteen pictures and diagrams which illustrate it, will interest many of our readers.

Dr. Charles L. Dana writes on "Giants and Giantism," in *Scribner*. Two years ago a man nearly seven feet in height, possessing very large feet, hands and head, came under his notice, and was found to be a victim of the peculiar disease known as acromegaly. The man died from the effects of his disease, and a portion of the brain—the pituitary body—was then found to be enlarged to many times its original size. This gave support to the idea that enlargement of the pituitary body is the cause of the gigantic growth of the extremities in acromegaly, and that giants generally are not simply freaks, but victims of a nervous disorder. The skeleton of the famous Irish giant was studied some time ago by Prof. Cunningham, and found to be characteristic of a case of acromegaly, and an examination of photographs of nearly all the living giants now on exhibition leads Dr. Dana to believe that about one half of them are acromegalics. According to Dr. Dana, "extraordinary size is a disease, a neurosis of nutrition, rather than a chance disturbance of development. . . . It is possible by certain kinds of gland-feeding, to increase the stature of dwarfed persons very rapidly. There is, for example, a gland called the 'thyroid body' lying in the neck, the juice of which, when fed to certain kinds of dwarfs (cretins) causes them rapidly to grow. Experiments in feeding animals and men with the pituitary body are now in progress."

"The Method of Oganic Evolution" is expounded by Dr. A. R. Wallace in the *Fortnightly*, the article being really a critical and adverse review of Mr. Bateson's views on discontinuous variation, as set forth in "Materials for the Study of Variation." A second article on discontinuity in evolution, dealing with the theories advanced by Mr. Galton, will appear in a future number.

A posthumous essay, by Dr. G. J. Romanes, entitled "Longevity and Death," appears in the current number of *The Monist*, to which it was sent by Prof. C. Lloyd Morgan. In it an unpublished essay, written in 1875, is quoted, in which occur the following passages:—

"Those species whose ancestral types have frequently been required to vary would have gained much during the history of their descent, by having their constituent individuals short-lived; for in this way a comparatively great number of opportunities would have been afforded for the requisite variation to arise: in other words, a comparatively great number of variations would have occurred in a given time. Hence it seems natural to infer that it is in the power of Natural Selection to affect the *curtailment* of individual life, wherever such curtailment would be of advantage to the species, that is to say, wherever *flexibility* of type is required. Of course, length of life is not the only factor which determines flexibility of type. There are at least three other such factors: (1) the period at which puberty sets in, (2) the number of times the individual breeds during its life-time, and (3) the number of young which it bears at each time of breeding. Nevertheless, it is true that the length of life is a highly important factor, because, if the individual is short-lived, it becomes a necessary condition to the continuance of the species that parturition should be frequent. Or, more generally, there must be more or less of a direct proportion between the potential longevity of every species and the frequency of parturitions characteristic of that species—if not also of the number of offspring in each. Now, as Mr. Lankester has pointed out, there is, as a matter of fact, a highly remarkable correlation between potential longevity in the individual and frequency of parturition, as well as of numbers constituting the litter which are distinctive of the species. This correlation he attributes to generative expenditure acting directly to the curtailment of life; but in holding this view, I suspect that he is mistaking cause for effect. I do not think it is generative expenditure which causes curtailment of life, but that it is curtailment of life by Natural Selection which causes the high generative expenditure within the lessened period. It is as though all the conditions needed to secure flexibility of type were adaptively associated in these species which have survived in a comparatively fluctuating environment. Moreover, it is worth observing that all the organisms to which Mr. Lankester ascribes a practically unlimited potentiality of life, are organisms which, as far as we can judge, must always have been exposed to uniform conditions of life."

In addition to this, *The Monist* contains an article by Dr. E. Montgomery, who attempts "first to gain a scientifically justified and logically consistent physical basis, upon which a naturalistic conception of vitality can be reared; and then, to show to what special physical conditions vital activities and vital organisations owe their existence." We also notice a metaphysical paper on "The Natural Storage of Energy," by Mr. Lester F. Ward.

Pascal is the subject of a paper, by the late Mr Walter Pater, in the *Contemporary*, but his scientific researches are not dealt with. Towards the end of the notice, there is a note on the influence of imagination on his work. It is: "Hidden under the apparent exactness of his favourite studies, imagination, even in them, played a large part. Physics, mathematics, were with him largely matters of intuition, anticipation, precocious discovery, short cuts, superb guessing. It was the inventive element in his work and his way of putting things that surprised those best able to judge. He might have discovered the mathematical sciences for himself, it is alleged, had his father, as he once had a mind to do, withheld him from instruction in them." A bright and sensible paper on "Nervous Diseases and Modern

Life" is contributed to the same review by Prof. Clifford Allbutt. There is also a paper of interest to physical geographers, its title being "The Evolution of Cities."

The current *Quarterly Review* has among its articles a sketch of the history of the Ordnance Survey, wherein we read "the scope of the undertaking exceeds any programme heretofore attempted by any Government, the mode and style of its execution are second to none, either from a scientific, artistic, or utilitarian point of view, and the cost of the work, stroke for stroke, is probably lower than that paid by any other nation for a similar purpose." Prof. Huxley's collected essays, and other works, are reviewed under the title "Prof. Huxley's Creed," and in the article "England in Egypt," the irrigation of Egypt, and the construction of the Philæ dam, are noticed.

The *Reliquary and Illustrated Archæologist* is rich in good illustrations. Among the articles we notice an account of the exploration of a Hunnish cemetery at Czika, near Buda-Pesth. Parts of a number of skeletons have been found, and a complete skeleton of a woman, six feet three inches in length. Weapons, stirrups, earthenware vessels, and various ornaments have also been found. "The Burning of the Clavie," a ceremony still carried out on the last night of the old year at Burghead, in the north of Scotland, is described by Mr. H. W. Young. The custom appears to have come down from the most remote ages. The natives of Burghead assert that it is a Druidical worship, while Mr. Young believes it to be simply a revival of the worship of Baal—a remnant of that great fire worship which prevailed over the whole world as known to the ancients. In the notes is an illustration of the ancient Egyptian tomb in the island of Elephantina, discovered and explored by H. R. H. the Crown Princess of Sweden and Norway, and an illustrated description of the re-erection of those interesting pre-historic monuments, the Dartmoor mênhirs. Recent investigations have yielded some evidence which connects these stone-rows with the Neolithic period.

A passing notice must suffice for the remaining articles on scientific subjects in the magazines received by us. *Good Words* contains Sir Robert Ball's concluding paper on "Sir Isaac Newton," and a brief paper "On the Anti-toxin Cure for Diphtheria," by Dr. W. J. Fleming. A visit to the tomb at Dashur, where the jewels of an Egyptian princess of the Twelfth Dynasty were found last year, is described by Mrs. St. Loe Strachey in the *National*. The *Humanitarian* has an article on "The Prevalence of Nervous Diseases," by Dr. S. Althaus. "Some Curiosities of Modern Photography" are brought together by Mr. W. G. FitzGerald in the *Strand Magazine*. The illustration he gives of an image photographed through the eye of a beetle is, however, quite eclipsed by a photograph taken by Dr. Spitta through the lenses of the composite eye of a water-beetle, and reproduced in *Knowledge* for July 1894. Mr. Grant Allen contributes a rhapsody on quails to the *English Illustrated*. *Chambers's Journal* contains its usual complement of readable articles on scientific topics.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In a Congregation held on Tuesday, February 12, the amendments to the proposed Statute on Research Degrees came under consideration. There were sixty-three amendments, and of these only fourteen came under consideration, as the debates on some of them were of some length. The first amendment, proposed by the Provost of Oriel, and seconded by Prof. Odling and Mr. Strachan Davidson, proposed that the Degree of Bachelor of Arts should be substituted for the proposed Degrees of Bachelor of Letters and Bachelor of Science. After a prolonged debate the amendment was negatived by 137 votes against 33.

An amendment by Prof. Case, defining "Science" as including Mathematics, Natural Science, Mental and Moral Science, was carried by 137 votes against 34. An amendment, proposed by Mr. C. Cannan, of Trinity College, and seconded by Mr. Bourne, provided that the supervision of the candidates for Research Degrees should be vested in the Boards of Faculties, instead of in a special Delegacy as proposed by the Statute under consideration. This amendment was carried by 110 votes against 49. Another amendment, by Prof. Holland, which proposed that candidates for Research Degrees, not being already Graduates of the University, should have obtained a degree in some other University, was rejected by 107 votes against 39. The other amendments were either consequential on those already mentioned, or were of a formal character. The further consideration of the amendments was fixed for Thursday, February 21.

CAMBRIDGE.—The Sedgwick Prize in Geology has been awarded to Mr. Henry Woods, of St. John's College, Demonstrator in Palæontology. The subject proposed for the prize of 1898 is "The Glacial Deposits of East Anglia." The essays are to be sent to the Registrary by October 1, 1897. Candidates must be Graduates of the University who have resided sixty days during the preceding twelve months.

Mr. M. Laurie, of King's College, has been appointed by the Special Board for Biology and Geology, to occupy the University's table in the Naples Zoological Station, for three months from March 1.

A course of lectures in Anthropology, with practical work, is announced by Prof. Macalister for the Lent and Easter Terms. The lecturer is Prof. A. C. Haddon, of the Royal College of Science, Dublin. The subject of the first lecture, on February 14, at 3.30, is "The Methods of Anthropology."

The degree of Sc.D. *honoris causa* is to be conferred on Sir William MacGregor, Administrator of British New Guinea, in recognition of his able contributions to anthropology and ethnography.

The following appointments of electors to Professorships in Natural Science and Medicine are announced. Chemistry, Dr. T. E. Thorpe; Plumian of Astronomy, Dr. A. R. Forsyth, and Mr. W. H. M. Christie, Astronomer Royal; Anatomy, Dr. Allbutt; Botany, Mr. A. Sedgwick; Geology, Prof. Newton; Jacksonian of Natural Philosophy, Lord Rayleigh; Downing of Medicine, Dr. A. Macalister; Mineralogy, Prof. J. J. Thomson; Zoology, Dr. D. Macalister; Cavendish of Physics, Lord Rayleigh; Mechanism, Prof. Osborne Reynolds; Physiology, Mr. J. N. Langley; Surgery, Dr. A. Macalister; Pathology, Dr. Gaskell.

A grant of £50 from the Worts Travelling Scholars Fund has been made to Mr. P. Lake, of St. John's College, for the purpose of investigating the distribution of Trilobites in Russia and Sweden.

A PARLIAMENTARY PAPER dealing with the moneys received by the Councils of Counties and County Boroughs in England and Wales under the Local Taxation (Customs and Excise) Act, 1890, and available for technical education, has just been published. The following summary shows how the moneys have been expended:—

	Counties (other than London and County Boroughs.	County of London.	Total.
	£	£	£

1 £6700 of this amount had been appropriated to County buildings and museum.

Seventy-one out of the 126 Councils had expended on, or appropriated to, Technical or Intermediate Education the whole of the moneys they had received from the residue of the Beer and Spirit Duties.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, February 8.—Annual General Meeting.—The chair was taken by the retiring President, Prof. Rücker.—The Treasurer, Dr. Atkinson, presented his report for the year 1894. The balance-sheet showed a somewhat larger expenditure than in previous years, the increase being partly due to the new system of publishing abstracts, partly to the rent of rooms and the expenses of tea. The balance in the bank had increased by about £33 during the year; but the Treasurer said that, strictly speaking, the Society had trenched on its capital to the extent of about £30, and that this would probably be the last report for some time to come which would show a balance in favour of the Society. The assets of the Society exceeded its liabilities by £2642 0s. 5d. Prof. Carey Foster asked whether it would not be possible, in estimating the assets of the Society, to make some allowance for the stock in hand. Dr. Atkinson replied that that had not hitherto been done, and the difficulty would be to assign a money value to the stock. The stock of the works of Joule, and of other memoirs, was of course decreasing, while the sale of the *Proceedings* was becoming somewhat greater. As regarded the securities of the Society, their actual value would be about £200 or £300 more than appeared on the balance-sheet. Prof. Rücker said that the Society had deliberately entered upon a policy of expansion, and that they must be prepared to find the expenditure increasing. On the other hand, it was hoped that by making the Society more attractive, a greater number of persons would be induced to join. In view of the great advantages now enjoyed by members, there had been some suggestion of raising the subscription; but, in any case, he thought that they might look forward to the future with confidence. The report was then moved and adopted.—The next business was the election of Officers and Council for the year 1895–6, and Messrs. Rhodes and Yule, being asked to act as scrutators, collected the balloting lists.—Prof. Carey Foster proposed a vote of thanks to the Lords of the Committee of the Council on Education, for having allowed the Society to meet at the Royal College of Science. At the commencement of the life of the Society, its founder and first President, Guthrie, had obtained permission for the meetings to take place at South Kensington, and the Society had continued to meet there until their recent migration to the rooms of the Chemical Society. The vote of thanks was duly seconded and was carried unanimously. Major-General Festing then proposed, and Mr. Croft seconded, a vote of thanks to the auditors, Messrs. Inwards and Trotter. This also was carried. Mr. Trotter then proposed a vote of thanks to the retiring Council; they had shown an energy which was rare in such societies, and had inaugurated an active and original policy, which must prove of the greatest benefit to the Physical Society and to physical science generally. Carried unanimously.—Mr. Elder gave notice of a proposed alteration of the rules, the object being to allow the Council under certain conditions to admit persons into the Society without requiring from them the usual number of recommendations from members. It was pointed out that sometimes eligible persons, especially those resident abroad, were unable to enter the Society because they were unknown to any of the existing members. The motion to sanction the proposed alteration was put from the chair and carried, but this decision will need to be confirmed at a subsequent meeting, of which due notice will be given.—Mr. Rhodes then read the following list of the Officers and Council elected for the year 1895–6: President, Capt. Abney. Vice-Presidents who have filled the office of President: Dr. Gladstone, Profs. Carey Foster and Adams, Lord Kelvin, Profs. Clifton, Reinold, Ayrton, Fitzgerald, Rücker. Vice-Presidents: Mr. W. Baily, Major-General Festing, Prof. Perry, Dr. Stoney. Secretaries: Messrs. Blakesley and Elder. Treasurer: Dr. Atkinson. Demonstrator: Prof. Boys. Other members of Council: Mr. Shelford Bidwell, Mr. W. Crookes, Messrs. Fletcher, Glazebrook, G. Griffith, Profs. Henrici, Minchin, Mr. Swinburne, Profs. S. P. Thompson and S. Young.—Prof. Rücker then vacated the chair in favour of Captain Abney, and the meeting being resolved into an ordinary meeting, Mr. W. B. Croft gave "an exhibition of simple apparatus." An optical bench was shown which consisted of a wooden lath of rectangular section, furnished with a millimetre scale, and clamped on to the table, together with three flat wooden blocks, whose contacts with the table and the lath left them only freedom to slide in a direction parallel to the scale. Another apparatus was designed for observing anomalous dispersion. A cork supported two rectangular pieces of microscope cover-glass, which were inclined at a small angle to one another; and a drop or two of a strong alcoholic solution of fuchsine being introduced between them was maintained in position by capillary action. Photographs were shown of Chladni's sand-figures, some of the forms being of an unusual character. Mr. Croft also exhibited a polariscope in which the polariser was a thin piece of glass stuck on to cork by means of black sealing-wax, and the analyser a plate of tourmaline; as well as a miniature model of Grove's gas battery. Photographs of some curious optical phenomena were projected on the screen, including 12-rayed stars seen on looking at a bright source of light through certain specimens of mica, and pairs of intersecting or non-intersecting circles of light, obtained under similar circumstances with (doubly-refracting) fibrous calcite. These last, it was suggested, were similar in origin to the curves obtained by reflection at, or transmission through, a diffraction-grating held obliquely. Clock-springs broken by frost were also exhibited, each spring having given way in a very great number of places simultaneously. Dr. Johnstone Stoney said that many years ago he had published in the *Transactions* of the Royal Irish Academy an investigation of the circles seen in fibrous calcite, and had shown geometrically that they had nothing to do with the regularity of the fibrous structure, but were due to reflection and refraction within the crystalline plate. The distribution of the planes of polarisation round the circumferences of the circles was also accounted for by his investigations. Mr. Price said he had found that when a clock-spring during the process of hardening was kept in shape by wires, subsequent fracture was most apt to occur at those places where the wires had been in contact with the spring.—Mr. Rhodes asked if Mr. Croft had ever tried Newton's experiment of admitting sunlight between two sharp edges inclined at a small angle to one another. He had not been able to obtain the hyperbolic bands described by Newton. Mr. Croft said he had not tried the experiment exactly in that form. Captain Abney said that this experiment had succeeded very well in his hands.—Mr. S. Skinner read a paper on the tin chromic chloride cell. He said that his attention had been attracted to the cell by an account published by Mr. Case, of New York. The cell had been stated to give no E.M.F. at ordinary room-temperatures, while it gave a considerable E.M.F. at 100° C. The author had found that when the cell was directly connected up to a galvanometer, there was no current at ordinary temperatures, and some current at 100° C.; but when he had measured the E.M.F. by Poggendorff's method, he had found ·44 volt at 15° C. and ·40 volt at 97° C. The cell as originally described consists of a tin plate and a platinum plate immersed side by side in a solution of chromic chloride; when the temperature of the cell is near to 100° C., and the poles are connected, the following reaction occurs:—

$$Cr_2Cl_6 + Sn = 2CrCl_2 + SnCl_2;$$

and when the poles are disconnected and the cell cooled, the reverse change takes place. The author prefers to use as electropositive metal an amalgam of tin and mercury instead of a tin plate, so that when the tin precipitated during cooling falls to the bottom of the solution, it is redissolved in the mercury, and the cell has regained its original state. When silver nitrate solution is added to chromic chloride, only two-thirds of the chlorine comes down as silver chloride, and this has led the author to suppose that the proper formula for chromic chloride is $CrCl . Cl_2$. Hence he works out the electrolytic action by means of a Grotthus chain. Prof. Rücker asked whether a change of polarisation would explain the behaviour of a cell at different temperatures. Prof. Carey Foster asked whether the reversed chemical action on cooling from a high temperature were accompanied by a reversed E.M.F. Mr. Skinner said no. The tin was precipitated throughout the solution, and not at the surface of the tin plate, so that no E.M.F. of the kind was to be expected. Mr. Appleyard thought that Prof. Minchin had used tin chloride cells with two tin plates for electrodes, the cells only working when one plate was illuminated. Mr. Trotter wished to know whether heating the cell supplied energy to it, or simply removed an obstacle in the form of polarisation. Mr. Skinner thought that heating acted by removing an obstacle. Captain Abney: And so doing work.

PARIS.

Academy of Sciences, February 4.—M. Marey in the chair.—The proceedings were commenced by the announcement of the decease of Prof. Arthur Cayley, correspondent of the Astronomy Section from 1863. M. Hermite then gave a short account of the scientific work of the great mathematician.—On argon, a new constituent of the atmosphere, discovered by Lord Rayleigh and Prof. Ramsay. An abstract by M Berthelot of matter that has already appeared in these columns. He concludes with the observation that, although argon has no action on the higher animals, it cannot be predicted that bacteria may not be affected by it, for it is known that they absorb nitrogen. The suggestion is made that nitrogen obtained from the total destruction of animal or vegetable matter should be examined for argon.—On abelian functions, by M H. Poincaré.—Propellers with tangential penetration, by M. Guyou A description of a model of a new type of propeller.—The present state of investigations on the vegetation of French colonies and protectorates, by M. Ed. Bureau.—On a passage of the shadow of Jupiter's fourth satellite, by M. J. J. Landerer. The calculated time of half-passage is 27m. 9s.; observation gives the time as 21m. 30s.—Solar observations made at Lyons Observatory during the fourth quarter of 1894, by M. J Guillaume. There appears to have been a general decrease of spots and faculæ since the first quarter of 1893.—On continuous straight beams rigidly connected with their supports, by M. Eugène Lave.—On the nature of the "displacement current" of Maxwell, by M. Vaschy. A mathematical paper in which the author shows that certain properties admitted by Maxwell as hypotheses are mathematically exact, and may be deduced from his theory.—On the anomalous rotatory dispersion of crystallised absorbent media, by M. G. Moreau.—On Fresnel's biprism, by M. Georges Meslin.—Influence of low temperatures on the attractive power of artificial permanent magnets, by M. Raoul Pictet. The tabulated mean results of four sets of experiments, agreeing well together, show a continuously increasing attractive power as the temperature becomes lower. The range of temperature in these experiments was from + 30° to − 105°.—Monoiodammonium derivatives of hexamethyltriamidotriphenylmethane, by M. A. Rosenstiehl. Methyl iodide forms with the complex triamines A_3:C.R (where A represents $(CH_3)_2.N.C_6H_4$. and R indicates an electropositive radical such as H, OH, or OCH_3) two series of colourless combination. (1) The first contains one atom of pentavalent nitrogen. Compounds of this class exchange the radical R for an acid radical, and form colouring matters. (2) The second series, formed by the addition of three molecules of methyl iodide, contains three pentavalent nitrogen atoms. Colouring matters are not formed in this case, as the radical R cannot be exchanged for an acid radical.—On laccase and the oxidising power of this diastase, by M. G. Bertrand.—Reactions of chelidonine with the phenols in sulphuric solution, by M. Battandier. With a drop of guaiacol dissolved in 0.5 c.c. of concentrated sulphuric acid, chelidonine moistened and exposed to the air gives a fine carmine colouration. A list of colour reactions with other phenols is given.—On the development of the body in the shrimp (*Palemon serratus*, Fa r.) and the crayfish (*Astacus fluviatilis*, Gesn.), by M. Louis Roule —On the production of females and males among the Melponas, by M. J Pérez.—On the influence of climatological conditions on the growth of trees, by M. Émile Mer. The author shows that the dryness of 1893 caused a diminution in the growth of wood in forest trees. A similar effect was produced by the excessive rainfall of 1888.—On refraction in polychroic auréoles, by M A Michel Lévy. When the auréoles are well developed, with free contours deeply coloured, the refraction of the pigmented part is clearly superior to that of the unmodified substance. The difference between the similar indices of refraction may amount to a decimal of the second order. It follows that the constitution of the mineral is profoundly modified, as its ellipsoid of optical elasticity is different.—On the existence of numerous remains of sponges in the *phtanites* of the Precambrian of Brittany, by M. L. Cayeux. Conclusions: (1) There exist, at the base of the Precambrian of Brittany, numerous and varied sponge spicules. (2) Almost all, if not all, the orders of sponges with siliceous skeletons are represented at this early epoch.—On the existence of a submarine delta in the Upper Cretaceous near Châtillon-en-Diois, by MM. G. Sayn and P. Lory.

SIR ANDREW CROMBIE RAMSAY.

Memoir of Sir Andrew Crombie Ramsay. By Sir Archibald Geikie. (London: Macmillan and Co., 1895.)

THE memoir of Sir Andrew Crombie Ramsay, by Sir Archibald Geikie, is a valuable addition to literature and to science. We will refer our readers to the book itself to learn when Sir Andrew was born and when he died: what support the theories of heredity obtain from the scientific tendencies and noble courage of his parents and fore-elders: who were the teachers and friends, and what were the surroundings of his early years: what, in fact, made Ramsay such as we find him in later life—a prominent person in whatever circumstances he was thrown, whether in the small society of a provincial town or in scientific gatherings in London—a welcome guest at every table, a critic whom any author bolstering up wild theories with bad evidence would fear to have to reckon with. "Of an eminently social temperament, he made acquaintances easily wherever he went, and these chance acquaintanceships sometimes ripened into lifelong friendships. In one family circle we find him reading aloud Shakespeare, or Scottish ballads, or a good novel; in another, he takes part, heart and soul, in singing glees and madrigals; in a third, he joins in dancing and all kinds of merriment." "English literature was to him a vast and exhaustless garden, full of alleys green and sunny arbours, where from boyhood he had been wont to spend many a delightful hour. When he found among his colleagues one whose talk was not always of stones, but who had ranged like himself far and wide in literary fields, he opened out his inner soul, and his conversation glowed with an animation and power, as well as a gleeful exuberance, which astonished and charmed his companion." And "though he was not in any sense an antiquary, he knew a good deal about the history of architecture, and took a keen delight in visiting ruins and trying to form a mental picture of what they must have been before the gnawing tooth of time had dismantled them. Whatever, indeed, linked him with the past had a charm for him. He never willingly missed an opportunity of seeing a ruined castle or keep, a mouldering abbey, a grass-grown encampment, or a lonely cairn. If tradition or song invested any spot with a living interest, he would not consider his geological inspection complete if it had not included a visit to that site." With his quick sympathy and conversational powers, with his wide knowledge of nature, as well as of history and her monuments, no wonder that he was welcome in any society of intelligence and culture. He would unbend in congenial and sympathetic company, like a strong man who had been out in the cold and had at last gained a warm fireside, but he always made room for others round the fire. His impulsive and generous nature was, however, tempered with native judgment and caution. He soon gauged the character of those with whom he was thrown, and quickly estimated the amount of receptivity and the temper of an audience.

These qualities and acquirements with a strong and clear memory gave him much wealth of illustration in scientific discussion and in lectures. But his power lay more in the lucid exposition of his subject, the keen insight into the real points at issue, and the clearness with which he brought forward his array of facts and arguments. After one of his lectures at the Royal Institution, Faraday ran up to him, shook him by both hands, and asked "where did you learn to lecture?"

In the memoir will be found an account of his appointment to the chair of Geology at University College, from which he was always spoken of as Prof. Ramsay; also of his lectures there and elsewhere, and of his various other literary work.

In 1841 he was appointed Assistant Geologist on the Government Survey, under Sir Henry De la Beche, and throughout his forty years of service he was more and more identified with all its active work, either as himself taking part in the mapping, or as superintending others, though it was not until he had been appointed Director-General, in succession to Sir Roderick Murchison, that he officially represented the Survey to the public and the Government. An account of his life is therefore the history of the Survey, and no one is more competent than our author to tell the story.

The great difference between the work which has to be done by the Geological Survey and by amateurs is this. The amateur may examine a district in more or less detail, may pick out the points of interest, or the facts which illustrate some theory which he is developing, but, where he sees nothing, he may say nothing about it. The Geological Surveyor, on the other hand, must colour all his map, and sometimes has to put in by inference whole formations of which he has seen nothing whatever.

"He spends the day, map in hand, over the ground assigned to him for survey. Every exposure of rock is noted by him on his map or in his note-book, with all the needful details. Each stream is followed step by step up to its source; each hill-side and ravine is traversed from end to end; each quarry, sometimes each ditch, and even the very furrows and turned-up soil of a ploughed field are scrutinised in turn. . . . He is brought into every variety of scenery, and is compelled by his very duties to study these varieties and make use of them in his daily work."

But even after all this careful search it often happens that he can find no direct evidence of the solid rocks below the soil and subsoils. He has to plot sections and see what, with the known thicknesses and dips, should be found there. He has to examine the surrounding country to see what occurs in the same relative position elsewhere, and whether any lines of disturbance which might complicate the results are running into the area respecting which, with little evidence, he must make up his mind and say something. The survey work is thus a grand training in the faculty of keeping one's wits about one, and of detecting sources of error. The habit of mind thus formed is often exhibited in the criticism of amateur work by trained survey men, and many can recall Ramsay's indignant protests against impossible or exaggerated sections when appealed to as evidence in support of any view.

He had a wonderful "eye for a country," to use one of

S

his own favourite expressions. He rapidly took in the lie and relation to one another of the rock masses. To this any geologist who has worked with him in the field can testify, and this is what lends its value to his classical memoir on the geology of North Wales, and to the maps and sections of which it is explanatory. But when he had sketched out the outlines of the history of the ancient volcanoes of that area, and had noted the choked craters now exposed by the denudation of the overlying masses of lava and cinder and mud, and when he had described the isolated portions of the volcanic and marine deposits which, building up mountains round the ancient roots of the volcano, still remained the record of great sheets that once spread continuously far and wide over the whole area; when he had done all this, he turned to another aspect of the question, and sought a clear answer to the inquiry how much rock, which we know surely once covered this area, has been removed by denudation? and we find in the same memoir sections illustrating the conclusions at which he had arrived.

For when "he had traced out the structure of a complicated geological region, and was able to show what should have been the form of the surface had it depended on geological structure," he was then "in a position to demonstrate how much material had been removed by denudation," namely, all that was above what he called the *Plain of Marine Denudation*, that is the old base level of ancient erosion, down to which all the agents of waste—rain, rivers, ice, and sea—had reduced the uplifted land; or perhaps, as we should now say, giving greater prominence to subaërial action, to the level at which the sea had arrested the work of the various agents that were reducing all dry lands to sea level.

Few men's work illustrates better than Ramsay's the place and value of a good "working hypothesis" in some kinds of higher scientific research. Imaginative and fertile in suggestion, no one was more sorry when further observations did not clearly support his first impressions, and he tried and tried and tried again to make it fit; yet he bowed always with deference to established evidence and logical consequence.

Besides his regular survey work, which was itself full of new observations and original treatment, and besides many papers giving the results of his researches on special points, he from time to time plunged into more speculative questions, and advanced some theory in explanation of the larger phenomena, especially those connected with surface configuration. For instance, reflecting on the great quantity of fine mud, "flour of rock," carried down by glaciers, and observing that ice was not, like water, restricted in its flow to continuous downward slopes, and holding that ice charged with stones would grind away more rock where the pressure was greater or the rock softer, he propounded the theory of the glacial erosion of rock basins.

His explanation is probably true in some cases, but he gave it a wider application than has been borne out by subsequent investigations.

Unfortunately he adduced as his first example the Lake of Geneva, a basin to which even those who agree with him upon the general probability of there being glacially eroded hollows such as his theory requires, would not now be prepared to apply it.

The public will read with profit and pleasure the biography of such a striking personality by a graceful and accomplished writer, who knew all about the man and his work, and had the skill to select with judgment and the good sense to keep the whole within the modest bounds of one volume of large print. Ramsay's many friends will love to have the record of his struggles and his triumphs, so many of which are told in his own words. Every survey man, not only of Great Britain, but throughout the world, will turn to this account of the commencement and growth of the geological survey of Great Britain, and cannot fail to profit by the insight it gives into the methods, life, difficulties, and results of that important branch of the public service.

So easily does the story run, that we cannot say whether the general reader, or the scientific student, will best appreciate this sketch of the progress of geological research through the most active and interesting half-century of its history.

OUR BOOK SHELF.

Harvard College by an Oxonian. By George Birkbeck Hill, D.C.L. (London: Macmillan and Co., 1894.)

DR. BIRKBECK HILL spent two months in 1893 in Cambridge, Massachusetts, and has compiled this little volume giving some account of the history of the celebrated college and university of Harvard. So far as Dr. Hill relies upon previous publications, his account is accurate, but his own observations and impressions are—as is very natural—often quite erroneous. Scant justice is done to the important and costly arrangements for the study of the various branches of the natural sciences which exist either at or in connection with the Massachusetts university. Dr. Hill is not fitted by his own education and experience to report on these matters, nor, indeed, can much value be attached to his somewhat antiquated standpoint as a critic or observer of university institutions. He contrasts Oxford and Harvard at every step, but he fails to give any picture or presentation of the real characteristics of the student's life at Harvard. He does not sufficiently emphasise the fact that the undergraduate at Harvard enjoys the immense benefit of true *university* education, at the hands of distinguished professors, with freedom and independence in regard to his choice and method of study, and as to such personal details of life as board and lodging; whereas the Oxford undergraduate is treated throughout his career as a goose to be nursed, monopolised and plucked by college ushers, who (owing to the system under which they are appointed) are, as a rule, as little capable of good teaching as they are of managing the domestic and disciplinary details of the college-boarding-houses. Dr. Hill notes that the rage for athletics is almost as serious an injury to study at Harvard as it is at Oxford. L.

Tableau Métrique de Logarithmes. By C. Dumesnil. (Paris: Librairie Hachette and Co., 1894.)

THE use of logarithms for calculations is, as every one knows, a great saving of labour and time, and what otherwise would be complicated pieces of work are reduced to simple computations. The facility of working depends, after some time, on the good or bad arrangement of the tables, but instances often occur where much time is lost by having to turn pages backward and forward. For the case of logarithms to five places of decimals, M. Dumesnil has devised a means of eliminating altogether the use of tables, by adopting a series of scales neatly printed on stout sheets. From these scales the divisions are so arranged that all the logarithms of the numbers from 1 to 10,000 can be easily read off, and *vice versâ*. The scales, or tables as they are called, are published in two qualities. The cheaper are neatly and clearly printed, and on a smaller scale than the other; but, on the whole, we recommend the more expensive sheets, as the numbering is more easy to follow (coloured numbers being used), and the divisions are more legible on them.

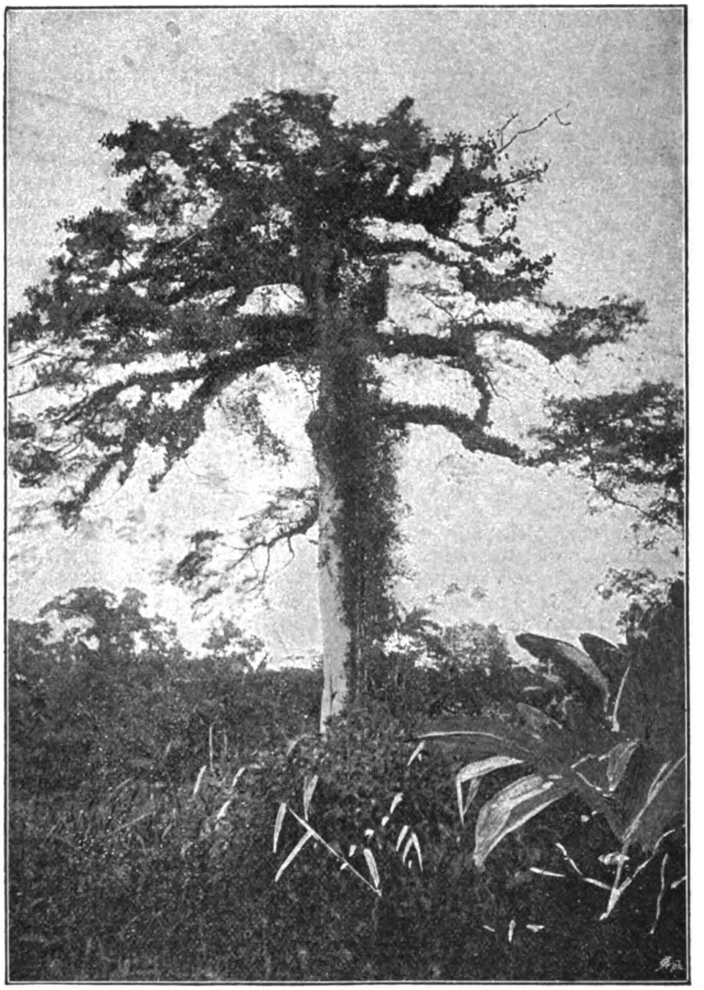
To understand the method of working the tables is a matter of only a few minutes' attention, and when grasped, either the logarithm of a given number, or the number from a given logarithm, can be read off without the least hesitation. The book of instructions, which is separate from the tables, contains all that the user of the tables can require. The explanations are full and concise, and the worked-out examples will prove an excellent help in acquiring the methods of solution.

In the Guiana Forest. Studies of Nature in Relation to the Struggle for Life. By James Rodway, F.L.S With an Introduction by Grant Allen. Illustrated. (London: T. Fisher Unwin, 1894.)

WE have read Mr. Rodway's book with a good deal of pleasure. Such a subject as the struggle for existence amongst the animals and plants of the Tropics, could not fail to be full of interest when dealt with by an enthusiastic lover of nature. For it is in the Tropics that nature's principal workshops are situated, and no naturalist can afford, nowadays, to neglect that essential element in a liberal biological education—a visit to these regions. There the struggle for life is no longer, as in our own climates, a cold-blooded process which only a trained eye can follow, but a fiercely active competition for the means of subsistence which is everywhere apparent in every detail of the structure of the individual and of the economy of the species. The "heartless vegetable" amid such surroundings seems no longer a reality, but the cold figment of a northern imagination.

Mr. Rodway describes the vegetation of the forest, the swamp, the sand-reef, and the sea-shore, and each is sketched in vigorous outline. One cannot, however, avoid wishing that the author had been contented to give his impressions of the actual facts, without indulging in metaphysical moralising which is not scientific, and is not always common sense. Occasionally, too, he gives way to great prolixity, as, for instance, in an excursus on the interdependence of animals and plants, which is all very like something we have heard before, only that Mr. Rodway's story is longer. The author is on dangerous ground when he ventures to dip into the philosophy of natural selection, or to deal with problems of variation.

But notwithstanding these defects, the book is worth reading. It is well illustrated, and contains a large amount of really interesting observation which may stimulate the general reader, and which will recall many a half-forgotten scene to those who have themselves been travellers. The accompanying illustration, for which we are indebted to the publisher, shows a silk cotton-tree crowded with epiphytes.



Lehrbuch der Experimentalphysik. Von A. Wüllner. Band i. 5te Aufl. (Leipzig: Teubner, 1895.)

STUDENTS who wonder when we are to have an English treatise on experimental physics worthy of comparison with this well-known German one (and the French text-books of Jamin and Violle), will find food for reflection in the fact that thirteen years have elapsed since the last edition of Wüllner (the fourth) was published. Much the same thing holds good of other German scientific treatises, notwithstanding that publishing firms of repute in the Fatherland do not consider it beneath their dignity to quicken the sale of the remnant of an edition by having notices posted up in the Universities intimating that *bonâ fide* students of the subject can secure copies at a reduced price by application through the University Professor.

In the present case the interval has been well employed. The first volume has grown to 1000 pages—or 150 more than in the fourth edition—and the most important researches published up to the end of 1892 have been incorporated. In the last edition the article on internal friction contained simply a discussion of torsional vibrations and logarithmic decrement, followed by a page in which mention was made of the researches of Schmidt and others, with a statement of the conclusion arrived at, viz. that in such elastic oscillations the motion is opposed by an internal resistance or friction which is measured by the logarithmic decrement and is distinct from the elastic after-effect. In the new edition six pages are devoted to Boltzmann's theory of internal friction of solid bodies, according to which the damping of oscillations is regarded as due to the elastic after-effect, the result of which is that the force urging the wire towards its position of equilibrium is not proportional to the displacement. In the fourth edition there was little about "Hardness," beyond a list of the substances forming Moh's scale; indeed, the whole article on the different kinds of *Festigkeit* was rather unsatisfactory. Now the researches of Hertz and the experiments of Auerbach have made it possible to measure the hardness of a substance absolutely and without reference to the properties of any other substance.

Instead of being relegated to the volume on heat, as in some text-books, the kinetic theory of gases is here described at considerable length in the section treating of the properties of gases. This section has been overhauled, and Stefan's theory of gaseous diffusion is given in place of O. E. Meyer's. Prof. Wüllner attaches so much importance to recent developments of the electromagnetic theory of light, that he has determined to alter the sequence of the subjects in his treatise, so that light and radiation may come at the end. In the edition now appearing, the second volume will therefore treat of heat, and the third of electricity. *pv.*

Peru. Beobachtungen und Studien über das Land und seine Bewohner während eines 25-jährigen Aufenthalts. Von E. W. Middendorf. (Berlin: Robert Oppenheim, 1893-94.)

DR. MIDDENDORF commences his treatise on Peru by a long preface detailing the circumstances which led him to choose that country for his home. Starting as the surgeon of an Australian emigrant ship from Hamburg in 1854, he narrates the incidents of the voyage, an epidemic of cholera and other irrelevant accidents included, until on the return journey, sick of the sea, he left his vessel in Valparaiso, and after some further wandering took up his residence in Peru, and was led by degrees to pay closer and closer attention to the land and people of his choice.

The work is planned in three parts. The first volume deals nominally with Lima, the capital of the republic, but is really much wider in its scope, commencing with the history of Peru, and after describing the town with its streets and public buildings in somewhat tedious detail, proceeding to discuss the general institutions of the country from the standpoint of the capital. People, church, government, law, education, commerce, transport, and charities are all discussed; and at the end two chapters describe the municipal markets, slaughter-houses, water-works, bull-fighting arenas, theatres, and other places of amusement. The second volume describes the coast lands of Peru northward and southward of the capital, the towns and seaports, the provinces now ceded to Chile, the railway communications, and the antiquities. A third volume is promised dealing with the highlands, but presumably the scheme does not include an account of trans-Andine Peru.

We cannot look on Dr. Middendorf's work as an exhaustive or even a comprehensive work on Peru. It is indeed a book for the general reader rather than the student. Abounding as it does in personal reminiscences, and written in an easy conversational style, it should do much to further the knowledge of the country it describes amongst German-speaking people. But it is, we fear, too diffuse and bulky to serve this purpose with the same degree of satisfaction that a smaller work might have secured, and it lacks firm and wide generalisations which could present a clear picture of the land and people as a whole.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Liquefaction of Gases.

A CAREFUL study of his letter in NATURE of February 14 shows that Prof. Dewar makes four claims.

(1) He claims that in his lecture in 1884 he employed an apparatus "more readily and quickly handled" than that of Messrs. Wroblewski and Olszewski, in the illustrations he gave of the work of these investigators.

(2) He claims that in his lecture in 1884 he used liquid nitrous oxide for the production of liquid oxygen.

(3) He claims that in 1886 he liquefied oxygen by passing the gas through a long copper coil surrounded by liquid ethylene, and that his apparatus made it possible to transfer the liquid oxygen to a glass vessel wherein it could be used as a cooling agent.

(4) He claims that, in conjunction with Prof. Liveing, he determined the refractive index of liquid oxygen before the publication of Prof. Olszewski's first paper on the subject.

I shall consider these claims in order.

(1) The apparatus used by Messrs. Wroblewski and Olszewski in 1883 is fully described and figured in *Wiedemann's Annalen* for that year (xx., 243). The gas to be liquefied was strongly compressed in a glass tube, imbedded in an iron cylinder, and connected by a capillary tube with a glass vessel, which in turn was connected with a store of liquid ethylene, previously cooled by passing through a narrow copper tube two metres long immersed in a bath of solid carbon dioxide; the glass vessel was also connected with a double oscillating Bianchi air-pump. The liquefied gas was collected in the glass vessel, and its properties were examined. A comparison of the apparatus of the Polish Professors with the brief description in the *Proceedings of the Royal Institution* of the apparatus used by Prof. Dewar in 1884 "for the purpose of lecture demonstration" will, I think, show that I stated the matter fairly in my former letter by saying that Prof. Dewar "describes and figures an apparatus which is a slightly modified form of that of the Polish Professors, which in turn was derived from the apparatus of Cailletet."

(2) If anything was gained by using liquid nitrous oxide for the liquefaction of oxygen, why has not Prof. Dewar continued to use this refrigerator?

Prof. Dewar claims to have devised a method for liquefying oxygen which was so much inferior to that brought into practice by Wroblewski and Olszewski that it was abandoned almost as soon as it was devised. I suppose his claim may be admitted here.

(3) Granting that the substitution of a long copper coil for a strong glass tube was an improvement, it must not be forgotten that the apparatus of Messrs. Wroblewski and Olszewski, described in 1883, enabled the liquefied gas to be collected in a vessel wherein its properties not only might be, but were, studied. That this apparatus was an efficient instrument is shown by the facts that before the year (1886) in which the copper coil method was described, Profs. Wroblewski and Olszewski had liquefied oxygen, nitrogen, and carbon monoxide: Prof. Olszewski had liquefied air, nitric oxide, and marsh gas; had determined the boiling points, at atmospheric pressure, and the critical temperatures and pressures, of these six gases; had solidified nitrogen, chlorine, hydrogen chloride, nitric oxide, carbon monoxide, and marsh gas; and had made careful determinations of the behaviour of hydrogen at $-211°$ and $-220°$. But with his copper coil 45 feet long Prof. Dewar did nothing; for, so far as can be judged from his published papers, he did not initiate experiments on the properties of liquefied oxygen, nitrogen, or air, until 1891-92. I think we may conclude that the apparatus of the Polish Professors was better adapted for accurate work than "that made wholly of metal" to which Prof. Dewar refers. If Prof. Dewar's apparatus of 1886 was "safer and better" than "that used in Cracow in 1890"—as he says it was—why was not this safer and better apparatus turned to some scientific use before a description appeared of the apparatus of Prof. Olszewski, in which the gases were liquefied in a steel cylinder and then transferred to

a glass vessel? In his letter of February 14, Prof. Dewar tells us that by means of the copper coil apparatus of 1886 "liquid oxygen was made and decanted or transferred from the vessel in which it was liquefied to another by means of a valve, and thereby rendered capable of use as a cooling agent." Why, then, did he not use the liquid oxygen as a cooling agent? It is strange that seven years after this, when Prof. Dewar wished to "prosecute research at temperatures approaching the zero of absolute temperature," he says he had "no recorded experience to guide [him] in conducting such investigations." Had he forgotten his own apparatus with its copper coil 45 feet long?

Prof. Dewar's apparatus of 1886 must have been peculiar; in one sentence in his letter of February 14, its deviser speaks of it as "entirely different in type from the crude plan Olszewski adopted in 1890," and in another sentence he assures us it was "practically identical in principle with that used in Cracow in 1890."

The apparatus of 1886 succeeded, in Prof. Dewar's hands, in producing solid oxygen; why have we heard nothing of that solid oxygen? Determinations of some of the constants of that substance would be interesting and important.

I must beg attention to an instance of Prof. Dewar's boldness. In 1883 Messrs. Wroblewski and Olszewski liquefied oxygen, and other gases, in a strong glass tube; in 1884 Prof. Dewar repeated some of the experiments of the Polish Professors, using, as they had done, a strong glass tube, but adapting some parts of their apparatus so as to make it "for the purpose of lecture demonstration . . . more readily and quickly handled"; in 1890 Prof. Olszewski described an improved and enlarged instrument, based on that described by his colleague and himself in 1883, wherein the liquefaction was effected in a steel cylinder. Yet, in his letter to NATURE of February 14, Prof. Dewar says "replace the glass tube in *my* apparatus of 1884 by a small steel cylinder, and attach to its lower end a narrow copper tube with a stopcock, and the Olszewski apparatus of 1890 is produced." (The italics are mine.)

(4) As regards Prof. Dewar's joint claim to priority in the determination of the refractive index of liquid oxygen, I admit he is right and I was wrong. I was misled by the date at the beginning of the paper which contains the earliest measurements by Messrs. Olszewski and Witkowski of the refractive index of liquid oxygen. The paper is headed *Extrait du Bulletin de l'Académie des Sciences de Cracovie, Octobre* 1891. At the end of the paper is the date 15 *Juillet* 1892; this, and the footnote, quoted by Prof. Dewar, make it evident that 1891 at the beginning of the paper is a printer's error for 1892. I am sorry I made this mistake. Nevertheless, considering that Olszewski's quantitative experiments on the optical properties of liquid oxygen were begun in 1887 (*Wied. Ann.* xxxiii., 570), and were continued in January 1891 (*ibid.* xlii., 633), I hold I was justified in referring to Prof. Dewar's experiments on the optical properties of liquid oxygen as "mainly repetitions of the work of Olszewski and Witkowski."

Towards the end of his letter Prof. Dewar refers to a quotation I made from one of his lectures ("Having no recorded experience to guide us . . ."); he follows my quotation (of which he gives only a part) by another to the effect that "the necessity of devising some new kind of vessel for storing and manipulating exceedingly volatile fluids, like liquid oxygen and liquid air, became apparent when the optical properties of the bodies came under examination." I had expressed admiration "of the skill which produced" Prof. Dewar's new vacuum receivers. Prof. Dewar now tells us that when he prefaced his account of the making of these receivers by the sweeping assertion that he had no experience to guide him in conducting investigations at very low temperatures, he did not mean what he said; it was merely his way of saying that the vacuum receivers he was about to describe had not been made before. It was not I who made, it was Prof. Dewar himself who has made, a "glaring misrepresentation of the meaning" of his own words.

Prof. Dewar lays no stress, in his letter, on his own experiments on chemical action, phosphorescence, &c., at very low temperatures. It is these experiments, I suppose, that are referred to when he speaks of "throwing his bread upon the waters"; or does he abandon them as trifling, in that strange sentence—"Have I ever suggested that Prof. Olszewski was anticipated, or attempted to raise any question of priority?"?

Prof. Dewar hides the essential questions in a mist of words. If he has made marked improvements in the methods of liquefying and manipulating the more permanent gases (besides his invention of vacuum receivers); if he has conducted original, accurate, and thorough investigations into the properties of the liquefied gases, where are the accounts of this work to be found? Every student of the subject knows he can lay his finger on the work of Olszewski, and also on that of his deceased colleague Wroblewski; and he knows that work to be thorough, accurate, and important. But where can there be found some distinct account of the scientific work in connection with the liquefaction of the more permanent gases that is attributed to the Fullerian Professor at the Royal Institution?

I asked, and I still ask, for an "instant and serious consideration" of the whole matter brought forward in these letters by "those who are truly interested in the advance of science, and are jealous of the good name of the scientific men of this country."

M. M. PATTISON MUIR.

Cambridge, February 17.

Argon.

THE beautiful research of Lord Rayleigh and Prof. Ramsay has proved up to the hilt that in argon they have discovered an unknown gas which is remarkable for some of its physical properties, and especially for its extraordinary chemical inertness.

Among the interesting questions which have been raised, but not fully solved, are: Is argon an elementary body? If so, how does it stand related to the other elements?

There are some who advocate its being an allotropic form of a previously known element, just as ozone is allotropic oxygen; but it has not yet been produced from, or resolved into, nitrogen or any other element; and, until that should happen, it has the full right to take rank as a new element.

At first sight the fact of its giving two different line spectra under different circumstances might favour the idea of its being resolved into two bodies; but the fact that these two very compound line spectra have twenty-six lines in common, which are not all of them among the strongest lines, appears to me an argument for the fundamental unity of the substance.

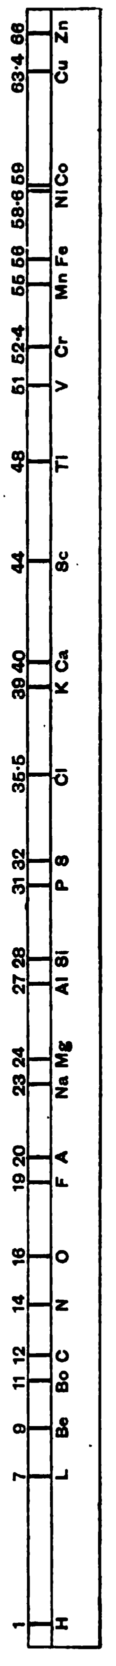
If argon be an element, what is its place in Mendeléeff's table? This is at present agitating the minds of chemists and physicists. The specific gravity of the gas would lead to an atomic weight of close upon 20; but it is argued from the velocity of sound through it that it is a monatomic gas, and therefore close upon 40. Now, if 20 be the atomic weight, it will fall in admirably with the periodic law; if 40, it will be perfectly inconsistent with it. The argument in favour of 20 is at least five-fold:—

(1) It will fill an existing vacancy in Mendeléeff's arrangement; that at the top of the eighth column. This is the first "even" series; and it should be remembered that the later "even" series in that last column are represented by the iron, palladium and platinum groups of metals; the "uneven" series being as yet unrepresented.

(2) It will follow the periodic law in regard to its melting point. That should be very low, like nitrogen, oxygen and fluorine; and so it is.

(3) It will follow the law in regard to its atomic volume. That is small; and so it should be by analogy.

(4) A great characteristic of argon is its not forming stable compounds with other bodies, at any rate at a temperature high above its boiling



point. This property characterises the other occupants of the eighth column; to some extent in the iron group, and certainly in the palladium and platinum groups.

(5) The introduction of a new element with the atomic weight of 20 (not 21 or 22), will extend the range of certain recurring numbers which appear near the beginning of the series of atomic weights. In the existing arrangement of the atomic weights it will be observed that between oxygen 16 and fluorine 19 there are three units; between fluorine 19 and sodium 23 there are four; then the numbers run 1, 3, 1, 3, 1, 3½. Adding argon at 20 the series becomes symmetrical all the way from oxygen to chlorine, as will be seen in the diagram on the previous page.

If, on the other hand, we were to adopt 40 as the atomic weight of argon, we should meet with the following serious difficulties:—

(1) There is no room for it. To place another figure just before or just after calcium would disarrange the whole subsequent series.

(2) It would break the periodic law in regard to its melting point.

(3) It would break the law in regard to its atomic volume.

(4) The inactive argon would be associated with metals of the earths, the compounds of which are remarkably stable.

(5) It would bring the atomic weight of three elements, potassium 39, calcium and argon each about 39·9, within one unit. This never occurs elsewhere in Mendeléeff's table.

Against these considerations there is the forcible argument deduced from the ratio of the specific heats of argon. I will not attempt to weigh the respective merits of these lines of reasoning, especially in the absence of the details of the experiments on the velocity of sound, and until we have some knowledge of the compounds of argon. Trustworthy conclusions will not be possible till this further information is obtained. It is not a question of physics *versus* chemistry, for the true theory of its place among the elements must be able to coordinate all the facts upon which both the chemist and the physicist rely.

J. H. GLADSTONE.

London, February 8.

The Aurora of November 23, 1894.

PERMIT me to call attention to a significant fact disclosed by a scrutiny of the observations of the aurora of November 23, 1894, and having an important bearing in discussing the auroral dimensions, and which appears to have escaped notice (see NATURE, January 10). I refer to the *invisibility* of the objects at Dingwall, to the observers at Tynron, Dumfriesshire. Extracts from the synchronous accounts in NATURE, November 29, p. 107, and January 10, p. 246, will prove this statement.

Tynron, 7.30.—Luminous mist in the northern sky, strong enough to cast shadows on the shining surface of the wet ground. The mist moved from the horizon to the zenith, forming a detached luminous belt in patches, disappearing at 8.30, leaving only the light in the north.

Dingwall, 7.30.—Sky covered in all directions by a canopy of streamers. At the same time the arch disappeared, and occasional streamers up to eight o'clock. It is not possible that the arch seen at Dingwall could be the same as the one at Tynron, because the former had vanished when the latter commenced to form, whilst there is a total absence of streamers, and phenomenally brilliant mist not recognised at the other place. Until methods of observation and analysis can be introduced that will eliminate the errors of identification, the solution is likely to be indefinitely postponed.

W. H. WOOD.

Birmingham, February 3.

MAKING the necessary allowances for increased apparent luminosities of bright streaks, or of layers of light in the atmosphere, by the foreshortening effects of end-on, and of edge-presentations, the observations at Dingwall and in Dumfriesshire of the aurora of November 23 last, scarcely seem to recount very much which was not at the two places, at least partially, a fairly comparable and nearly contemporaneous description of the same phenomena. The first-formed light-band of the glow was very strong at Dingwall from the east to west, a little southward from the zenith, until 7.30 p.m., when with the usual drift of such displays to southwards, it became less prominent there than the approaching canopy of streamers which supervened, drifting up from the north-eastern sky in rear of it. But it assumed at the same time increasing prominency in Dumfriesshire (150 miles south of Dingwall), where between 7.30 p.m. and 8 p.m., it passed overhead in the shape of detached patches of light, a form which the belt was also seen to assume and to break up into, in a slow extinction stage at Slough, in that interval. The display of streamers rising from a large tract of light-mist approaching Dingwall from the northward and increasing constantly in lustre at 7.30 p.m., did not extend far south of Dingwall before it faded out soon afterwards; and being (as it was seen at Slough) a dense local discharge of them, its corona of brightly-foreshortened beams overhead would naturally be a very impressive sight at Dingwall, although from a position 150 miles distant in Dumfriesshire, the broadside aspect of the short outbreak, seen from afar, instead of from underneath, would only have the appearance of a sheaf of coloured light projected up from the usual flat streamer-base, neither very wide nor extraordinarily lofty, but of the massive berg-like form, which was its description at Slough, not unfrequently noticeable in rather strong auroras; and it may even have been quite easily hidden from view entirely at Tynron, although a clear horizon in the north near Slough allowed its observation there, by trees or by other obstructions in the landscape.

If Mr. Wood can happily devise a practical means of perfectly recording the times and descriptions of *all* the rapidly changing features of an aurora, and the shifting variations of its misty light-glows, he could no doubt achieve results from observations which would be no less a benefit to astronomers and terrestrial magneticians, than an exact continuous registration of cloud phenomena would be of welcome interest to meteorologists and terrestrial electricians; but it needs no great familiarity with auroral exhibitions to be quite certainly assured that results of records even so elaborate as those might be, would never be found to confute, but only to confirm the generally accepted view of the really cosmical heights and dimensions of all truly auroral lights and corruscations; of all such lights, that is to say, as show in their spectra the yellowish auroral line, or some of the other well-recognised spectral indices of the aurora.

A. S. HERSCHEL.

The American Association.

AT the Brooklyn meeting of the American Association for the Advancement of Science last summer, it was decided to meet this year at San Francisco, provided reasonable rates of fare could be secured from the trans-continental routes, as it was supposed could be done. Prof. Joseph Le Conte for three consecutive years had crossed the continent, laden with earnest and cordial invitations from the Universities and Scientific Societies of California, and the Common Council of San Francisco, to hold the meeting for 1895 in that city. The short-sighted policy of the railroads, however, refused to grant any concessions; and it has at last been decided to meet at Springfield, Mass., August 29—September 4. The meetings of affiliated societies will begin on Monday, August 26—rather later than the usual time of meeting.

Springfield is a small city, located in the heart of New England. It is the seat of the principal arsenal of the United States; and, while not a University city itself, it is within two or three hours' ride of nearly, or quite, a score of institutions of learning of the highest grade, including the two oldest and most powerful Universities in America, Yale and Harvard. This will be the second meeting at Springfield, the first having been held in 1859.

The Association is incorporated by the State of Massachusetts, and its office and museum are at Salem in that State; but no meeting has been held in New England since that at Boston in 1880, the most brilliant in all the history of the Association. The return to New England after this longest absence, gives unusual interest to the approaching meeting.

WM. H. HALE.

Brooklyn, New York, February 2.

Earthquake in Norway.

ABOUT midnight on the 4th and 5th of this month, a fairly strong earthquake occurred in the southern part of Norway. The greatest disturbance was felt in the environs of the town of Aalesund, upon the west coast (about 60° 30′ lat. N.). From there the shocks extended to the region of the Trondhjems fjord, the Swedish border, and the Christiania fjord, and Bergen, but the extreme south-west part of the country seems to have been undisturbed. The earthquake is also reported from Fünen, in Denmark. The movement proceeded in about seven minutes from the west coast to Christiania (at Christiansund 11h. 38m. Christiania time, 11h. 15m. Greenwich time). It is interesting to notice that the earthquake resembles one which occurred on March 9, 1866, and was felt across the North Sea at the lighthouse of Fluggarrock, on the Shetland Islands. As I am engaged in collecting data about the earthquake of this month, I should be glad to know whether it was observed in the British Isles.

Christiania, February 11. HANS REUSCH.

"The Black-veined White Butterfly."

MY experience of this species in England enables me to support Mr. W. Warde Fowler's opinion (NATURE, February 14, p. 367) as to the preference of the species for open ground. I met with it in abundance in the New Forest in 1866 1868, 1869, and 1870. It rarely occurred in or near dense woods, but preferred the open heaths and wastes of the Forest, where thistles were plentiful. In 1867 I found the species swarming, about midsummer, in hay fields on hill-sides in Monmouthshire. There were a few small orchards, but not much wood, in the neighbourhood. For a detailed account of the former distribution of *Aporia cratægi* in this country, I would refer Mr. Warde Fowler to my article on the subject in the *Entomologists' Monthly Magazine* for March 1887. H. GOSS.

Surbiton Hill, March 16.

The Zodiacal Light.

AT the present moment—7 p.m. February 16—the zodiacal light is more distinct than I ever remember to have seen it in England. The middle of the base is about 2° to the northward of the point where the sun set, and the axis is directed towards the Pleiades, and can be traced as far as the middle of Aries. The afternoon has been remarkably clear, and it is now a brilliant starlight evening. J. P. MACLEAR.

Cranleigh, Surrey, February 16.

OYSTERS AND TYPHOID.

THE statements that have recently appeared, both in the general and in the medical press, concerning the communication of typhoid fever through the agency of oysters when eaten raw, make it desirable to review some of the data on which the suspicion in question is based. For many years past it has been a matter of assumption, when typhoid fever has followed, within some ten to fifteen days, on the consumption of raw oysters, and when no obvious cause for the disease could be detected, that the oysters stood to the fever in the relation of cause; and this attitude received no inconsiderable impetus when, a few years ago, a member of our Royal family sickened of typhoid fever under circumstances that were suggestive of oysters as the vehicle of the disease. Then again, it must be admitted that it has been a matter of no very uncommon experience amongst medical men to have to treat typhoid fever in patients who, at an antecedent date corresponding with the incubation period of typhoid fever, had indulged in an oyster supper after leaving some place of entertainment. And the suspicion has been confirmed, in some cases, when it has been ascertained that another member of the same party, having nothing but the oyster supper, in common with the sufferer referred to, has also had typhoid fever about the same date, or had suffered from vomiting and other symptoms the day after the consumption of the oysters. The assumption in cases of this latter class has been, that the specific poison of typhoid fever was, with other matter that had become objectionable to the system, got rid of by the attack of sickness. A case generally illustrative of this class of occurrence was recently recorded in the *British Medical Journal*. Four friends had an oyster supper on November 5. Two of them lived not far apart, but the others had nothing in common as regards residence or anything else. On November 23 three of them sickened, and they were, later on, all found to have typhoid fever. One of the patients, during convalescence, disclosed both his profession and his views by re-naming his malady "bivalvular disease."

Amongst leading medical men who have adopted the view that oysters are a source of typhoid fever, we may name Sir William Broadbent, who early this year announced that from time to time he had seen cases of typhoid fever "apparently attributable to oysters," but that during the course of last autumn the evidence as to the communication of the infection through this agency has been of such a character as to produce "conviction" in his mind.

This naturally leads us to ask how the oyster becomes the vehicle of such a disease; and the evidence already forthcoming on this point is such that we could only wonder if typhoid fever were not occasionally conveyed to those who eat this favourite mollusc in an uncooked form. Investigation of some of the river estuaries and other places where oysters are cultivated and prepared for market, would almost lead us to believe that conditions favourable to typhoid fever were deliberately chosen for the purpose. Indeed, it is notorious that a number of our British oyster-beds are in such relation to sewer outfalls, that the oysters must of necessity be bathed in a solution of sea-water and sewage at every tide. According to a commissioner appointed to inquire into this matter by the *British Medical Journal*, a well-known Essex oyster fishery has "a sewer discharging between oyster-beds on either side"; and at a "health-resort" (!) on the same coast, it is a common practice to moor the oyster-boxes to a pier or groyne, within a few feet of which the evidences of sewage are too palpable to be specified. In both the places referred to, the typhoid fever poison. which it is known finds access to drains, had had ample chance of fouling the sewers in question.

It has been alleged, on the evidence of certain recent bacteriological investigations as regards the contents of London sewers, that the organism producing typhoid fever cannot live and multiply in sewers. But the organism has been found in sewers; it also lives in sea-water; and the fact remains that sewage bathes our oysters during cultivation to an extent that is essentially disagreeable, and that ought not to take place; and, also, that typhoid fever follows the use of oysters so cultivated. It may also be alleged, as is done by certain oyster-growers, that sewage is fatal to the oyster itself. In answer to this, we can only say that such evidence as we have obtained, as to some of our oyster-beds, is absolutely opposed to this statement; and not only so, but we know of more than one instance where the oysters are deliberately brought from the beds to fatten in still nearer proximity to outfall sewers for a week or more preliminary to their sale. In brief, if sewage and noxious micro-organisms can be retained in the beard and other portions of the oyster, or in the "juice," which is so much relished, everything seems contrived to secure such retention of filth at some of our oyster fisheries.

Doubtless the same applies to many foreign oyster-beds. Indeed, the recent experience embodied in a report by Prof. W. N. Conn, as to an epidemic of typhoid fever amongst the students of a college at Middletown, Connecticut, not only supplies convincing evidence of this, but it affords the most connected and complete proof of "oyster-typhoid" as yet published. Quite an epidemic of typhoid fever occurred amongst the students of certain fraternities, and amongst a number of their friends who had joined them at their "initiation suppers," but who had subsequently returned to their distant homes, where they sickened. The incidence of the epidemic was on those fraternities only who had included raw oysters in their *menu ;* and even amongst these some marked escapes were in persons who, for one and another reason, had not consumed oysters. The suspected oysters came from Long Island Sound, where they had been put to "fatten" in a fresh-water estuary within 400 feet of a sewer known to have been receiving typhoid material. The last piece of evidence bearing upon this subject comes from an official source. It is announced that, on the strength of a report by the Medical Officer of the Local Government Board, as to the diffusion of cholera in England during 1893, which report is now passing through the press, an inquiry has been commenced into the circumstances under which oysters are cultivated and stored round our coasts. The reference is clearly to the serious outbreak of cholera at Grimsby and Cleethorpes, and to the diffusion of the epidemic from those places, whence a large distribution of oysters and other shellfish is constantly in progress.

Whatever be the outcome of the inquiry which has been instituted, it is certain that two questions will come to the fore: (1) the need for control over our oyster-beds, and (2) the desirability or not of allowing crude sewage to be discharged direct into the sea, or into tidal estuaries.

NOTES.

SIR HENRY ROSCOE has been made Chairman of the Select Committee of the House of Commons appointed to enquire whether any, and what, changes in the present system of weights and measures should be adopted.

WE regret to announce that Mr. John Whitaker Hulke, F.R.S., president of the Royal College of Surgeons of England, died on Tuesday, from broncho-pneumonia. An obituary notice in the *Times* furnishes us with the following particulars with regard to his career. Mr. Hulke was born in 1830, and was the elder son of a well-known and highly-esteemed surgeon at Deal, where his family had been settled for several generations. He was educated at King's College School, and subsequently spent two years in Germany, where he thoroughly acquired the language. After a varied experience as surgeon to the hospital at Smyrna, during the Crimean War, and in King's College Hospital, he migrated to Middlesex Hospital. In 1859 he received the Jacksonian prize of the Royal College of Surgeons for his Essay on Diseases of the Retina, and soon afterwards he brought out a treatise on the ophthalmoscope, then a novelty in eye-practice. This led to his being regarded mainly as an ophthalmic surgeon; but he contributed to general surgery in the Medico-Chirurgical *Transactions*, and joined Mr. Holmes in editing the third edition of his "System of Surgery." He was elected a fellow of the Royal Society in 1867. In 1876 he was appointed an examiner in anatomy and physiology at the College of Surgeons; and in 1880 became a member of the Court of Examiners, an office which he held for ten years. In 1881 he was elected a member of the Council; and, after twice serving the office of vice-president, he became president in 1893, and has died in office. He had been president of the Pathological and Ophthalmological Societies, and at the time of his death was president of the Clinical Society and librarian of the Royal Medical and Chirurgical Society. Mr. Hulke was, however, much more than an accomplished surgeon. He was a good comparative anatomist, botanist, and geologist; and was at one time president of the Geological Society of which he was elected the Treasurer on February 15. He was an artist in water colour, and was able both to model in clay and to carve in marble. His loss is a real one to the medical profession, in which he was esteemed as a man of the highest probity and sagacity.

WE notice the death, at the age of eighty-eight, of a gifted mathematician, the Rev. T. P. Kirkman. He was elected a Fellow of the Royal Society in 1857.

THE following deaths have occurred among scientific men abroad:—Dr. Gerhard Krüss, Extraordinary Professor of Chemistry in the University of Munich. M. Jules Regnauld, Professor of the Paris Faculty of Medicine, at the advanced age of ninety. The Rev. J. Owen Dorsey, a well-known ethnologist, at Washington, February 5. Prof. Dorsey had been connected with the Bureau of Ethnology, since 1877. He was the president of the Anthropological Section of the American Association for the Advancement of Science in 1893. We also have to record the death, at the early age of forty-five, on January 28, of Dr. F. Schmitz, Professor of Botany at Greifswald. For many years past, Dr. Schmitz had turned his attention chiefly to the study of the Algæ, and especially of the red sea-weeds or Florideæ, to our knowledge of the life-history of which he had made substantial additions. He published, in the year 1877, an account of the formation of auxospores in the diatoms, and, in 1879, a description of the green Algæ of the Gulf of Athens.

PROF. L. GUIGNARD, President of the Botanical Society of France, has been elected to succeed the late Prof. Duchartre in the Section de Botanique of the Paris Academy of Sciences.

LORD RAYLEIGH will deliver a course of six experimental lectures on "Waves and Vibrations," at the Royal Institution, on Saturdays, March 2, 9, 16, 23, 30, and April 6. He will also deliver the Friday evening discourse on April 5, when his subject will be "Argon, the New Constituent of the Atmosphere."

A NEW thallium mineral has just been described, under the name of Lorandite, by Prof. Krenner, of Buda-Pesth. The new mineral occurs sparingly, in association with realgar, at Allchar in Macedonia. It is found as transparent crystals belonging to the Monosymmetric system, and having the form of plates or short prisms; its colour varies from cochineal-red to kermesite-red. The mineral proves on analysis to correspond to the formula $TlAsS_2$, and contains 59·5 per cent. of thallium.

WE have received from the Russian Chemical Society a pamphlet devoted to the description of the new chemical laboratory which has been erected at the St. Petersburg University. The laboratory has been built in accordance with the requirements of modern scientific investigation, and has cost £32,720. All branches of research have separate large halls, special rooms being allotted to physical chemistry and accurate physical measurements. Although the laboratory is behind many of the largest laboratories of West Europe, it has the advantages of perfect arrangements for each separate worker, and it decidedly has no rivals for the perfection of ventilation. The total amount of warmed air supplied to all the halls of the building attains 823,000 cubic feet per hour, so that the air will be totally changed from one to five times per hour in each separate hall.

THE Russian Geographical Society awarded, at its meeting of January 30, the Constantine medal to S. N. Nikitin for his numerous works on the geology of Russia; the Count Lütke medal to P. K. Zalesskiy for geodetical work in Turkestan; the great gold medal, to N. A. Karysheff for his work, "The Land rented by the Peasants"; and the Prjevalsky premium, of £60, to V. A. Obrucheff for his last journey in Turkestan and Central Asia. Small gold medals were awarded to the French geodesist, M. Defforges, and the Austrian geodesist, Baron Sterneck, for their pendulum observations in Russia, and to M. Sieroszewski for his MS. on the Yakutes; and the great silver medal of Prjevalsky's name to Baron Toll and Lieutenant Shileiko, for their last journey to Arctic Siberia. Eleven silver medals were also awarded for minor works.

SEVERE frost has continued in nearly all parts of the British Islands, but in England and Ireland the cold was rather less intense last week. The frost has now continued for over four weeks, and although the period is shorter than in some other frosts during the present century, the intense cold experienced has been seldom equalled. There were no instances of temperatures below the zero, as in the preceding week, but readings of 20°, and even 30°, below the freezing point have been recorded. At Greenwich the mean temperature since the commencement of the frost is 28°, and the mean of the night readings is only 22°. Very little snow has fallen in any part of the British Islands, but the ground is still covered with snow from the fall during the earlier part of the frost. The type of weather has undergone a very considerable change, and the last few days have been much less cold, although frost occurs each night. The European anticyclone appears to have thoroughly given way, and in the course of two or three days the barometer has fallen to the extent of nearly an inch over Scandinavia. An anticyclone is, however, situated over the British Islands, and while this continues frost is still likely to be experienced.

AT the meeting of the Anthropological Institute on February 12, Mr. Brabrook drew attention to the work of the Ethnographic Survey Committee of the British Association, on which the Institute was represented by Mr. Francis Galton, Dr. Garson, and himself. He said the committee had been successful in obtaining a long list of places suitable for survey, and had prepared an octavo pamphlet, of twelve pages only, which gave comprehensive instructions to those who were willing to engage in it. What the committee now desired was to increase the number of observers, and he appealed to the members of the Institute for assistance in this respect. The committee were especially anxious to induce medical men to interest themselves in obtaining the necessary physical measurements in suitable places. For this purpose, they would be glad to furnish instruments, and render any other assistance that might be necessary and practicable. All their experience had shown them how valuable the results of their work would be likely to be, and how desirable it was that it should be proceeded with without delay.

THE magnanimous spirit which the Academy of Natural Sciences of Philadelphia has shown towards the circular sent out by the Royal Society, asking for co-operation and suggestions in making a subject-catalogue of scientific papers, is an indication of the unity of the interests of scientific societies. A report has been adopted by the Academy to the following effect:—(1) That a catalogue of scientific papers as proposed by the Royal Society is desirable, and that international co-operation should be engaged in its preparation. (2) That in order to secure uniformity in all parts of such a catalogue, a central bureau, as suggested by the Committee of the Royal Society, appears to be necessary, rather than that separate portions of the catalogue should be prepared by various institutions, such central bureau to be under the direction of the Royal Society, from which the proposition emanates; all publications of societies and monographs to be sent to such central bureau; the expenses to be met by returns from the sale of copies of the catalogue. (3) That such a catalogue should be classified, and should be issued at least once a year, each volume to be provided with an alphabetical index. (4) That the scope of such a classified catalogue should embrace the various yearly bibliographies of special sciences now issued. (5) That whenever translations or summaries are believed to be desirable, English should be made the basis of the catalogue.

THE fragility of human promises is proverbial. The following dialogue, which took place in the House of Commons on Monday, furnishes another illustration of this quality:—Mr. Bartley asked the Chancellor of the Exchequer whether work was resumed last autumn at South Kensington Museum, as promised by him, so as to leave everything ready for the commencement of those buildings as soon as the money was voted by the House of Commons; and what sum was to be taken in the coming year's Estimates for the completion of those buildings in accordance with the pledge of the present President of the Local Government Board in March, 1894, on behalf of the Government. The Chancellor of the Exchequer said the demands upon the Estimates under other heads had proved so heavy that it had been found necessary to restrict the expenditure on bricks and mortar to the lowest possible point, and he feared that it would not be possible to undertake any large expenditure in connection with South Kensington Museum at present. Mr. Bartley: May I ask the right hon. gentleman whether it is not the fact that last year a certain estimate was allowed to pass on the distinct pledge from the Government that this year there would be a vote for this building? The Chancellor of the Exchequer: It was intended to do so, but, as we were reminded the other night, we ought to cut our coat according to our cloth, and the hon. member must allow me to know what our cloth is.

THE anniversary meeting of the Geological Society was held at Burlington House, on Friday, February 15, when the medals and funds were awarded as follows:—The Wollaston Medal, to Sir Archibald Geikie, F.R.S.; the Murchison Medal, to Prof. G. Lindström,; the Lyell Medal, to Prof. J. F. Blake; the Bigsby Medal, to Mr. C. D. Walcott; the balance of the proceeds of the Wollaston Fund, to Mr. W. W. Watts; that of the Murchison Fund, to Mr. A. C. Seward; a moiety of the balance of the proceeds of the Lyell Fund, to Mr. P. F. Kendall; and the remaining moiety to Mr. B. Harrison. The President delivered his annual address, the subject bearing on the Palæozoic Crustacea. The following is a list of the officers and Council elected at the meeting for the ensuing year. (The names in italics represent new officers and members of Council.) President: Dr. H. Woodward, F.R.S. Vice-Presidents: Prof. A. H. Green, F.R.S., *W. H. Hudleston*, F.R.S., R. Lydekker, F.R.S., *Lieut.-General C. A. McMahon*. Secretaries: J. E. Marr, F.R.S., J. J. H. Teall, F.R.S. Foreign Secretary: J. W. Hulke, F.R.S. Treasurer: *Dr. W. T. Blanford*, F.R.S. Members of Council: H. Bauerman, Dr. W. T. Blanford, F.R.S., *Prof. W. Boyd Dawkins*, F.R.S., Sir John Evans, K.C.B., F.R.S., Prof. A. H. Green, F.R.S., Dr. J. W. Gregory, *R. S. Herries*, Dr. G. J. Hinde, T. V. Holmes, W. H. Hudleston, F.R.S., J. W. Hulke, F.R.S., Prof. J. W. Judd, F.R.S., R. Lydekker, F.R.S., Lieut.-General C. A. McMahon, J. E. Marr, F.R.S., *H. A. Miers*, *E. T. Newton*, F.R.S., F. Rutley, J. J. H. Teall, F.R.S., *W. Whitaker*, F.R.S., Rev. H. H. Winwood, Dr. H. Woodward, F.R.S., H. B. Woodward.

THE first scientific account of the Chilo-Argentine earthquake, which has reached Europe, is probably that written by M. A. F. Noguès (*Comptes rendus*, vol. cxx. 1895, pp. 167–170). The earthquake was remarkable for its intensity and long duration, the amplitude of the oscillations, and the absence of subterranean sounds. The epicentral zone is elliptical in form, its longer axis being directed nearly north and south, and passing by Rioja, San Juan, and Mendoza. The first two of these towns were severely damaged, and a large number of persons in them were killed and wounded. The boundary of the disturbed area is as yet undetermined, but it must have included a great part of the Argentine Republic and of the north of Chili. Within the epicentral area, the duration of the shock was fifty-five seconds; at Santiago Observatory, where it was registered by a seismograph, the duration was 1m. 40s., and the amplitude of the oscillations 2·5 c.m.

THE *Revue Scientifique* contains a full discussion of the causes of mountain sickness, by M. H. Kronecker, who was sent to investigate the conditions under which the proposed railway to the top of the Jungfrau could be worked without endangering human life. M. Kronecker and six other persons from Berne were carried from Zermatt to a point near the summit of the Breithorn, 3750 m. above sea-level. It was proposed to reach the summit itself, but it was impossible to proceed without additional carriers, the work being much more laborious at high altitudes. But at the altitude reached, all the symptoms of mountain sickness had shown themselves—acceleration of the pulse and of respiration, desire for rest, even after a very slight effort, and headache. M. Kronecker arrived at some interesting conclusions regarding mountain sickness. It sets in at altitudes varying with different persons. Beyond 3000 metres it attacks all persons as soon as they indulge in the least muscular effort, but children and very old people are much less subject to it than others. It also varies with the character of the mountains, being usually less serious on isolated peaks. Persons in good health can stand passive transport to about 4000 m. without inconvenience, but they should not remain more than two or three hours at the top. A prolonged sojourn may be disastrous in its effects upon health, as it proved to be in the case of Dr. Jacottet. For the purposes of the railway, M. Kronecker recommends that all guards and other officials should be carefully selected and, if possible, acclimatised or frequently changed between the stations. Finally, the summit station should be arranged so that no further ascent whatever is necessary to get the full benefit of the view.

AT a recent meeting of the Société Française de Physique, M. de Kowalski read a paper on the conditions necessary for the production of kathode rays. Starting from an experiment due to Goldstein, in which in a vacuum tube having a constriction at its middle, it is found that the kathode rays are formed not only at the negative electrode, but also at the constriction, the author has made several experiments, using tubes of different shapes. He finds that wherever the electric discharge is sufficiently dense, as near the electrodes or in a capillary tube joining the two parts of a vacuum tube, kathode rays are produced. These rays are propagated in straight lines, are deviated by a magnet, and produce a bright patch where they strike the glass. The author has also succeeded in obtaining kathode rays in a tube without electrodes. This tube had somewhat the shape of an elongated hour glass, and was placed alongside a discharger, through which "Tesla currents" were passed. Under these circumstances kathode rays are produced at either end of the capillary tube forming the central part of the vacuum tube. M. de Kowalski concludes from his experiments (1): that the production of kathode rays is not connected with the disintegration of metallic electrodes in a rarefied gas; (2) that these rays are produced wherever the density of the discharge is sufficiently great; (3) that the direction of the rays is the same as that of the lines of flow of the current at the point where they are produced, and that they are propagated in the opposite direction to that in which positive electricity is supposed to flow.

AT the same meeting at which the above paper was read, M. Curie described some experiments he had made to see whether light rays were deviated by a magnetic field in the same manner as kathode rays. He has obtained no deviation, although his apparatus permitted him to pass the light rays for a distance of 20 cm. in a field having an intensity of 14,000 units, the direction of propagation of the light being perpendicular to the lines of force of the magnetic field. The experiment was made in air, as well as in carbon bisulphide in which sulphur had been dissolved. The author, although he does not think the above experiments are conclusive proof that kathode rays are radiation of a different nature from that which constitutes light, yet thinks they tend to show that there is some difference. Furthermore, if the kathode rays are analogous to light rays, it is difficult to explain the absence of double refraction when a magnetic field acts on the kathode rays.

THE triple number, pp. 10–12, of the *Bulletin* of the Botanical Department, Jamaica, is entirely occupied by a list of the more interesting trees and shrubs, 109 in number, grown in the Botanic Garden at Castleton, near Kingston.

IN the most recent part of the *Records of the Botanical Survey of India*, the Indian Government publishes a report of a Botanical tour in Kashmir, by Mr. J. F. Duthie, director of the Botanical Department of Northern India, accompanied by a map.

THE *Bulletin* of the Royal Gardens, Kew, No. 96, for December, 1894, contains an interesting article on "Cultural Industries in Dominica," an island which, since the abandonment of the coffee plantations, which were at one time its staple industry, is very far from yielding the economical products which might be expected from its climate and the fertility of its soil. A brief account is given of the four Botanic Stations in the Leeward Islands, those of Antigua, St. Kitts, Dominica, and Montserrat.

THE 1895 *Annuaire* of the Royal Observatory at Brussels, edited by M. F. Folie, has been received. The *Annuaire* is is second only to that published by the French Bureau des Longitudes. It comprises ephemerides containing the principal astronomical data for the current year; geographical, meteorological, and other statistics; physical constants; and several articles, among them being three by M. Folie, on diurnal and annual aberration.

THE Smithsonian Report for 1893 has recently been issued. The report comprises a selection of miscellaneous memoirs embracing a considerable range of scientific investigation and discussion. This collection of reprints and translations, running into very nearly seven hundred pages, contains articles of interest to workers in all branches of science. Among the contributions to the Report is a monograph on "North American Bows, Arrows, and Quivers," by Dr. O. T. Mason. The paper, which is illustrated by fifty-seven plates, deals with the types of bows, arrows, and quivers of the North American aborigines, with incidental references to similar forms found elsewhere.

MESSRS. J. AND A. CHURCHILL have nearly ready the second volume of "Chemical Technology," edited by Mr. C. E. Groves, F.R.S., and Mr. William Thorp. This volume is devoted to lighting by candles and oils, and is illustrated by about 350 figures; the section on fats and oils being written by Mr. William Y. Dent; stearine, by Mr. John McArthur; candle manufacture, by Messrs. L. Field and M. A. Field; the petroleum industry, by Mr. Boverton Redwood; lamps, by Mr. Boverton Redwood; and miners' safety lamps, by Messrs. Boverton Redwood and D. A. Louis. The third volume of the same work, containing gas lighting, by Mr. Charles Hunt, of Birmingham, and electric lighting, by Prof. Garnett, of the Technical Board of the London County Council, is in a very forward state.

MESSRS. MACMILLAN AND CO. will publish early in March the treatise on "Bessel Functions and their Applications to Physics," by Profs. Gray and Mathews, which has already been announced. The work, after an introductory chapter on the problems which gave rise to the functions, deals with their properties, expansions involving them, semi-convergent expansions, Fourier-Bessel expansions, complex theory, definite integrals, and the relation of the functions to spherical harmonics. The physical applications embrace flow of heat and electricity, vibrations of membranes, hydrodynamics, electrical waves along wires, diffraction, and a number of miscellaneous problems. Numerical tables are appended, and also the Tables of Functions with imaginary argument, which have been prepared by Prof. A. Lodge for the British Association. A note containing useful formulæ for the calculation of the roots of Bessel Functions and others related to them, has been added from a manuscript placed at the disposal of the authors by Prof. J. McMahon.

WE have received Parts iv. and v. of *Indian Meteorological Memoirs* (vol. v.), containing the discussion of hourly observations made at Allahabad and Lucknow, forming a portion of the harmonic analysis of the observations recorded at twenty-five observatories in India, since the year 1873. The investigation is carried out in a most thorough manner, and there can be no doubt that when the work is complete, and the results correlated, much light will be thrown upon the laws which regulate atmospheric movements in those parts. In any case, the discussion will take rank amongst the most important of the kind hitherto undertaken by any country.

A COMPOUND of grape sugar with one of the acid radicle derivatives of hydrazine recently prepared by Herr Struve, a pupil of Prof. Curtius, is described by Dr. Wolff, of Berlin, in the current *Berichte* of the German Chemical Society, and, on account of its properties and mode of formation, appears likely to be of considerable service in the commercial extraction of pure dextrose from syrupy mixtures. It is first shown that the sugars of the aldose type react with the acidylhydrazides to produce an aldose-acidylhydrazide by direct addition with elimination of a molecule of water. Thus, in the case of dextrose and benzhydrazide the following equation represents the change :

$$C_6H_5.C:O.NH.NH_2 + O:C_6H_{12}O_5 = C_6H_5.C.O.NH.N.C_6H_{12}O_5 + H_2O.$$

When dextrose and benzhydrazide are digested with 96 per cent. alcohol for five or six hours in a flask provided with an upright condenser, the new compound is produced in solution in the alcohol, and upon subsequent evaporation it separates in the form of acicular crystals, which can readily be purified by recrystallisation from alcohol. The crystals melt at 171–172° with partial decomposition. As lævulose does not react with benzhydrazide, pure dextrose can readily be isolated from the mixture of lævulose and dextrose in ordinary invert sugar by utilising the above reaction. The invert sugar is evaporated to a thick syrup, and the latter digested with alcohol and benzhydrazide for about six hours in a reflux still. The alcoholic solution is then evaporated over a steam-bath almost to dryness, the lævulose is extracted by washing with a minimum of alcohol, and excess of benzhydrazide removed by means of ether. Pure dextrose-benzhydrazide is then obtained in good crystals by two recrystallisations from alcohol. The recovery of dextrose from this compound with benzhydrazide is a very simple matter, for the compound is immediately broken up by boiling water into dextrose and benzhydrazide. It is found convenient in practice, however, to remove one of the products of the dissociation, the benzhydrazide, by precipitation as the insoluble benzal-benzhydrazide by means of benzaldehyde, which is found to be a most valuable reagent for the purpose. After filtration the liquid is evaporated to dryness, dissolved in cold water, whereby any traces of unprecipitated benzal-benzhydrazide are left behind, and again evaporated to dryness. The last traces of impurities, chiefly benzaldehyde and benzoic acid, are finally removed by dissolving the dextrose in alcohol and precipitating with ether. The dextrose eventually obtained by evaporation of the clear solution is quite pure. Dr. Wolff lastly states that the above is a general process for separating aldoses from mixtures of sugars, and he is experimenting with a view to its adoption on the large scale.

THE additions to the Zoological Society's Gardens during the past week include a Snowy Owl (*Nyctea scandiaca*) from Norway, presented by Miss Wright; a Dunlin (*Tringa alpina*), British, purchased.

OUR ASTRONOMICAL COLUMN.

MARS IN 1894.—Signor G. Schiaparelli remarks, in No. 3271 of the *Astronomische Nachrichten*, that the unfavourable state of the atmosphere during the opposition of Mars last year rendered magnifications beyond 200 impossible except in rare instances. Speaking generally, he says that the "seas" were less pronounced than in 1877, and the "canals" were better visible in 1894, and seen in greater numbers. Some of the largest ones showed faint traces of doubling, but, with the magnifying powers used, nothing could be made out with certainty on this point. The southern pole cap became invisible in the 18-inch Milan refractor at the end of October. On October 8 it had already become very faint. The total disappearance cannot have been later than October 29, *i.e.* on the 59th day after the southern solstice of the planet. This is unusually early. In 1877–78 it was well seen as late as 98 days after the solstice. In the present case it is pretty certain that the whole of the southern pole cap was melted. A great change was also observed in the isthmus or peninsula of Hesperia, which separates the Mare Tyrrhenum from the Mare Cimmerium. It was apparently separated into two unequal portions by a newly formed channel. The Mare Sirenum, which in October, 1892, had been separated into two parts, was in October, 1894, seen to have resumed its ordinary aspect. But on November 21 the separation had reappeared. "This fact," says Schiaparelli, "and other analogous ones which I have observed in previous oppositions, lead to the conclusion that the abnormal changes in the markings of Mars do not take place by chance and without regularity, but that the same variation may reappear, with the same aspect, even after a long interval of time. The form and extent of such changes is determined by some element which is stable, or at least periodic."

NOVEL METHODS IN PHOTOMETRY.—The determination of the times of exposure of a photographic plate which are required to produce the same density of film when exposed to different light sources, forms the basis of the methods recently adopted by Dr. Janssen for investigating the brightnesses of the heavenly bodies (*Bull. Mens. Soc. Ast. de France*, February). In the case of stars, the plate is placed a little within the principal focus of a telescope, so that a disc, or "stellar circle," replaces the almost point-like image ordinarily obtained; a series of exposures is made on one star, and another series on the star to be compared with it; the two images of the same density are thus identified, and the photographic brightnesses of the two stars are inversely as the durations of the corresponding exposures. To compare the light of a star with the sun, an opaque screen, pierced with holes of the same size as the stellar circles, is placed in front of the photographic plate, and these holes admit sunlight to the plate at the moment a triangular aperture in another metal plate is passed over them on releasing a spring; in this way a series of circles of increasing intensity is impressed on the plate, and can be compared directly with the stellar circles.

In its application to nebulæ, Dr. Janssen's method promises to be of great value. On the same plate which has been exposed to a nebula, a series of "stellar circles" is formed by directing the instrument to a star in the neighbourhood which shows no signs of variability. In the future, when one wishes to obtain a photograph of the nebula which will be strictly comparable to one taken previously, it will only be necessary by means of stellar circles to determine the exact exposure which should be given.

From an inquiry into the photographic luminosity of the tail of comet *b* 1831, Dr. Janssen finds that the intensity decreased in a ratio between the fourth and sixth power of the distance from the nucleus.

ATMOSPHERIC DISPERSION.—The fact that the image of a star as seen in a telescope is drawn out into a short vertical spectrum, with the red end uppermost, was noticed as long ago as 1729 by Bouguer, and the effect of the difference in colours of stars upon refraction appears to have been indicated in a general way by Lee in 1815. Even in small instruments this atmospheric spectrum is very noticeable in the case of bright stars at low altitudes, but, if necessary, it can be corrected by means of a thin prism placed in front of the eyepiece, or by employing an eyepiece of the form devised by the late Sir George Airy. In a recent paper (*Monthly Notices R.A.S.*, January), Dr. Rambaut points out the importance, in these days of extreme accuracy, of introducing a correction for atmospheric dispersion—according to the varying colours of stars—more especially in connection with observations of two stars in close proximity, as in measures of double stars, and observations for parallax. The claims of this hitherto rather neglected factor appear to be fully substantiated by a series of measures at different hour angles of β Cygni, in which double star the colours of the components are strongly contrasted; they "show clearly a systematic difference affecting the distance between them, of the sort, and in the direction, that theoretical considerations indicate." Dr. Rambaut also shows that the systematic differences depending upon hour angle in the measures for the parallax of α Centauri by Drs. Gill and Elkin, which they corrected by empirical formulæ, are due to a difference in the mean refrangibility of the light of the star and of the comparison stars. Further confirmation is derived from a re-discussion of the Dunsink observations on the parallax of 61 Cygni, and the resulting value is corrected from 0″·465 to 0″·400.

An ingenious method of measuring atmospheric dispersion has been devised by M. Prosper Henry, and values determined for different colours (NATURE, vol. xliii. p. 400).

THE SUN'S PLACE IN NATURE.[1]

I.

I AM anxious to give in these lectures a statement, as clearly and as judicially as I can, of the discussions which have been going on since these results were published, to show what holes have been picked in the new views, and what new truths may be gathered from the new work which has now been brought to bear upon the old, so that as a result the place I have given to the sun among its fellow stars may be justified or withdrawn. These lectures will be different from the former ones, inasmuch as I then attempted to give you a piece of quiet history of several regions of fact and knowledge which had been well surveyed and mapped, and had become part and parcel of the common property of mankind. But now I shall have, in considering the discussion, rather to take you with me into the forefront of those who are fighting the battles on the confines of the unknown. I have to bring you news from the front, something like that which we are promised to-morrow or the next day from Port Arthur. I have to show how the battle is waging, who has lost, what positions have been occupied, and what things new and true and beautiful have been wrested from the unknown region; and I am the more anxious to do that because it enables me to bring before you the enormous advantages under which such work is now carried on; advantages in that now, when any question is put to any part of the heavens, we know that there are many good workers employed under the best possible conditions to get the particular information that we want; besides these advantages, in every branch of inquiry we find advances gigantic, marvellous, almost beyond belief.

I am sorry to say that in this work the centre of gravity of the activity has left our country and has gone out West. We have to look to our American cousins for a great deal that we want to know in these matters, for the reason that now they not only have the biggest telescopes, and most skilled observers, but also they have been wiser than we—they have occupied high points on the earth's surface, and thus got rid of the atmospheric difficulties under which we suffer in England, and especially in London.

[1] Revised from shorthand notes of a course of lectures to working men at the Museum of Practical Geology during November and December, 1894. (Continued from page 377.)

Let me bring before you one of the most perfect pieces of workmanship in the world constructed to investigate the phenomena of the heavens. It is a photograph of the Lick Observatory, situated at an elevation of 4000 feet on Mount Hamilton. Mr. Lick, the founder, was a very ambitious man. He was, I believe, an hotel-keeper at San Francisco, but however that may be, he has made his name immortal by helping on the progress of mankind. I wish we had some hotels like the San Francisco hotel in this country, and some Mr. Licks, because then some Englishman might immortalise himself in the same way. This, then, is the magnificent locality in which a great deal of the work that I shall have to refer to has been done. The principal instrument of this great Observatory is a refracting telescope having an object-glass three feet in diameter, and a tube fifty-four feet in length. This is practically the most important telescope in the world at the present moment, and to give you an idea of the wonderfully

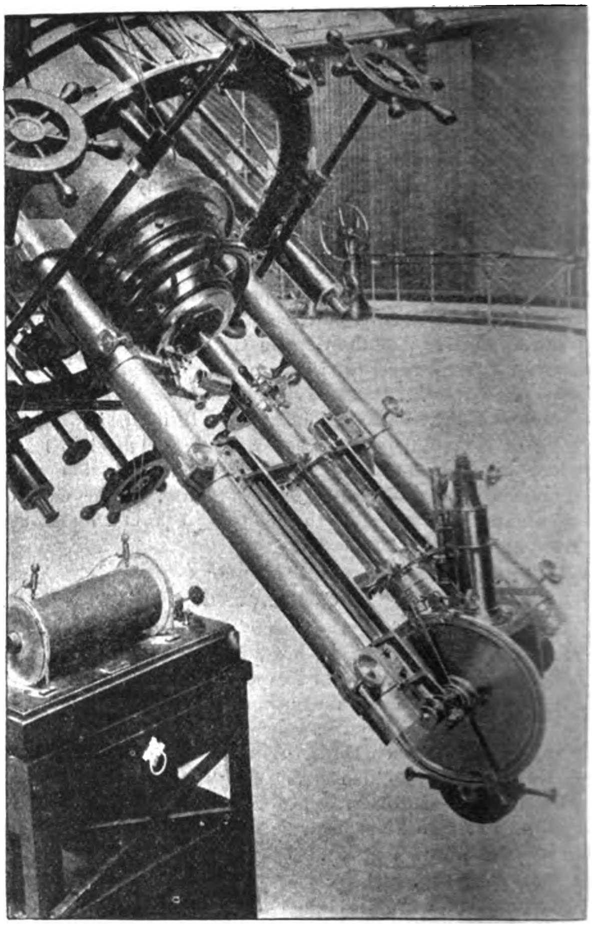


FIG. 4.—Spectroscope attached to the eye-end of the Lick Telescope

broad way in which the authorities have gone to work, I need only state the following fact. Some of you who have been in an observatory may remember that it has sometimes been very difficult to get the observatory chair at the right height, or in the right position, for observing a star or any celestial body with any comfort. The Americans get over this by simply raising the floor. By means of hydraulics the enormous floor, some 80 feet in diameter, is moved up and down with the chair. The importance of spectroscopic work has not been lost sight of in the equipment of the Observatory, and a very powerful spectroscope can be used in conjunction with the great equatorial for observing or photographing the spectra of the various celestial bodies (Fig. 4).

One of the most important telescopes in England at present is Dr. Roberts' reflector, with which several majestic representations of the heavenly bodies have been produced; these I shall have to show you at one time or another in relation to different branches of our subject. In this instrument (Fig. 5) a reflecting telescope of 20 inches aperture is combined with a refractor of 7 inches aperture. The refractor is used as a guiding telescope, and ensures that the images of the stars and nebulæ fall on the same part of the photographic plate which is being exposed in the reflecting telescope throughout the whole

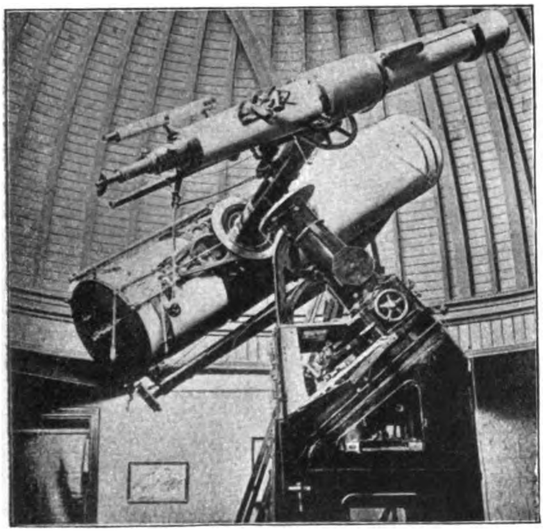

FIG. 5.—Dr. Roberts' twin telescope.

time of the exposure. Even with the best driving clocks, such a guiding telescope cannot be dispensed with when the exposures are prolonged for the number of hours necessary in some cases.

First for the nebulæ. What is the difference, written down in this way, between a nebula and a star cluster? A comparison of Figs. 6 and 7 will at once show that in the case of a star cluster we have to deal with a collection of separate stars, while in the case of a nebula there is a filmy sort of

FIG. 6.—The Cluster 15 M Libræ, from a photograph by Dr. Roberts.

luminosity which is quite distinct from the neighbouring stars. Here and there the nebulosity is suddenly brightened, but, as I shall show hereafter, these condensations are not to be regarded as stars in the ordinary sense. Here is the nebula of Orion, which we owe to that wonderful telescope of Dr. Roberts. Several of you may have seen the nebula of Orion with a telescope, but you have never seen it exactly like this. You get here the idea which gave rise to the old notion of a candle shining through horn; this nebula is the one which, on account of its brightness, spectroscopically gives us most easily indications of those bright lines which for ever set at rest the idea that we are dealing with solid or liquid bodies.

At the beginning of the present century it was found that in

FIG. 7.—The spiral nebula in Canes Venatici, from a photograph by Dr. Roberts.

order to get the spectra of stars the best thing to do was to put a prism outside the telescope, and to let the light enter the telescope and be brought to a focus after it had passed through the prism; and it is a most unfortunate thing, that the

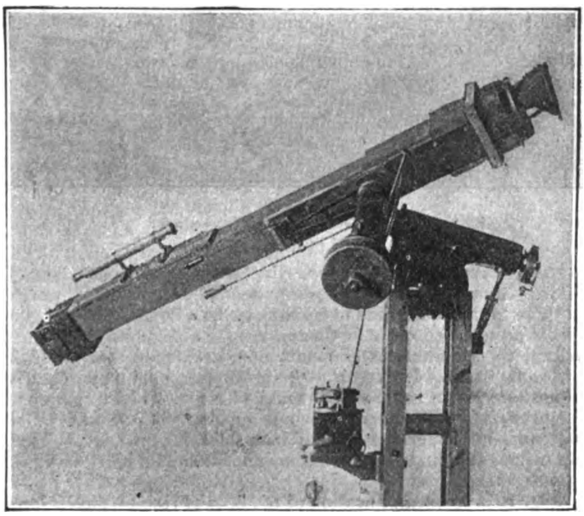

FIG. 8.—Showing method of photographing stellar spectra by the objective prism.

neglect of the application of this principle has landed us probably in a delay of fifteen or twenty years in gathering knowledge on this subject. The whole credit of reviving this idea is due to Prof. Pickering, of the Harvard College, who since its application has been able, with the aid of the large funds that he has at his disposal, and the magnificent help which he has accumulated round him, to obtain practically the spectra of all the stars down to the fifth or sixth magnitude in both hemispheres. In a few years' time we shall be able to work on the spectra of all the stars in both hemispheres, just as well as we can at present deal with their magnitudes and positions by the star charts.

An instrument of this kind (Figs. 8 and 9), having an aperture of only 6 inches, has been in use at Kensington for some time, and some of the results which have been obtained by its aid are shown in Figs. 3, 10, and 11. They are absolutely untouched photographs.

Without going into minute differences, we can, and, if we are wise, we shall deal first of all with the larger differences presented by the various classes of stars which people space. Here we have photographs of stars of different classes (Fig. 3). You will understand from these photographs how perfectly justified Rutherfurd and others have been in attempting to classify the

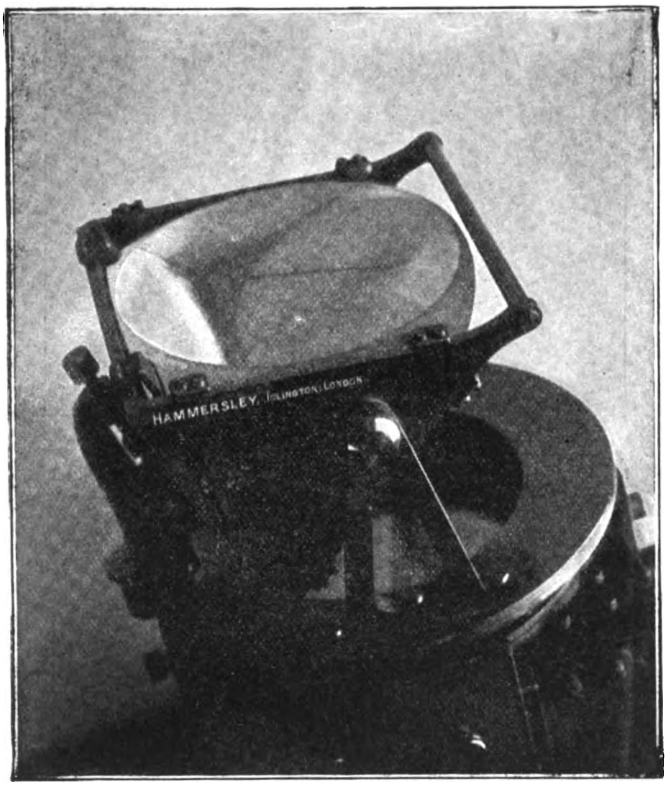

FIG. 9.—Details of objective prism.

stars by means of their spectra. In Sirius we get one class of stars, distinguished by the development of certain lines, which are due to the absorption of hydrogen. In α Cygni the hydrogen gas is represented quite distinctly, but the absorption there with regard to certain lines is much more developed than in such a star as Sirius. In Arcturus the absorption of the hydrogen is almost hidden in an enormous mass of lines. Here again we have another class, and it is not too early to remark that Arcturus in its spectrum exactly resembles our own sun. Thus we can say the sun is like Arcturus, not like α Herculis, α Cygni, and so on.

Fig. 10 is an exemplification of the kind of result which is now being obtained, and the kind of work which can now be carried on with regard to the minute structure of these spectra. One is the star Arcturus, and the other a star in the constellation of the Swan. You see at once that, if it is a question of attempting to determine whether stars are like each other, or whether they are unlike each other, and the points in which they differ, with the resources of modern science at the present moment—small

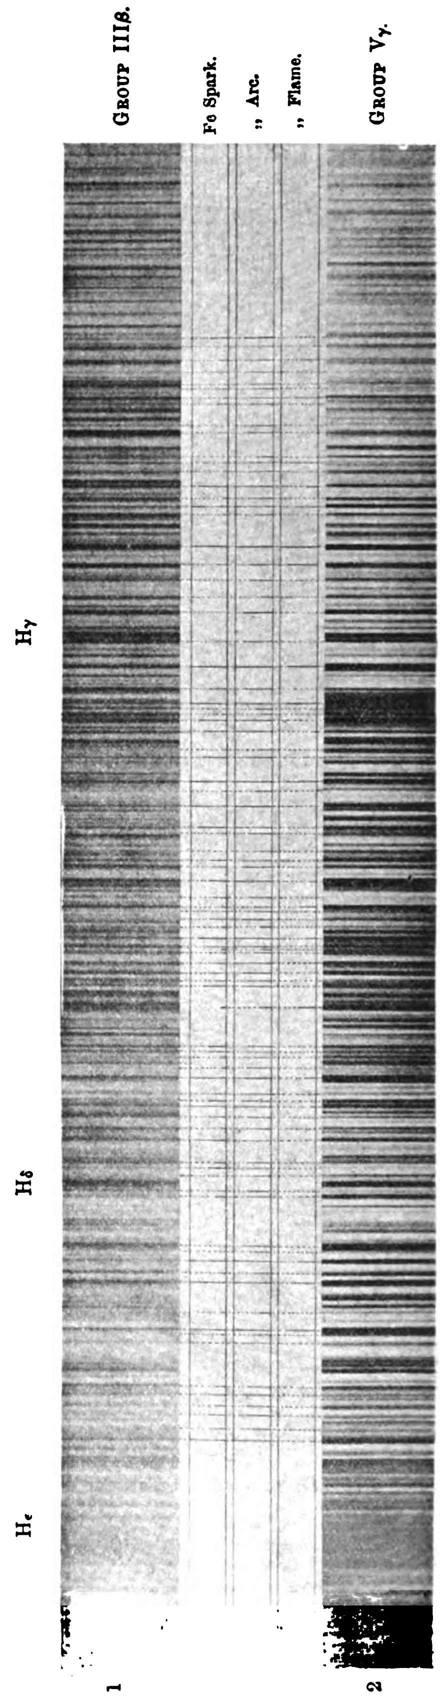

FIG. 10.—Spectrum of γ Cygni (1) compared with that of Arcturus (2). From photographs taken at Kensington.

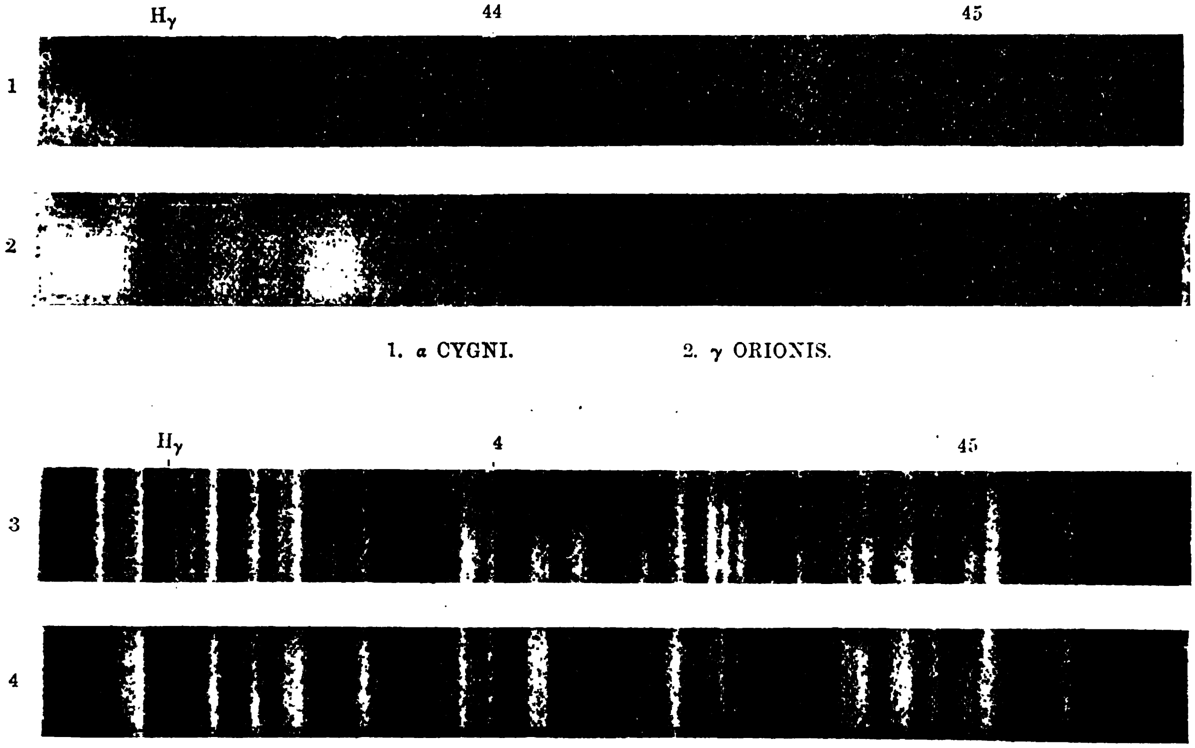
as those resources are in some instances—we have really an opportunity of doing a considerable amount of work. The particular bit of work which is represented in this diagram is an inquiry showing how the iron lines observed in the spectra are represented in these different stars; we can see whether the condition of the iron vapour is the same in a star like Arcturus as it is in a star like γ Cygni. You will see that from this point of view there is a great difference in the atmospheres of these two stars.

The definition of the negatives obtained by means of the objective prism is of such excellence that they may be almost indefinitely enlarged, and this gives them a special value when we come to investigate the smaller differences between stars which have more or less resemblance to each other. Practically, we are able to dispense with elaborate micrometric measurements, and by placing the enlargements alongside each other, to see at a glance which lines agree in position and which are different.



1. α CYGNI. 2. γ ORIONIS.

3. α TAURI. 4. α ORIONIS.

FIG. 11.—Portions of stellar spectra, greatly enlarged.

The spectra represented in Fig. 11 have been enlarged twelve times from the original negatives, and on this scale the whole of the visible spectrum would be more than a yard in length. Here we observe, in the first place, the immense difference between two groups of stars, one in which the lines are very numerous, the other in which the number of lines is relatively small. We also have an opportunity of studying the more minute differences between stars like α Tauri and those like α Orionis, and between stars like α Cygni and those like γ Orionis. In some cases, differences which might easily be overlooked altogether in an examination of the negatives alone, become apparent when the scale is enlarged in this way.

Thus, by means of the aids which have been placed at our disposal, by the recent improved condition of our stock in trade, and the wonderful diligence and skill of observers, chiefly in America, who have taken up the new work, we are now in a very much better position than we have ever been before to investigate this subject. J. NORMAN LOCKYER.

(*To be continued.*)

NATHANAEL PRINGSHEIM.

BOTANISTS throughout the world will have heard, with deep regret, of the death of Prof. Pringsheim on October 6, of last year. His name is inseparably associated with the modern progress of the science, and there must be many, who, like the writer of this notice, can trace their first interest in scientific botany, in no small degree, to the fascination of Pringsheim's discoveries. Pringsheim was born in Silesia, in 1823. His career, though an active one, was unusually free from official cares. Except during four years, when he was Professor at Jena, he does not appear to have held any teaching post of importance. During the greater part of his scientific life, his work was carried on in a private laboratory, founded by himself at Berlin, and devoted entirely to the researches of original workers.

Pringsheim was founder and editor, from 1858 to the time of his death, of the famous *Jahrbücher für Wissenschaftliche Botanik*, and was President of the German Botanical Society from its first origin. He was among the many distinguished foreign men of science who attended the meeting of the British Association at Manchester, in 1887.

The scientific activity of Pringsheim extended over a period of fully forty years (1848–1888), a time which covers what was perhaps the most brilliant epoch in the history of botany. His work began in the days when the science of histology was being built up on the basis of the cell-theory of Schleiden and Schwann; he himself contributed essentially to its construction. Pringsheim's greatest services to science, however, were in the department of the morphology and life-history of the lower plants, a line of research in which he was unsurpassed. Comparatively late in life his attention became directed to physiology, but in this direction his success was less conspicuous.

Pringsheim's earliest contribution to science was his Latin dissertation, "De formâ et incremento stratorum crassiorum in plantarum cellulâ" (Linnæa, 1848), in which he discusses a question much agitated at that time, whether the increase in thickness of the cell-wall takes place from without or from within. He decides, chiefly from observations on the cells of the testa in seeds, in favour of apposition from the interior, a conclusion which no doubt holds good for the great majority of cases, though the researches of Strasburger have shown that this is not a universal rule.

Not long afterwards, Pringsheim made his first investigation of a question which continued to occupy him, at intervals, for more than thirty years, namely, the development of the Saprolegniaceæ, a family which lies on the confines of the Algæ and the Fungi. At that time the delimitation of genera and species among these plants had fallen into great confusion. Pringsheim's memoir of 1851 bears the title, "On the development of *Achlya prolifera*," but its subject was really a *Saprolegnia*. The zoospores of this family had long been known, and their resting-spores had already been observed by Schleiden and Nägeli. Pringsheim, however, was the first to prove that the two kinds of spore are produced by the same species; he watched the germination of the resting-spores, and saw that they gave rise to the ordinary form of the plant, with its zoospores. At that time he regarded it as an open question whether these plants are to be classified as Algæ or Fungi; they are now assigned to the latter class, but placed near its lower limit, where there has not been much divergence from the original algal stock.

Six years later, Pringsheim discovered the sexual reproduction of the Saprolegniaceæ, an observation of the greatest importance, though his account was not free from mistakes, most of which he corrected himself in subsequent memoirs. It is a remarkable fact that in certain species of the family some individuals are entirely without male organs, and produce their oöspores parthenogenetically. In others the antheridia are present, but there is no penetration of the oögonium. The question whether actual fertilisation takes place in *any* Saprolegniaceæ was the subject of a keen controversy between Pringsheim and De Bary; the latter, for reasons which we have not space to enter into, held that the family, as a whole, is *apogamous*, *i.e.* that the sexual organs, even when present, have lost their function. Pringsheim, on the other hand, maintained that in the forms with fully developed antheridia true fertilisation takes place by means of "spermamœbæ." The question was under discussion up to the year 1883, and cannot even now be regarded as finally settled. Pringsheim's observations of the supposed amœboid male cells are not very convincing, but neither is the negative evidence against the occurrence of fertilisation in the family decisive. The higher Fungi are characterised, as most botanists now agree, by a total loss of sexuality; in the Saprolegniaceæ we can, at any rate, trace the beginnings of this retrogressive change.

It was, however, among the Algæ themselves that Pringsheim's chief triumphs were won. His earliest purely Algological paper was on the germination of the resting-spores of *Spirogyra*, in which he first demonstrated the interesting fact that the embryonic plant presents a distinction of apex and base, which is quite lost in the later stages of its growth. The supposed motile spores of *Spirogyra* (described in the same paper, 1852) really belonged to a Chytridiaceous parasite. These inconvenient intruders had already misled Pringsheim in some of his earlier observations on Saprolegniaceæ. In the same year, he made out the reproduction in an interesting little Alga (*Cœlastrum*) allied to the "Water-net."

Pringsheim's really fundamental investigations of the Algæ begin, however, with the year 1855, when he communicated to the Berlin Academy a memoir on the fertilisation and germination of the Algæ, and on the nature of sexuality. The chief point of this paper is the demonstration of the sexual reproduction of *Vaucheria*. Vaucher himself had discovered the "anthers" at the beginning of the century; it was reserved for Pringsheim to find the spermatozoids, and to observe the act of fertilisation. The proof of such an advanced mode of reproduction in an unicellular (or rather non-cellular) plant, was a startling discovery, and provoked some opposition among those who had not the skill to repeat Pringsheim's observations. This paper further contains researches on the fertilisation of *Fucus*, and on the sexual organs of Florideæ (which of course was only fully understood at a later time), and preliminary observations on the remarkable life-history of *Œdogonium* and *Bulbochæte*.

These latter discoveries were more fully announced in the next year (1856), and two years later the whole history was told in a magnificent memoir, published in the first number of the *Jahrbücher für Wissenschaftliche Botanik*. This work is a model for all such investigations, and has left very little for subsequent observers to do, as regards these plants, which in some respects present unique peculiarities. The Œdogoniaceæ possess (in addition to the asexual zoospores) highly differentiated ova and spermatozoids. Many species are monœcious, and a few diœcious; most, however, present a remarkable form of dimorphism. Certain cells produce ova; others (usually in the same plant) give rise to small zoospores, which become free, attach themselves to the oögonia, or to adjacent cells, and there germinate into dwarf male plants. Each of these dwarfs consists of a single vegetative cell and an antheridium, in which two or more spermatozoids are produced, by which fertilisation is effected.

Another interesting point discovered by Pringsheim, is the germination of the sexually produced resting-spores, which do not grow directly into new plants, but give rise, each, to four zoospores; we thus have a case here, either of polyembryony, or of alternation of generation, according to our interpretation of the phenomena.

Two years later (in 1860), Pringsheim published an equally important memoir on another group of freshwater Algæ—the Coleochæteæ. These curious little plants, which grow on the larger water-weeds, go through one cycle of development in each year. During the earlier part of the season, only asexual individuals, reproduced by zoospores, are formed. At the close of summer the last generation produces sexual organs also. After fertilisation (which is effected by spermatozoids) the oöspore passes into its winter rest, and then germinates in the spring, giving rise, not to a normal plant, but to a parenchymatous, fruit-like body, in each cell of which a zoospore is formed. There is thus an evident analogy with the life history of the Mosses, which Pringsheim at once recognised. Of all Thallophytes, the Coleochæteæ show the nearest approach to that form of alternation of generations which is so general among the Bryophyta. Whether this is anything more than an analogy, is still an open question.

A controversial Algological paper of the same date (1860) is of interest, because the author opposes the view (held at one time by Thuret) that only a *dynamical* reaction takes place between spermatozoid and ovum. Pringsheim showed that the two sexual cells undergo an actual material fusion, a fact which lies at the root of all sound views as to the nature of the sexual process.

A year later, Pringsheim added to our knowledge of the remarkable course of development of the "Water-net" (*Hydrodictyon*), by tracing the history of those minute zoospores which become free from the parent-plant, and give rise to resting-spores. In this case, however, he overlooked the occurrence of conjugation, which, according to a subsequent observer, takes place between these small motile cells.

In 1862, Pringsheim turned his attention to marine Algæ, and published some observations on the Red Seaweeds, in which he rightly described the structure of the sexual organs. Their function, however, was only demonstrated, five years later, by Thuret and Bornet.

To the year 1863 belongs an important memoir on the Characeæ, a group of plants, which, though so popular as text-book types, is still a mystery as regards its relationships. Pringsheim's observations were chiefly in the proembryo and allied structures. He established the existence of a striking correspondence between these organs and the protonema of the Mosses.

After an interval of six years, he returned, in 1869, to the investigation of the Algæ, and made known perhaps the most important of all his Algological discoveries, that of the conjugation of zoospores, a process which he regarded as the primitive form of sexual reproduction in plants. This striking discovery was first made in *Pandorina*, one of the Volvocineæ, a family which is often claimed by the zoologists, but which, in its reproductive phenomena, betrays the closest affinity to undoubted plants. The motile cells, which conjugate in pairs, sometimes differ considerably in size, while in other cases they are almost exactly similar. The product of their union is a resting-spore, which on germination ultimately, though not directly, gives rise to a new colony. Pringsheim observed the details of the fusion of the sexual cells, and found that they first become united by their anterior ciliated ends, which consist of clear protoplasm. He compared this part of the conjugating cell to the "receptive spot" of the ovum in the higher Algæ, to the canal-cells of archegoniate plants, and to the synergidæ of Angiosperms.

The conjugation of motile cells has since been observed in many other families of Algæ, of the most diverse affinities, and in several of these families we can now trace the advance from this primitive fusion of like cells, to the union of a differentiated ovum and spermatozoid. Pringsheim's discovery has thus proved to have all the far-reaching significance which his scientific insight attributed to it, from the first. It has now become customary to speak of active conjugating cells as "planogametæ," a word which is useful, as indicating their sexual function, but which must not be allowed to disguise their complete homology with the asexual zoospores.

In 1871, he discovered the male plants, and the presumable sexual cells of *Bryopsis*, a marine Alga, allied to *Vaucheria*; the process of fertilisation however, has not yet been observed.

Pringsheim's latest contribution to Algology was his interesting work on the course of morphological differentiation in the Sphacelariaceæ, a group of Brown Algæ, in which the progress from filamentous to cormophytic structure can be traced through a very complete series. His views on evolution were akin to those of Nägeli (*cf.* NATURE, vol. xliv. p. 582). He saw clearly the evidence of descent, but could not admit that natural selection is a sufficient explanation. It seemed to him that the highly differentiated *Sphacelaria* has no advantages, in the struggle for existence, over the simple *Ectocarpus*. He held that the first deviations from primitive simplicity of structure, are of a "purely morphological nature," and have no demonstrable relations to any physiological functions.

Views of this kind are widely spread among German naturalists. The greater, however, our knowledge of the conditions of life in plants becomes, the less room is left for these supposed "morphological characters," which are probably, at most, nothing more than adaptive characters which became fixed a long time ago.

We have endeavoured to give a connected account of Pringsheim's Algological work. During the same period, however, he had also made important contributions to science, in other directions; one or two of these must now be noticed.

A work bearing the date 1854, on the structure and formation of the vegetable cell, belongs to the period when the doctrine of the multiplication of cells by division had just gained the victory over the erroneous theory of free-cell-formation, so pertinaciously defended by Schleiden. Pringsheim's researches afforded valuable support to the new views. He observed cell-division in both vegetative and reproductive cells of many Algæ, as well as in the pollen-mother-cells of Phanerogams. His view of the formation of the cell-wall comes wonderfully near to the conception of this process, which we have attained at the present day.

Pringsheim's work on the morphology and development of *Salvinia* (1863) is his most important contribution to our knowledge of the higher Cryptogams. He completely worked out the entire life-history of this interesting plant, and a more perfect monograph has never appeared. His observations will always form the basis of our knowledge of *Salvinia*, which is one of the most highly modified forms of Pteridophyta; they also throw great light on the embryology and development of the class as a whole.

Pringsheim, in 1876, crowned his long series of morphological investigations by a remarkable essay on the alternation of generations in the Thallophytes, and its relation to that in the Mosses. In the opinion of the writer of this article, this is, from a theoretical point of view, his most important work.

The essay was suggested by the experiments of its author on the sprouting of Moss-fruits. These experiments were undertaken by Pringsheim with the express object of determining whether the Moss-seta could be induced to subserve vegetative propagation in the same way as the Moss-stem, which it so closely resembles anatomically. He found that the seta of *Bryum* and *Hypnum*, when divided, and kept in moist air, developed a normal protonema, from which true Moss-plants arose. In other words, he succeeded in producing the sexual from the asexual generation, without the intervention of spores, thus establishing the first case of *apospory*, our knowledge of which has since been so much extended. In the meantime the converse phenomenon of *apogamy* had been demonstrated by De Bary and Farlow, who showed that the asexual generation, in certain Ferns, may arise from the sexual prothallus, without the intervention of the sexual organs. These facts really formed the groundwork of Pringsheim's theory of alternation.

His leading idea is that the successive generations among the Thallophytes are to be sought in the free sexual and asexual forms of the plant, and not in the plant itself on the one hand, and its fruit on the other. To take only one example: in the case of the Florideæ, Pringsheim regarded the tetrasporic and the sexual individuals as constituting the alternate generations; the sexually produced crystocarp he interpreted, not as a distinct generation, but as a case of polyembryony. Having expanded this view, he proceeds to face the difficulty, how it is to be reconciled with the life-history of the Mosses (in the widest sense), in which the alternation is between vegetative plant and fruit.

His reply is very ingenious: in the germination of the sexually produced spore of many Thallophytes the young plant suppresses more or less completely its vegetative stage, and proceeds at once to the formation of asexual spores; this is the case, for example, in *Œdogonium*, *Sphæroplea*, *Hydrodictyon*, and more especially in the Phycomycetous Fungi, in which every transition can be traced between "sporangial" and "mycelial" germination of the sexually produced spore. Pringsheim goes on to say: "It may therefore hold good, as a general experience among Thallophytes, that the *first* neutral generation hurries by a short road to spore-formation, suppressing more or less the vegetative part of the plant." This change is most marked where germination takes place within the oögonium, as in *Coleochæte*. "Alternation of generations in the Mosses thus appears as a contracted form of that in Thallophytes; in the former the neutral generations are reduced to a single one, which remains in unbroken connection with the sexual plant. There is therefore no reason for comparing the sporogonium of a Moss with the fruits of the Thallophytes," and so on.

On this view it follows that all alternation of generations must be regarded as "homologous." Sporophyte and oöphyte, however differently modified, are homologous one with another, both having been derived from sexual and asexual individuals, which at one time presumably differed as little from each other as do the cystocarpic and tetrasporic plants in Red Seaweeds. It is therefore not surprising that in cases of apogamy and apospory, the one generation may still pass over directly into the other.

These views have been much criticised, and the case is still *sub judice*. In England the opposite theory—that the alternation in the higher Cryptogams is "antithetic," the sporophyte being an intercalated generation, not homologous with the oöphyte, is predominant, and appears to receive some support from certain minute histological differences between the two generations. Pringsheim's interpretation of the facts has, however, some advantages, perhaps the most conspicuous among which is that it would enable us to understand the existence of the immense and unbridged gulf which separates the sporophyte of the Muscineæ from that of the Vascular Cryptogams. The latter might well have been derived from ancestors, in which the "first neutral generation" had never suffered the extreme reduction which characterise it in the Moss series, but had always retained its vegetative organs. It would then no longer be necessary to endeavour to force the plant of a Fern or a Horsetail to fit into the Procrustean limits of a Moss-sporogonium.

We have endeavoured to give some idea of Pringsheim's varied activity in the field of morphology, which he cultivated with unsurpassed success. It remains to say a few words regarding his physiological investigations, though these are far from possessing the same importance.

So far as we have been able to find, Pringsheim's first entry upon the physiological domain dates from the year 1875, when he published papers on the spectrum of chlorophyll, and on the modifications of that pigment. His *début* as a physiologist thus almost exactly coincides with the climax of his brilliant career as a morphologist. It was not till 1879, however, that he became prominent in physiological questions. In that year he produced his first paper on the action of light and the function of chlorophyll. He investigated the action of light of great intensity on vegetable tissues, and observed the consequent destruction of the chlorophyll, in green tissues, and the disorganisation of the protoplasmic structures, both of which he attributed to excessive oxidation. The great conclusion at which he arrived, is that "the function of chlorophyll, by means of its powerful absorption, especially of the so-called chemical rays, is to limit the intensity of respiration, and to serve as a regulator of that process." He then proceeds further, and states that "the fact that only *green* parts of plants evolve oxygen, finds its sufficient explanation in the diminution of the amount of respiration, owing to the presence of the chlorophyll screen." Pringsheim thus regarded assimilation as a function of the protoplasm alone, with which the chlorophyll has nothing to do, except in a purely negative way, by keeping off rays which would induce the opposite process of oxidation.

In the same year, Pringsheim announced his discovery of a body which he called Hypochlorin. This he was able to demonstrate in the chlorophyll corpuscles by the aid of certain reagents, notably dilute hydrochloric acid. He regarded hypochlorin as the first and most constant product of assimilation.

Both of Pringsheim's conclusions were sharply attacked, and an extensive controversial literature soon grew up. As regards the hypochlorin, it seems certain that Pringsheim was mistaken in the importance he attributed to this body. It has been clearly shown by Arthur Mayer, and others, that hypochlorin is not a product of assimilation, but is derived from the chlorophyll itself, by the action of the reagents employed.

The other theory, that of the screen-action of chlorophyll, has not met with much favour from physiologists, and it is clear that this is, at any rate, not its only function. The investigations of Timiriazeff and Engelmann have proved that certain of the rays absorbed by the chlorophyll (principally those in the red) are just the rays most active in the decomposition of carbon dioxide. The chlorophyll, in fact, is not merely a screen, but is also a light-trap, which catches and detains those rays which are most effective in the assimilative work of the plasted. On the other hand, recent investigations as to the action of light on protoplasm have shown that many pigments (such as those of spores and pollen-grains) are useful as screens, and have rendered it probable that this may be a function (though not the most important one) of chlorophyll also. The discovery, by Winogradsky, that certain Bacteria can assimilate carbon from inorganic carbonates, without chlorophyll, and in the absence of light, is a striking confirmation of the view that the seat of assimilation is the protoplasm itself, and to this extent Pringsheim's opinion is completely justified.

It would be unfair to deny considerable credit to Pringsheim for the boldness and originality of his physiological theories, and the energy with which he supported them. Yet it must be admitted that his views on these subjects were one-sided, and not characterised by the same sober judgment which distinguishes his morphological researches. Entering, in mature life, upon an unaccustomed field of investigation, he failed to add greatly to his previons reputation; and though much of his physiological work is suggestive, it has not given us, as he intended it should, a consistent theory of assimilation.

Passing over some of the physiological papers of secondary importance, we come to Pringsheim's last work (1888), which treats of the origin of calcareous incrustations on water-plants. He explains this process by the removal of carbon dioxide from calcium bicarbonate during assimilation, causing the precipitation of the insoluble calcium carbonate. This theory is supported by the interesting observation that the incrustation only takes place in the light; but it may be doubted whether the explanation given is sufficient.

We have not attempted to record all Pringsheim's researches, but enough has perhaps been said to give some idea of his life's work.

In addition to his original investigations, Pringsheim rendered a great service to science by means of his magnificent Year-book for Scientific Botany, which shares, with the botanical portion of the French *Annales des Sciences Naturelles*, the honour of constituting the finest serial record of morphological and physiological botany. It is satisfactory to hear that, since the death of the founder, the editorship of this great publication has been undertaken by two such distinguished botanists as Profs. Strasburger and Pfeffer.

By the death of Pringsheim we have lost another of the leaders who guided scientific botany through the period of its most vigorous growth. Very few of his generation now remain; they have left worthy successors behind them, but the work of Pringsheim, in the field of morphology, will not soon be rivalled.

D. H. SCOTT.

THE ANTITOXIC SERUM TREATMENT OF DIPHTHERIA.[1]

THE subject with which we shall deal to-night, though at first sight of interest to the physician only, has been so fully discussed in the public prints, and has been so bitterly and irrationally opposed on the one hand (perhaps also unreasonably beplauded on the other), that those who take even a general interest in the public health, or who are wishful to obtain some insight into the practical and scientific aspects of a new system of treatment, may well be interested to know something of what is being so freely discussed in the columns of our daily newspapers. Beyond this, however, many take a more personal interest in a method of treatment which holds out promise of help in the cure or amelioration of the symptoms and conditions met with in diphtheria, a disease which, very justly, is looked upon as one of the most dangerous with which the physician has to deal. To begin with, I should like to make a frank confession. With that conservatism which is met with even in the most radical of natures, many, of whom I was one, felt disposed to treat antitoxic serum as belonging to the same group of substances as tuberculin, around which was constructed a theory of which the laboratory experimental basis, though apparently fair and firm, was as yet insufficient for the support of the structure of therapeutic treatment that was afterwards raised upon it. I followed the earlier experiments on this new method with great attention; I carefully analysed the principles on which the method was founded, and then with some misgivings watched the gradual development of the treatment as applied to actual cases of diphtheria. I was inclined to receive the statistics with great reserve, as I felt that this new method, like all new methods of treatment, might be making cures in the minds of the observer, and not on the bodies of the patients. Now, however, I am convinced that whatever justification my incredulity may have had from the consideration of previous experiments, none could be claimed in connection with the experiments that were carried out in the investigation of this special subject, and I am thoroughly satisfied that, although the antitoxic serum treatment may not come up to the expectations of all the rash writers on the subject—for many people seem to think that it should be a specific against diphtheria in all its stages—it promises, and this promise has in part been redeemed, to diminish the diphtheria case mortality in a very remarkable manner.

What is Diphtheria?

It is primarily an inflammation of the mucous membrane (the moist skin) of the tonsils, of the soft palate, of the upper part of the gullet, and of the upper part of the windpipe. During the course of this inflammation, which appears to be set up by the action of a special bacillus, there are usually thrown out some of the fluid elements of the blood and some of the white cells that float in the blood; these coagulate and form a soft toughish layer or film which offers an excellent food and resting place for this bacillus, which under such favourable conditions secretes or manufactures a most virulent poison. This poison is rapidly absorbed into the blood and is carried to various parts of the body; its effects are evident at first only on the nervous system, but afterwards on the muscles.

The Bacillus of Diphtheria.

First as to the bacillus. In 1875 Klebs described a short bacillus which he found on the surface of the greyish leather-like diphtheritic false membrane or film. Following up these observations, Loeffler traced a definite etiological relationship between this bacillus and diphtheria. First he obtained pure cultures of the bacillus by growing it on solidified blood serum, or on a mixture of three parts of blood serum and one part of neutralised beef bouillon containing extract of beef, 1 per cent. of peptone, 0·5 per cent. of common salt, and 1 per cent. of grape sugar. This organism may be readily detached from the surface of the false membrane by pressing firmly but gently with a little bit of cotton wadding twisted round the end of an iron wire or an ordinary penholder. When stained and examined under the microscope the diphtheria bacilli are found to be small rods from 3 to 6 μ (1 μ = $\frac{1}{25000}$th of an inch) in length, fairly plump, straight, or slightly curved, sometimes wedge-shaped or pointed, but usually somewhat enlarged and rounded at the ends, where also in stained

[1] A lecture delivered at the Royal Institution, on Friday, February 8, by Dr. G. Sims Woodhead.

specimens the protoplasm is more deeply tinted than in the centre. This organism grows singly or in groups, or felted together to form a net-work; it may occur in irregular masses of considerable size. When these bacilli have been growing for some time on an artificial nutrient medium, they appear to be segmented, the stained material accumulating in small round nodules placed at intervals within a kind of membrane which is only very delicately tinted. During the past five weeks I have examined about 600 specimens taken from the throats of diphtheria patients, and I may say that in nearly every case where the disease has been diagnosed by the physician in charge, as being one of diphtheria, these typical bacilli have been found, whilst in those cases in which there was any doubt as to the nature of the disease, similar bacilli were found in some, but not in others.

This is of importance, because we shall find that this bacillus gives us the substance with which animals are rendered immune to the attacks of the bacillus itself, these immune animals in turn supplying the antitoxic serum. To prove that this bacillus is really the cause of the disease, Loeffler, in an elaborate series of experiments, inoculated the pure cultures of the bacillus grown on artificially prepared media, into animals; he was thus able to set up characteristic lesions, especially if he took the preliminary precaution to abrade slightly the mucous membrane, thus as it were ploughing the ground before scattering the seed. On such abraded surfaces the bacilli grew very luxuriantly, and false membranes were produced; in these lesions the bacilli could afterwards be found and again separated in pure cultures, whilst the characteristic toxic symptoms of diphtheria were in each case experimented upon, repeated with the utmost fidelity. Loeffler also pointed out a most important fact in connection with the presence of the organism in the body. He found that it was strictly confined to the local wounds or lesions in the throat and posterior part of the nose, and he was also able to prove that in this position these organisms commenced to manufacture most virulent poisons, which, unlike the bacilli, can become diffused throughout the body. Klein and Sydney Martin in this country have both made very valuable contributions to our knowledge, the former concerning the bacteriology of the disease, the latter in regard to the chemical action on the tissues of the toxic or poisonous products of the bacillus.

The Toxines of Diphtheria.

Martin found that after the poison formed in the throat has made its way into the internal organs of the body it undergoes certain changes; it is broken down into somewhat less poisonous compounds, but these, accumulating at certain points, act especially on the nerves and muscles. It appears then that we have to deal with two sets of poisons: a very virulent poison formed by the bacilli directly from the fibrin and albuminoids of the fluids of the blood, exuded on the surface of the mucous membrane; and secondly, a less poisonous series which appear to accumulate especially in the spleen. So long as these poisons remain in the body we have the general fever, rise of temperature, and altered conditions of circulation (as evidenced by the pulse), so characteristic of the disease. At a later stage, sometimes after all the primary symptoms of diphtheria have passed away, there are often met with what are called post-diphtheritic paralyses, which are due apparently to alterations in the nerves going to muscles, especially those going to the delicate muscles of the soft palate and around the opening into the windpipe, though other groups of nerves and muscles may be similarly affected. These post-diphtheritic paralyses may be due then to the action either of the virulent poison (ferment) formed in the membrane, or of the somewhat less poisonous but more stable toxines that are formed in the later stages of the disease. Through the kindness of Dr. Martin I am enabled to show you figures of nerves and muscles, the degeneration of which is due to the action of these poisonous substances. It is here unnecessary to enter into any detail as to the minute changes that take place in the nerve and muscle fibres, but on comparison of the affected nerve fibres with a healthy nerve fibre, it is evident that we have here grave structural alterations which must interfere most materially with the power of the nerve to conduct nerve impressions from the spinal cord to the muscle. The outer part or sheath of the nerve is in some places entirely wanting, whilst in other cases the axis cylinder or core of the nerve is either greatly attenuated or entirely absent. The poison in these cases has set up changes by which the communicating paths between the muscles and the spinal cord and brain have become thoroughly disorganised. The muscles, too, instead of being formed of cleanly striated fibres, have this striation greatly obscured, first by a kind of cloudy or ground-glass look, and later by the appearance of a number of strongly refractile granules. These, when stained with osmic acid, become black, from which we argue that they are composed of fat, and it is said that the muscle has undergone a fatty degeneration, the muscular protoplasm being partially converted into fat; ultimately the striation may be almost lost. In a case of diphtheria, then, the following stages may be traced: a sore throat (often simple enough to begin with), by which the mucous membrane is prepared for the reception of the diphtheria bacillus. The diphtheria bacillus becomes implanted on this surface, gives rise to an acute inflammatory condition, and, subsisting on the inflammatory exudation, sets up a local manufactory of a most virulent poison. This poison, absorbed into the circulation, at once acts on the nervous system, although a certain proportion seems to be broken down into more stable, but less virulent, poison, which remains in the body, and may continue to act for a considerable time on the nerves and muscles.

Immunity against Diphtheria.

Whilst these poisons are attacking the more highly organised, and therefore less stable tissues, they are stirring up or stimulating the other tissues of the body to resist their invasion and action. If this were not the case, any one attacked by diphtheria must eventually succumb to the disease; but we know a considerable proportion of the cases of diphtheria recover even when no treatment at all is resorted to. Whatever may be the exact explanation of this recovery, we know that it depends upon the power of certain cells in the body to accommodate themselves to the presence of the toxines, and to go on doing their work of scavengering and of removing foreign substances from the body even under what originally were adverse conditions; during this process the cells become so profoundly and permanently altered that the patient is for some time protected against further attacks of the same disease. It was originally maintained that this alteration was entirely confined to the cells, but it is now generally accepted that these cells form or secrete substances which, thrown into the blood, either act directly upon the toxines so as to interfere with their activity, or so react upon the cells that they are able to continue their work in the presence of the toxine. At all events, a certain immunity against the disease is acquired. Upon these various theories is based the *rationale* of the antitoxic serum treatment of diphtheria. Ferran claims to have been the first to obtain such a condition of immunity against diphtheria in animals; shortly afterwards, Fraenkel in Germany obtained similar results. Seeing that this immunity depends upon an alteration in the composition of the serum, should it not be possible, argued Prof. Behring, to take the serum of an immunised animal and transfer it to a patient suffering from diphtheria, so as to help the tissues and cells of the patient to cope with the toxic products of the diphtheria bacillus during the earlier stages of the disease, inducing, as it were, a kind of artificial immunity to help the patient over the acute period of the attack when the poisons, though most virulent, are most unstable, and when the tissues have not yet become acclimatised to the presence of the toxic products of the bacillus; when, in fact, they are paralysed and are able to do little to protect themselves. Behring so followed up this idea, that he was able to initiate a system of treatment which promises to revolutionise our therapeutic methods in the treatment of certain specific infective diseases.

The Production of Antitoxic Serum.

Working on the fact that an animal might be rendered more and more insusceptible to the action of the toxic products of bacteria, Behring found that he might proceed in either of two ways. He might make an artificial wound with a needle, and introduce weakened bacilli into the animal, the weakened bacilli then growing but feebly and producing a modified toxine. After the effects of the first dose had passed off, he was enabled to increase the dose and to use more active bacilli, injecting them first into the tissues and eventually directly into the circulation, with the result that enormous doses of virulent diphtheria bacilli might ultimately be introduced without giving rise to more local swelling or general febrile disturbance than was first noticed when the small dose of modified bacilli was introduced. Such a method as this, however, was attended with considerable drawbacks, as it was almost impossible to gauge, at all accurately, the number and strength of the bacilli. Not so, however, with the products of the micro-organisms, the activity of which could of course be more accurately measured, and the dose more accurately graduated. The bacilli might multiply and continue their action on the tissues, but the poisons when injected alone would not alter in quantity or activity. As may be readily imagined, the fluid constituents of the blood can only contain those substances that are introduced into it from without, either through the vital activity of the cells of the body, the products of which must be thrown into this fluid before they can be excreted, or through artificial injection. The antitoxic substances then found in the blood of an immunised animal, must in the case of natural immunity following an attack of diphtheria be the result of the activity of the tissue cells, especially of the connective tissue and white blood cell groups which have been "stimulated" by the toxines introduced from without, from the false membrance in the throat. Where it is desired to produce an artificial immunity, and an "artificial" antitoxic serum, the cells are stimulated by the introduction into the body of artificially prepared toxine. The cells acted upon by the toxine elaborate the protective fluid, which is thrown into and accumulates in the blood. This substance may act in one of several, or even in several ways. (1) It may directly antagonise the diphtheria toxine, and may thus prevent the paralysing action of these poisons on the scavangering cells or phagocytes, as they are called; these, left free to perform their proper functions, can deal with the foreign elements that have got into the blood, and also with the bacilli at the seat of the local attack, for, as has been pointed out by several foreign observers, and by Ruffer in this country, immediately beneath the layer of bacilli in the false membrane there is usually a very considerable accumulation of leucocytes, especially in those cases in which recovery ultimately takes place. (2) The antitoxic substances may act on the bacilli, inhibiting their growth and interfering with their power of producing toxines. This of course can only be a local action should it play any part in the process. (3) These substances may act directly on the cells of the blood lymph and tissues, so stimulating and strengthening them that they are able to perform those functions above mentioned. It is at present difficult to state which of these processes is the one, or the most important, in protecting or curing the patient, and it may be that all play a part. It may be that the tissue cells, when acted upon by the specific diphtheria poison, become so modified that they are enabled to produce or secrete a substance which directly antagonises the action of that poison. This substance, thrown into the blood. remains there for some time, rapidly accumulates as larger and larger doses of the poison are thrown in, neutralising the poison, whose power of doing damage to the tissues is thus held in check, but remaining for some time after the toxine has disappeared; or this antitoxic substance, reacting upon the cells, may render them less susceptible to the action of the toxine.

The earlier immunising experiments were naturally performed upon the smaller animals, such as rabbits. Then Behring used sheep, and after various other animals had been tried, the horse was selected by Roux and Nocard as perhaps the best of all animals from which to obtain antitoxic serum. In the first place, he is comparatively insusceptible to the action of the diphtheria bacillus—even considerable doses of living bacilli may be injected under the skin without producing anything more than a slight local swelling and a rise of temperature. It has also been found that horse serum, when injected, produces little or no change in the healthy human subject—that is, the serum seems to mix perfectly well with human blood plasma, and there is comparatively little danger of the extra serum being excreted by the kidneys in the form of albumen. This is a most important point, and one that no doubt influenced Roux and Nocard in their selection of the horse as an animal from which to obtain immunised serum. Beyond this, however, the blood, when drawn from the vessels, separates very perfectly into two portions—a firm clot, which if the blood be caught in a cylindrical glass jar, forms a kind of column in the centre, and a clear straw-coloured serum which accumulates around the clot, and forms a layer often several inches deep above it. This serum contains the antitoxic substances. Lastly, considerable quantities of blood can be obtained from such a large animal as the horse, and if he be well fed, groomed and exercised, the process of bleeding may be repeated pretty frequently without causing any inconvenience to the animal; in fact, as one observer said, he stands bleeding as well as did our forefathers, who thought as little of being bled as we think of going to Aix or Buxton.

Let us now turn for a moment to the method of treating the horses that we wish to render immune, in order that they may supply the antitoxic serum that is to be used for the treatment of cases of diphtheria. Roux's method, which is that that has been most carefully described, and which is the one used in this country first by Dr. Ruffer at the British Institute of Preventive Medicine, and then by Prof. McFadyean at the Royal Veterinary College, consists in introducing diphtheria toxine of a given strength in gradually increasing doses, until the blood of the animal so infected is found to contain a sufficient quantity of the antitoxine.

Preparation of Diphtheria Toxine.

The toxine with which the animal is to be injected is prepared as follows:—A broth is prepared by soaking a pound of finely-minced beef in water. This is allowed to stand for twenty-four hours in the cold. To the fluid expressed from the meat fibre at the end of that time is added ½ per cent. of common salt and 2 per cent. of peptone (meat artificially digested by pepsine). This broth is then rendered faintly alkaline by the addition of soda salts or caustic soda. This is done because it is found that the diphtheria bacillus cannot grow at all vigorously, or form its poisons rapidly in an acid solution, and such poison as is formed is neutralised, or is unable to act in the presence of even a faint trace of acid. It is found that even in Roux's solution, which is always faintly alkaline to begin with, an acid reaction soon appears, but, after about ten days, this is replaced by an alkaline reaction, and as soon as this takes place, the growth of the bacilli takes on new activity, the quantity of toxine is increased, and it becomes much more virulent. Roux found that he obtained his most virulent toxines after a month's growth. If the growth is allowed to go on longer than this, a process of oxidation appears to take place, and I have found that the toxine from a culture carried on for two months had already lost much of its toxic activity. It should be noted that a virulent bacillus should always be taken in the first instance, otherwise the results may be very disappointing.

This nutrient material is placed in a layer of not more than half an inch thick in a flat-bottomed flask, which is plugged with cotton wadding, and then closed with an indiarubber cork or cap. Through this composite plug three tubes are passed into the flask; the two lateral tubes are bent at right angles, both inside and outside the flask; whilst the centre tube is fitted with a small thistle-head, which may be plugged with cotton wadding, and then closed with an indiarubber cap. The outlets of the lateral tubes are also plugged with cotton wadding, and the whole apparatus is kept for an hour or two in steam maintained at a temperature of 100° C. (Flasks so treated may be preserved for years without any change, beyond some slight evaporation, taking place in the broth.) A small quantity of a pure broth culture of the virulent diphtheria bacillus is now drawn into a long thin pipette, the indiarubber cap and the cotton wadding plug are removed from the thistle-head, and the contents of the pipette are introduced; the pipette is withdrawn, the cotton wadding is replaced, the indiarubber cap is fitted in position, and the flask is placed in an incubator which is maintained at the temperature of the body (98·4° F., or 38°·2° C.). As soon as the growth is well started (usually at the end of about twenty-four hours), a current of moist air is made to pass continuously over the surface of this cultivating fluid, the air being first warmed and saturated with moisture, in order as far as possible to prevent evaporation. A fine flocculent deposit soon makes its appearance on the bottom of the vessel, the supernatant fluid remaining clear. This deposit increases in thickness, much more luxuriant growth going on after the first ten days. Toxine is formed by the diphtheria bacilli so long as they can grow freely—that is, so long as they can obtain sufficient nutrient material from the fluid and from the air that is continually passing over the surface. At the end of a month, if all these precautions are taken, the toxine should be of such a strength that 1/10th of a c.c. (about two or three drops) injected into a guinea-pig weighing 500 grammes (over 17 ounces) will kill it within forty-eight hours. The strength of the toxine or poison may be a little greater or a little less than this, but it is a comparatively easy matter to measure the strength, and therefore to graduate the dose to be used in immunising the horse. This only holds good, however, if the active diphtheria bacilli are removed or destroyed; these, if left in the fluid, would be a complicating and inconstant factor in the equation. In order to kill these bacilli the Germans recommend the addition of ½ per cent. of carbolic acid to the culture; the dead bacilli falling to the bottom, leave a perfectly clear supernatant fluid. The French, on the other hand, recommend the separation of the bacilli from the fluid by means of a Pasteur-Chamberland filter. By this means a clear virulent poison which does not contain any diphtheria bacilli is obtained. With this fluid a horse with a good constitution, and which has been proved to be free from tubercle and glanders, is injected under the skin of the side of the neck in front of the shoulder. Small doses are first injected, either pure or with the addition of 1/3 of the volume of weak solution of iodine of potassium. If the fluid is of full strength, only about 2 c.c. can be given at the first injection. This is followed within twenty-four hours by a local swelling at the seat of injection, about the size of the palm of the hand, and the temperature may rise 1° or 2° F. (½° to 1° C.), otherwise the general health of the horse does not seem to suffer. He eats well, and unless regularly exercised may become very lively; of this we have had ample evidence during the recent frost and snow, when it has been unsafe to give much exercise to horses that are not very sound in limb, and as a result they have been very fresh indeed. As soon as the swelling has disappeared and the temperature has receded to the original level, a somewhat larger dose is given; the same process is repeated time after time (the dose being gradually increased to bring about the same amount of swelling and rise of temperature) for about three months, or until such time as the requisite amount of immunity is acquired, *i.e.* until the antitoxic action of the blood is sufficiently marked. That there is a gradually increasing immunity is evidenced by the fact that enormously large doses of the toxine in the later stages of the treatment produce even less local and constitutional disturbance than was observed after the first few injections of comparatively small quantities.

The blood is now drawn off from the jugular vein of the immunised horse by means of a metal cannula or tube to which is attached an indiarubber tube; these are first thoroughly boiled, in order that no living micro-organisms of any kind may remain on or in them, and the skin of the horse is carefully cleansed with antiseptic lotions. The indiarubber tube leads the blood into a flask or vessel which has also been carefully sterilised, and provided with a well-fitting cotton-wadding plug or glass-stopper. The vessel when filled is placed in an ice-safe until the solid part, the clot, is completely separated from the fluid—the serum. From each gallon of blood about one quart of serum is expressed, though this varies considerably in different cases, and according to the time that the separation is allowed to continue (24 to 48 hours). This serum, a limpid straw-coloured fluid, is carefully decanted under strict antiseptic precautions, and, mixed with carbolic acid or camphor, is stored in small phials, each of which contains about a sufficient quantity for the treatment of a single patient. In the Pasteur Institute, and in the British Institute of Preventive Medicine, the antitoxic serum is apparently brought up to such a strength that $\frac{1}{100}$ of a c.c. injected into a medium-sized guinea-pig (500 grammes, or over 17 ounces) will protect it against an injection twenty-four hours later of ½ c.c. of a culture of living diphtheria bacilli strong enough, if given by itself, to kill the guinea-pig in twenty-four hours. It is usually recommended that 20 c.c. of this serum should be given at the first dose, and that if necessary a second 10 c.c. should be given half an hour later. The method of testing the strength of the serum adopted by the Germans is that devised by Ehrlich, who takes ten times the lethal dose of diphtheria toxine, and in a test-tube adds a definite and known quantity of the blood to be tested. This mixture is then injected into a guinea-pig, and if the antitoxic power of the blood has been gauged aright, the animal does not suffer in the slightest degree from what under ordinary circumstances would kill ten guinea-pigs. The addition of less or weaker serum, or of more toxine would leave the mixture still toxic.

In order to obtain a definite standard with which to compare the antitoxic power of any serum, and to determine the dose of such serum, Behring and Ehrlich have described what they term a normal antitoxic serum—that is, a serum of such a strength that $\frac{1}{10}$th of a c.c. added to ten times the lethal dose of diphtheria toxine is exactly sufficient to render it innocuous. 1 c.c. of such normal serum contains one "immunisation unit," and should be sufficient, when added to a hundred times the lethal dose and injected, to render it innocuous. In horses wholly immunised the serum may be fifty or even a hundred times as active as the normal serum above mentioned and the dose to be given varies according to the number of immunisation units in any sample. It is not here necessary to go into the question of dose, but it may be stated that 500 of these immunisation units are usually necessary to produce the desired effects in cases of diphtheria, though in some cases still larger quantities have to be used. Behring now supplies four strengths of the serum, the weakest (marked with a yellow label) is sent out for injection of cases where the disease has not already been contracted. The next (marked with a green label) is of a strength of 600 antitoxine units, and is given to those cases in which the treatment is commenced at the very outset of the disease—that is, when the first symptoms of diphtheria manifest themselves. The next stronger antitoxic serum (white label) equals 1000 antitoxine units, and is used for cases somewhat more advanced in which the prognosis is at all grave; whilst in still graver cases, and where the symptoms have been developed for some considerable time, it is often necessary to give a serum of 1500 units; this is marked with a red label, and is of course highly concentrated in order that the size of the dose may not be unduly increased. In place of No. 1, healthy children and adults who are exposed to diphtheritic infection may receive a quarter of the dose of the green label flask, which Behring considers will protect against diphtheria with very great certainty. Although these general directions are laid down, it is strongly insisted upon by Behring, Kossel, Roux, and in fact by all those who have had experience of antitoxic serum, that the dose must vary according to the severity of the disease, so that much must be left to the discretion of the medical practitioner in charge of the patient. The great error into which those who first use this agent fall, is the administration of far too small a dose, especially in the case of children, for whom the dose is nearly as large as it is for adults. For this reason some of the statistics published in this country and abroad are far too unfavourable to the method. The great drawback with this method is that the dose necessary to be injected is so large; but in the loose tissue of the side of the chest, the back, or the buttock, immediately under the skin, the fluid soon disappears. It is hoped that before long, however, the active principle may be separated, and so obtained in smaller bulk.

So far we have dealt principally with the antitoxic serum as prepared by Behring and Roux and by Roux's method, which is certainly attended with comparatively few difficulties; these, however, have the disadvantage that they take from three to six months to give the desired results. In order to do away with this disadvantage, Klein has carried out a series of experiments in which he has been able to obtain serum of considerable activity in as short a period as twenty-three days. Instead of introducing the poison only, he adopts the plan used by Behring and Roux in their earlier experiments, of injecting living bacilli which have lost a certain degree of their activity, using for this purpose old cultures. He afterwards introduces toxine along with more virulent bacilli, and thus obtains in the animal such a degree of immunity that it is enabled to withstand or to react very slightly to more than a fatal dose of diphtheria bacilli. By the third week the animal will bear the injection of large quantities of virulent bacilli, and by the end of twenty-three or twenty-six days the serum has acquired such antitoxic properties that 1 c.c. of it will protect 40 to 80 guinea-pigs against a lethal dose of living diphtheria bacilli. It is difficult to compare these results with Roux's and Behring's, but Klein's serum has been used with marked success in certain cases of diphtheria. It appears to have a special power of causing the membrane to clear away, and so to remove the manufactory of the poison, as on this membrane the diphtheria bacilli accumulate. This method is mentioned as one that may be used especially where it is desired to obtain antitoxic serum quickly.

Smyrnow has suggested quite a different method of preparing antitoxine. Under Nencki's advice he passed electric currents through the serum of animals, and was thus able to endow it with a certain immunising power. But he was still more successful in obtaining powerful antitoxine by electrolysing diphtheria bouillon cultures; curiously enough, the more virulent the culture the more powerful was the antitoxic substance he obtained. When this antitoxic substance was injected into a rabbit, which twenty-four hours before had received about ½ c.c. of a two or three days old diphtheria bouillon culture, there was a rapid rise of temperature followed by marked improvement in the condition of the animal. This observer believes that antitoxine can be obtained by this method that will be much more suitable for the treatment of the human subject than those obtained by the ordinary methods. His experiments, however, are far too few to carry any great weight, though they open up a most interesting field for future investigation.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The extension of the buildings of the Cavendish Laboratory is about to be undertaken, at an expense of over £4000. About half the cost will be met from the accumulated fees of students working in the laboratory.

Mr. E. Hamilton Acton, Fellow and Lecturer in Chemistry of St. John's College, died suddenly, from heart disease, on Friday night. Mr. Acton was only in his thirty-third year; but he had earned a considerable reputation as a chemist, and his researches in vegetable chemistry, in particular, were of importance. He was an able and successful teacher. His funeral on Tuesday was attended by some hundreds of the junior members of the University, and by representatives of all the scientific departments.

MR. ROBERT PERKINS, of Jesus College, Oxford, leaves England next week for Honolulu to resume his investigations on behalf of the Joint Committee appointed by the Royal Society and the British Association for the zoological exploration of the Sandwich Islands. The large collections he made there during his former stay (March 1892 to September 1894) have been submitted to various specialists, with results that show him to be an indefatigable observer in all branches of terrestrial zoology; and, since his return to England last autumn, he has been busily engaged in discovering what has yet to be done to complete our knowledge of the indigenous Fauna which is so rapidly disappearing.

THE County Councils of Northumberland and Durham are truly advancing technical education by affording assistance to Dr. W. Somerville, Professor of Agriculture in the Durham College of Science, to carry out extensive manurial trials. The experiments were begun in 1892, on nine farms in Northumberland; in 1893, when Durham joined in the work, the number of farms rose to twenty-six; while during 1894, the trials were made at no less than forty-three different centres in the two counties. The investigations must have a not inconsiderable influence upon the prosperity of the agriculture of the district to which they refer.

THE Technical Instruction Committee of the Essex County Council, with a view to promoting the spread of scientific knowledge among those engaged on the coast in the fishing industries, started a modest biological station at Brightlingsea last year, and, under the superintendence of Mr. J. T. Cunningham, a number of specimens were collected for the purposes of demonstration. Some experiments on the continental method of growing oysters were also commenced, but, owing to the unfavourable character of the season, the results could not be carried very far. We are glad to learn, however, that the Committee, in conjunction with the Borough Council of Colchester, propose to carry on the work of the station, and that the Fishmongers' Company have also shown their appreciation of the movement by giving a grant of £50 per annum for three years.

THE Manchester Town Council have accepted a tender for the erection of a technical school at a cost of £140,000.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xvii. No. i. (January, 1895).—Sur une transformation de mouvements, P. Appell, is a treatment of Elliot's problem (*Comptes rendus*, 1893), and of a question solved by Mestschersky, in the *Bulletin des Sciences Math.* 1894, as a particular case of transformation of movements.—An extract from a letter addressed to Dr. Craig by M. Hermite, gives the result of an investigation of the asymptotic value of log Γ(a) when *a* is large.—On the first and second logarithmic derivatives of hyperelliptic *σ* functions, by Oskar Bolza, opens with a statement of certain well-known theorems of the theory of elliptic functions, and then extends these and some allied theorems to hyperelliptic functions.—Sur la definition de la limite d'une fonction. Exercice de logique mathématique, by Prof. Peano. The definition is one previously used by the writer, and also by two or three previous writers. It is practically given by Abel (*Works* ii. p. 199), in the form. "Pour qu'une série Σu_n soit convergente, il faut que *la plus petite des limites* de nu_n soit zéro." The same general idea of a limit is given in Cauchy's "Cours d'Analyse algébrique" (1821, p. 13), "quelquefois . . . une expression converge à-la-fois vers plusieurs limites différentes les unes des autres." Prof. Peano works on this definition, and demonstrates at some length its principal properties. To this end he employs la logique mathématique, "Cette science s'est rapidement développée de nos jours, et on l'a appliquée dans plusieurs travaux."—Dr. E. McClintock contributes an article on theorems in the calculus of enlargement (a paper read before the American Mathematical Society, August 14, 1894). It is an interesting sequel to his essay on the calculus of enlargement (vol. ii. pp. 101–161).—In his note on Foucault's pendulum, Mr. Chessin considers the motion of a physical pendulum on the surface of the earth, taking into account the rotation of the earth about its axis. The initial velocity relatively to the earth of the pendulum is supposed equal to zero, as in Foucault's experiment. Hence he retains the name of "Foucault's pendulum," although oscillations of any finite amplitude are considered. The portrait which is given with this number is that of M. E. Picard.

Wiedemann's Annalen der Physik und Chemie, No. 2.—Fluorescence of solutions, by O. Knoblauch. There is a constant ratio between the intensity of the fluorescence and the existing light, even when the intensity of the latter is altered in the ratio of 1 to 6400. The author proves experimentally and theoretically that the effect upon the various fluorescent bodies of varying the solvent is very different.—The potential gradient in the positive portion of the glow discharge, by A. Herz. The potential gradient in the positive unstratified glow discharge of a vacuum tube decreases as the current increases, and also as the diameter of the tube is increased; but it increases with the pressure, though not as rapidly.—Unipolar induction, by Ernst Lecher. The author discusses the different aspects of the question whether, when a cylindrical magnet rotates about its axis, the lines of force due to it are stationary, or rotate with the magnet. The former was Faraday's original view, the latter has been maintained by Tolver Preston and others. After showing that all the experiments hitherto quoted as decisive one way or the other may be equally well interpreted on either assumption, he describes some test experiments which show that the lines of force stand still while the magnet rotates.—Electric dispersion, by P. Drude. A method is described for investigating the relation between the dielectric constant of a substance and the period of the electric waves traversing it, or what may be described as the electric dispersion of the substance. If the dielectric constant decreases as the period increases, there will be normal, if it increases, anomalous dispersion. For alcohol the dispersion was found to be normal, and of the same order of magnitude as its optical dispersion. Water showed abnormal dispersion with the large wave-lengths used, whereas ebonite showed no perceptible dispersion.—Effect of kathode rays upon some salts, by E. Goldstein. Lithium chloride, when exposed to kathode rays, assumes a heliotrope or dark violet colour, which it retains for some time in a sealed tube. Chlorides and other haloid salts of potassium and sodium show similar effects. The colours are very superficial, and disappear on heating, or by the action of moisture.

SOCIETIES AND ACADEMIES.

LONDON

Geological Society, January 23.—Dr. Henry Woodward, F.R.S., President, in the chair.—Carrock Fell: a study in the variation of igneous rock-masses. Part ii. The Carrock Fell Granophyre. Part iii. The Grainsgill Greisen, by Alfred Harker. The augite-granophyre of Carrock Fell was first described in its normal development, special attention being drawn to the various types of micrographic intergrowths which it exhibits. The variation of the rock was next examined, and, in particular, a curious basic modification which occurs near its junction with the gabbro described in a former paper. The granophyre here passes into a coarse type rich in augite, iron ores, and apatite, its silica-percentage falling to as low as 58. The author attributed this to the acid magma having incorporated in itself portions of the highly basic margin of the gabbro. The latter rock seems to have been fused or dissolved by the magma, with the exception of certain of its more refractory minerals which survive in the modified marginal part of the granophyre. The latter part of the paper dealt with a remarkable quartz-mica rock found on the north side of the Skiddaw granite. It differs in some respects from the Cornish greisens, and resembles in its mode of occurrence certain pegmatites in the Scottish Highlands. The author considered the rock to have been extruded from the granite in connection with the post-Silurian crust-movements of the district, while its composition has probably been further modified by subsequent chemical changes.—The geology of the country around Fishguard (Pembrokeshire), by F. R. Cowper Reed.—The tract of country forming the subject of this communication occupies the northern part of Pembrokeshire, from Newport to Strumble Head.—On the mean radial variation of the globe, by J. Logan Lobley. The author submitted considerations (chiefly derived from the characters of the earlier sediments) which led him to suppose that crust-folds have not been produced by continuous contraction of the earth, and that the planetary heat and mean radius of the earth have been practically invariable during the period which has elapsed since Cambrian times.

Zoological Society, February 5.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—A communication was read from Dr. E. A. Goeldi, in which he described the breeding habits of some tree-frogs observed by him in the Province Rio Janeiro. *Hyla faber*, Wied, constructs nests of mud on the shallow borders of ponds, wherein the young are protected from enemies whilst in the larval state. *Hyla goeldii*, Boulenger, dispenses with the metamorphoses, which are hurried through within the eggs, these being carried by the female on her back. *Hyla nebulosa*, Spix, deposits its eggs in a slimy mass attached to withered banana-leaves, the young remaining in this sort of nest until in the perfect, air-breathing condition.—Mr. Edgar A. Smith gave an account of a collection of land-shells made principally by Mr. A. Everett at Sarawak, British North Borneo, Palawan, and other neighbouring islands.—Mr. Oldfield Thomas read a paper upon the long-lost mammal *Putorius africanus*, Desm., and its occurrence in Malta.—Mr. F. E. Beddard, F.R.S., read a paper on the visceral anatomy of the tree-kangaroo (*Dendrolagus bennettii*), and pointed out the structure of the brain and other organs.

CAMBRIDGE.

Philosophical Society, January 28.—Prof. J. J. Thomson, President, in the chair.—The following resolutions were proposed by Prof. Sir. G. G. Stokes, seconded by Mr. Glazebrook, and passed unanimously: (1) "That the Cambridge Philosophical Society desires to express its sense of the great loss sustained by the University and the Society by the death of Prof. Cayley; whose eminence conferred honour on the Society which reckoned him amongst its Presidents, and whose simple and earnest character was an example to all and endeared him to those who knew him." (2) "That the Society do now adjourn without transacting the business of the meeting, as a mark of respect to Prof. Cayley."

PARIS.

Academy of Sciences, February 11.—M. Marey in the chair.—M. Faye gave a short account of the contents of volumes iv. and v. of the *Annales de l'Observatoire de Nice*.—On the presence and distribution of alumina in plants, by MM. Berthelot and G. André. Alumina is found in quantities comparable with the amounts of other bases present, mostly in the roots of plants having deep and abundant roots.—Preparation and properties of titanium, by M. Henri Moissan. Titanium has been prepared in the electric furnace. It requires the most intense heat capable of production, and even then contains at least 2 per cent. of carbon. It forms friable masses, having a bright white fracture. It is harder than quartz and steel. Its specific gravity is 4·87. The chemical properties are given in detail. Its silicide and boride are as hard as the diamond. The carbide, TiC, and nitride, Ti_2N_2, are also fully described.—On some derivatives of phenolphthaleïn, by MM. A. Haller and A. Guyot.—M. Guignard was elected Member of the Botany Section.—Report on a work by M. E. Hardy relative to the application of sound vibrations to the analysis of two gases of different densities. By means of an instrument (termed a Formènophone) consisting essentially of two pipes tuned to give the same note, and blown with air and with air containing a lighter gas, the quantity of lighter gas present may be ascertained by the production of beats between the sounds emitted by the two tubes.—On a property of meromorphic functions, by M. Émile Borel.—On certain systems of equations to the derived partials, by M. J. Beudon.—On the electrostatic capacity of resistance bobbins, and its influence in the measurement of coefficients of induction by the Wheatstone bridge, by M. J. Cauro. Bobbins with double coils should only be used for small resistances; if the resistance increases, a capacity-error greater than that due to self-induction may be caused. To minimise capacity-errors the Chaperon winding should be used. These capacity effects may be neglected in measurements made with ordinary Wheatstone bridges; but they come into play with bobbins having small coefficients of self-induction with great resistances.—On the measurement of luminous flux, by M. A. Blondel.—On the passage of light across a thin plate in the case of total reflection, by M. Ch. Fabry. The formulæ of thin plates are shown to apply without modification to the case of a transparent spot at and surrounding the point of contact of a convex and plane-glass surfaces when the included thin plate is viewed at the angle of total reflection.—On the lowering of the freezing-point of dilute solutions of sodium chloride, by M. A. Ponsot. The author obtains results by his own method differing from those of previous observers. He finds that in the limit the lowering of the freezing-point is proportional to the number of grams of salt existing in 100 grams of solution.—On sulphide of gold, by M. A. Ditte. The behaviour of gold sulphide in presence of alkaline sulphides, with and without excess of dissolved sulphur, is described. The compounds: $Au_2S.2Na_2S.20H_2O$ and $Au_2S.Na_2S.10H_2O$ and $Au_2S.4K_2S_2.12H_2O$ are noted.—On a method of causing the crystallisation of precipitates; manganese and zinc sulphides and cupric hydrate, by M. A. Villiers.—On cinchonigine, a case of dimorphism of a compound having a specific molecular rotatory power, by MM. E. Jungfleisch and E. Léger. Cinchonigine is dimorphous, its two forms readily passing from one to the other. The monoclinic form is stable at the ordinary temperature, the rhombic form at about 35°.—On the plurality of chlorophylls; the second chlorophyll isolated from lucerne, by M. A. Étard.—A comparison between the coloured and colourless derivatives of hexamethyl-triamidotriphenylmethane, by M. A. Rosenstiehl.—On a new type of ethereal salt, methylene lactate, by M. Louis Henry. The preparation and properties are described of the substance represented by the formula

$$\begin{array}{ccc} CH_3 . CH & . & CO \\ | & & | \\ O.CH_2 & & O \end{array}$$

.—On the relation between the general form and the composition of the body in protozoa, by M. Félix Le Dantec.—A study of the agricultural value of the phosphate of aluminium from Grand-Connétable, by M. A. Andouard.—On the contact phenomena of the lherzolite of the Pyrenees, by M. A. Lacroix.—New relations between the barometric movements in the northern hemisphere and the movements of the sun and moon in declination, by M. P. Garrigou-Lagrange. (1) In the northern hemisphere the atmosphere oscillates about the 30th parallel, corresponding to the movement of the moon in declination, so that the pressures are lower with boreal than with austral moon below 30°, and inversely above. (2) The gradients take corresponding modifications. The barometric slopes from 30° south and north, are alternately increased and lowered, more strongly with boreal moon below 30°, more feebly above, and inversely with austral moon. (3) These differences in pressures and gradients augment towards the pole, at least up to the 70th parallel. (4) These movements are superposed on more general movements.

AMSTERDAM.

Royal Academy of Sciences, December 29, 1894.—Prof. Van de Sande Bakhuyzen in the chair.—A treatise on a simple method of roughly distinguishing between Scandinavian and southern diluvial sand, and between alluvial and diluvial sand, by separating the heavy minerals from the sand through immersion of the sand in a fluid of a specific gravity of 2·88, invented and described by Dr. J. L. C. Schroeder van der Kolk, formed the subject of a report drawn up by Mr. Van Diesen and Dr. Behrens—Mr. Schols and Mr. Martin reported upon an essay by Mr. J. J. A. Muller, in which the author calculated the dislocation undergone by some parts of the mountain system of Sumatra, in consequence of the earthquake of May 17, 1892. These calculations, which are based on data supplied by the measurements executed in the said island, on behalf of the secondary triangulation, prove with great certainty a horizontal shifting of the following three points to the extent, and in the direction indicated :—

Sorik Merapi	1·23 M.	344° 57′
Tor Si Hite	0·64 M.	149° 2′
Goenveng Malintang ...	1·24 M.	304° 28′

the directions being counted from the north point, going round through the east.—Dr. Jan de Vries discussed some methods of deducing from given configurations more complicated configurations. In particular a series of configurations, first described by Andreef, was deduced from the tetrahedron by means of a system of polar coordinates.—Dr. Bakhuis Roozeboom, in considering the experiments of Prof. Spring, on the conversion of black into red HgS, showed that this author was mistaken in the nature of the phenomenon, which belongs to the category of the conversion of unstable modifications into stable ones. The pressure required for a conversion of this description does not admit of being expressed by a simple law.—Dr. P. van Romburgh has examined, in the laboratory of the "culture" garden at Tjikeumeuh, a number of coca-leaves grown in Java, in order to ascertain their volatile constituents. Those of *Erythroxylon Coca Lam.* var., *Spruceanum* (Burck), when distilled with water, produced methyl-salicylate (about 20 c.c. was obtained from 140 kgrs. of fresh leaves). In the water was also found a little acetone and methylic alcohol, and perhaps also traces of salicylic aldehyde. The quantity of methyl salicylate decreases in proportion as the leaves grow older; in fresh unexpanded top-leaves Dr. van Romburgh found 0·13 per cent., in young leaves from 0·06 to 0·07 per cent., in old leaves even less than 0·02 per cent. The leaves of *Erythroxylon Bolivianum* (Burck) were also proved to contain methyl salicylate, but only 0·004 per cent., as well as those of *E. ecarinatum* (Burck), but not those of *E. Burmanium* (Grift) and *E. longepetulatum* (Burck), while in the case of *E. spec. insul. Comor* the results were doubtful.—Prof. Kamerlingh Onnes read a paper on the Kryogene Laboratory at Leyden, and on the production of extremely low temperatures. The object of the author in starting his investigations, upwards of ten years ago, viz. the combination of Wroblewski's and Olszewski's labours with those of Pictet, has been quite satisfactorily attained with the least possible means. Liquid oxygen is stored in a glass vessel adapted for experimenting and observing purposes; the oxygen vapours are continuously compressed, liquefied, and again poured into the said vessel, so that the evaporation from the surface takes place at a level pretty nearly constant. With the aid of a small quantity of circulating oxygen, a bath of liquefied gas of quarter to a half litre can be maintained under normal or reduced pressure, *ad libitum*. With this method no use is made of Dewar's vacuum vessels. The vessel is protected from convective transference of heat by the oxygen vapour, which cools a special chamber with plate-glass windows. These windows remain quite free from hoar-frost, and do not interfere with the formation of images. The condensation of oxygen is obtained in a spiral tube immersed in liquid ethylene boiling in a copper flask connected with a conjugate vacuum pump and compressor. The circulating ethylene is liquefied in a condenser cooled down to − 80° by a circulation of methyl chloride, or in some cases by carbonic acid. The apparatus is so arranged, and the flask especially is so devised, that only a minimum of condensed gases is required. Only *one and a half* kilogrammes of ethylene is used in the author's ethylene circulation to obtain the above-mentioned permanent liquid oxygen bath, in contradistinction to the great quantities mentioned in the accounts of Dewar's experiments.—The purifying of gases by means of fractionating at low temperatures was also treated, and a modified form of Cailletet's mercury plunger compressor, used specially for this purpose, was described. The author concluded with a few observations on certain investigations and apparatus in course of execution, and intended to be preparatory to the manipulation of liquid hydrogen in the Kryogene Laboratory of the future.

GÖTTINGEN.

Royal Academy of Sciences.—In the *Nachrichten*, part 4 (1894), the following papers of mathematical and physical interest appear:—Fv. Schilling, the fundamental polygon of Schwarz's *s*-function for the case of complex exponents; O. Bolza, a *pu* function for the general hyperelliptic case; R. Dedekind, on ideals (in the theory of numbers); E. Riecke, the equilibrium between a deformed homogeneous solid and liquid in contact with it; E. Riecke, Clausius' condition equation; A. Hurwitz, on the theory of ideals; R. Haussner, the numerical coefficients of Weierstrass's σ-series; G. Pick, invariant processes for higher binary forms; A. Schönflies, the hexagonoid of Eberhard; P. Bachmetjew, results as to electrical earth-currents in Bulgaria; E. Ritter, extension of the Riemann-Roch theorem to sets of forms; A. Sommerfeld, mathematical theory of the inflexion of light and electricity; W. Voigt, on piezo-electricity in crystals without a centre of symmetry.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Cod-Liver Oil and Chemistry: Dr. F. A. Möller (Peter Möller).—Mechanics, an Elementary Text-Book, Theoretical and Practical. Dynamics: R. T. Glazebrook (Cambridge University Press).—Colour Vision: Captain W. de W. Abney (Low).—The Student's English Dictionary: Dr. J. Ogilvie, new edition (Blackie).—The Story of the Stars: G. F. Chambers (Newnes).—Universal Electrical Directory, 1895 (Alabaster).—On the Geographical Distribution of Tropical Diseases in Africa: Dr. R. W. Felkin (Edinburgh, Clay).—Philosophy of Mind: Prof. G. T. Ladd (Longmans).

PAMPHLETS.—Le Service Chronométrique a l'Observatoire de Genève, &c.: Prof. R. Gautier (Genève, Aubert Schuchardt).—Origen Poliédrico de las Especies: A. Soria y Mata (Madrid, Establicimiento Tipográfico).

SERIALS.—Engineering Magazine, February (Tucker).—Journal of the Franklin Institute, February (Philadelphia).—Himmel und Erde, February (Berlin, Paetel).—Internationales Archiv für Ethnographie, Band viii. Heft 1 (K. Paul).—Journal of the Anthropological Institute, February (K. Paul).—Journal of the Asiatic Society of Bengal, Vol. lxiii. Part 2. No. 3 (Calcutta).—Astrophysical Journal, February (Wesley).—Journal of the Chemical Society, February (Gurney).

WHAT DOES THE CHEMIST MEAN BY "VALENCY"?

Handbuch der Stereochemie. Von Dr. C. A. Bischoff, unter Mitwirkung von Dr. P. Walden. II. Band (Schluss). (Frankfurt: H. Bechhold, 1894.)

THE author of the review of the first part of this book (NATURE, vol. xlix. p. 409) has given an account of it with which the present writer entirely agrees. Dr. Bischoff's book embodies a tolerably complete epitome of all that is known of a subject which at the present time has probably a larger number of cultivators than any other department of chemistry, and as a register of facts and references to original sources of information it is indispensable to the worker engaged upon stereochemical problems. On the other hand, the book is not only eminently unreadable, but the arrangement is sometimes far from clear.

Of this second and concluding volume about one third is occupied with an enumeration, continued from vol. i., of the various known cases of isomerism, inorganic as well as organic, which may be possibly referred to the geometrical hypothesis. The second third deals with chemical changes, such as ring formation and intramolecular changes regarded from the stereochemical point of view. The last part consists of additions to preceding pages, so as to bring the matter up to the most recent date possible. Examination of a volume such as this compels the reflection that spite of the great array of established fact, confusion still prevails among stereochemical writers, chiefly for want of some common agreement as to fundamental ideas.

"Atomicity," as it used to be called, meant originally the power exhibited by the several elements to combine in the proportions of one atom to 1, 2, 3, 4 or *n* atoms of some other element. Hence arose the idea of different atomic values in the process of exchanging one element for another. Later, from these notions about "quantivalence" it was assumed (without sufficient evidence) that when an atom, say, of carbon combines with four other atoms, the force of attraction or union for each of these four atoms is the same. Attempts were then made to estimate by thermal methods the mechanical value of each unit of "atomicity" or "quantivalence."

During all this time much discussion has occurred as to what becomes of units of "valency," to use the more modern term, which are not exercised as in unsaturated compounds generally, and Frankland's idea that even the "bonds" belonging to one and the same atom may saturate each other in pairs has been commonly used.

Since the observations of Van t'Hoff and Le Bel on the relations of chemical constitution to optical activity, and the revival of the hypothesis of spacial arrangements, and especially in the generally adopted theory of tetragonal carbon, the idea of *direction* which is implied in all space arrangements has been universally adopted. As to whether the direction in which valency can act is fixed or variable, opinion seems a little divided, and yet it is obvious that double linkage between two atoms, or the formation of any closed chain of tetragonal carbon atoms (whether conceived according to Van t'Hoff or Wunderlich, or otherwise), would be impossible on the assumption that the valency of carbon atoms can act only in certain directions which are quite fixed. Concerning this question the conclusion seems inevitable that we must suppose something analogous to a magnetic field between combining atoms.

But what, after all, is valency?

The fact is that while one atom of chlorine combines habitually with one atom of hydrogen, an atom of oxygen combines with two atoms of hydrogen, an atom of nitrogen with three, and so forth, and it is hardly assumption to say that so long as the hypothesis of atoms is used to express chemical combination, *some* geometrical arrangement of combined atoms in space is an inevitable part of the hypothesis. This was long ago pointed out by Wollaston. The valency of an element is then the numerical expression of its habit of combination. It is well known to be variable, and to depend to a great extent upon physical conditions. It may be that one atom can only act upon another in certain directions, but this does not render *necessary* the assumption that each atom is always doing something in these several directions, whether other atoms are present or not. This, however, is what is assumed by those who use the term "bond" in any of the recognised senses, or who attempt to determine the dynamical value of units of valency. There is some evidence in favour of the hypothesis that combination can only occur when atoms get within a certain maximum distance from each other, and the possibility that isomerism may result from changes in the distance between the atoms united within a molecule, is deserving of greater consideration than it has hitherto received. If we think, for example, of the exchange of an atom of chlorine for an atom of hydrogen in, say, marsh gas, it is difficult to believe that the chlorine atom occupies exactly the same place relatively to the carbon as the hydrogen atom for which it is substituted. Reasons may possibly be found for this in the difference of the force of "affinity" between carbon and chlorine on the one hand, and between carbon and hydrogen on the other, or it may result from the "residual valency" of chlorine acting upon the neighbouring hydrogen atoms, or from the difference of "mass" of the chlorine and hydrogen. But throughout all the various hypotheses used generally by chemists, runs the idea of direction variable within narrow limits, already referred to. Now, however much the direction along which a force acts may be supposed to vary according to circumstances, it is inconceivable on any mechanical principle that one force can act in several directions at once unless there is reason to suppose that it is divided in some way into component forces. Hence the "centric" formula for benzene, which has lately come into vogue, represents a wholly new idea which is incompatible with previously received ideas about valency and with the hypothesis of the tetragonal carbon atom. According to this formula an atom of carbon is capable of acting in eight different directions—that is, it acts directly, in the conventional sense, upon one atom of hydrogen and upon two atoms of carbon, at the same time that it "influences" these two atoms of carbon and three others. This idea is wholly unnecessary to the explanation of the stability of the benzene molecule, which can be accounted for quite simply in other ways; but it shows how prevalent is the idea that valency means, not only the power to do something, but that that power is always being exercised, and that in every chemical formula every unit of valency must be accounted for. This example is sufficient to illustrate the state of confusion about valency and chemical combination, which seems to grow more serious and more tangled every day.

The doctrine of Stereoisomerism as at present used may be compared to the fluid theory of electricity. It is a working theory which some day, perhaps, will be superseded, but no great advance is likely to be made until some more clear idea as to the meaning of valency can be brought into use. In the meantime experimental inquiry is undoubtedly proceeding rapidly, and will prepare the way for the next step in theory. To this end such a book as Bischoff's "Stereochemie" will afford much assistance in the laboratory, and can be safely recommended to all who are working in this direction.

W. A. T.

CAVES AND SWALLOW-HOLES.

Les Abîmes, les eaux souterraines, les cavernes, les sources, la spelæologie. By E. A. Martel. 4 phototypes and 16 plans, with 100 smaller illustrations. (Paris: C. Delagrave, 1894.)

AT the outset the author remarks that the man is happy who realises in ripe manhood a project of boyhood. As a youth he was fascinated by the stalactites of the cave of Gargas, and the underground stream near Eaux Chaudes. The impression, at a later date, was deepened by the marvels of Adelsberg; and a visit to Han-sur-lesse (Belgium) in 1888, determined him to explore thoroughly the swallow-holes and caves of Les Causses—the limestone plateaux to the south and west of the Cevennes and Auvergne—with which he had already made acquaintance. Here the rivers often flow through deep gorges—almost cañons, such as is illustrated by Fig. 1. In 1888 and the following year the author investigated the underground topography of the Departments of Lozère and Gard, and then extended his researches from Vaucluse to La Charente, going as far as the Puy-de-Dôme, the Côte-d'Or, and Provence, and, yet further afield, to Belgium, the Karst, and the Peloponnesus. Altogether he explored 230 "holes in the rock," which he thus classifies: Swallow-holes (*abîmes*), 110, into 90 of which no descent had been previously made; emissaries of rivers (*sources*), 40, up 30 of which no one had penetrated; caves, 80, of which 45 were but imperfectly known. Besides these he had sounded, without descending, 35 swallow-holes, and examined 55 large emissaries, which could not be entered. Plans were made of underground galleries, the total length of which amounts to 50 kilometres; rather more than half the work being done by himself, the rest by collaborators. The result of this indefatigable, and sometimes rather risky, work is the most complete original memoir on "cave hunting" that has ever been published, a quarto volume of nearly 600 pages, containing many plans, and still more numerous illustrations, the latter mostly from photographs, together with a full bibliography of the subject.

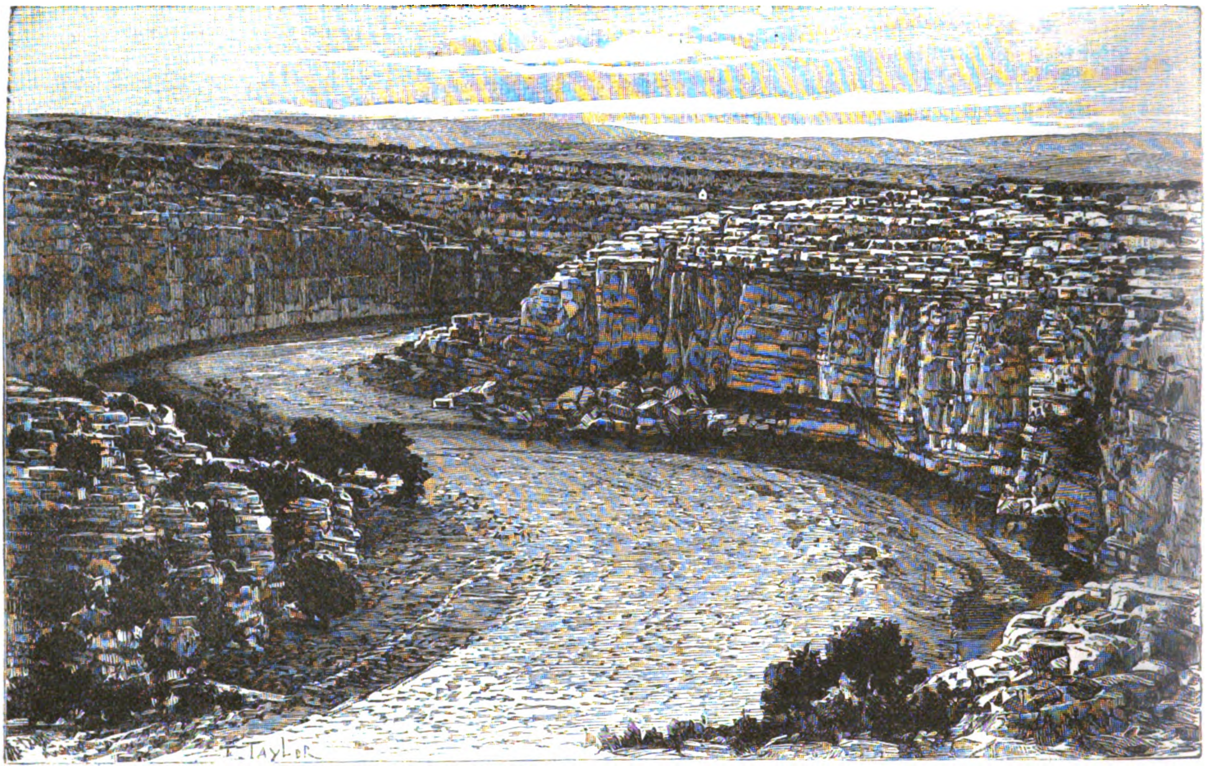

FIG. 1.—Cañon de la Baume.

To give any account of even the caverns of the Causses, which occupy the larger part of the book, would occupy too much space; so we content ourselves with a brief sketch of one of the most remarkable—that of Padirac, in the Causse de Grammat; and, after all, caves generally exhibit a strong family likeness. On a rocky plain a gulf, nearly forty yards across, opens out suddenly, as shown in Fig. 2, for which and the one on p. 410, we are indebted to the courtesy of the publishers. The greatest depth is just over twice the breadth, but a huge pile of débris rises from the bottom up to nearly fifty-nine yards from the surface. This leads on either side to a gallery. One of these ascends gently upwards, for about a couple of hundred yards, to a spot where a stream bursts from the rock. The other gallery, which is also traversed by this stream, extends for about a mile and three-quarters, following a rather serpentine course, which, in one part, bends at right angles to its former direction. At last it ends in a lake and a *cul de sac*. The cave is generally rather narrow, not many feet in width, but here and there broadens out into a large hall; the roof, also, rises and falls, its height not unfrequently being from forty to sixty feet—occasionally a good deal more. Padirac contains stalacites, stalagmites, and basin-shaped deposits of calcic carbonate; in short, is a thoroughly typical cave, with the not infrequent addition of a huge swallow-hole. Dozens of similar caverns may be found in this curious limestone region. They are abundant, under various names, in the Jura and in the limestone districts of the Alps, being most frequent in the more eastern region, where sometimes a bare rocky tract is almost riddled by swallow-holes (*dolinas*) great or small. From the Karst district they may be followed through the Alps of Dalmatia into the limestone region of Greece; they exist also in the carboniferous limestone of England, Belgium, and America. One might almost say *ubi calx, ibi spelunca*.

M. Martel notices, but appears to have paid less attention to, the curious caves called *glacières*, so pleasantly described by Canon Browne in his "Ice Caves of France and Switzerland." In these the walls are hung with sheets and festoons of ice, and thick masses of it cover the floors. In summer-time the temperature inside them keeps very near to the freezing-point. M. Martel suggests that in winter they become filled with cold air, which remains there like the carbonic anhydride in a *grotto del cane*. But such as we have seen, appear to be better explained as natural ice-houses, where the summer warmth is insufficient to dispose of the snow and ice which had accumulated in the winter.

FIG. 2.—Shaft leading to the Cave of Padirac.

Is it possible that occasionally these swallow-holes and caves may be memorials of an age when the climate was colder than it is at present? Both are sometimes dry. In the case of the cave, this may be explained by the water having worked out a new, and as yet undiscovered, path; but some swallow-holes open out, like the mouths of wells, on gentle slopes or rocky plains, apparently disconnected from any system of drainage. They seem too large to be explained—like those countless pipes in the rock of the *Steinerne Meer*—as only the work of rain. Is it possible that they were chiefly excavated in the Glacial epoch, when many elevated rocky plateaux would be buried under permanent, or nearly permanent, snow-beds, the drainage from which would give a supply of water, which was engulfed before it had the opportunity of excavating a glen? Some things seem not unfavourable to this suggestion. T. G. BONNEY.

OUR BOOK SHELF.

Bulletin of the Botanical Department, Jamaica. April 1887 to September 1894. Edited by the Director, W. Fawcett, B.Sc. (Published by the Department of Public Gardens and Plantations.)

SINCE the increase of botanical stations in the British West Indies, there has been greater activity in the older establishments, and the Directors have followed the example of Kew, in issuing a monthly budget of information useful to planters and others, whether they plant for profit or pleasure. We have lately received a complete file of the organ of the Jamaica Garden, bearing the above title. This was started in 1887, and it has increased from a single page of foolscap size to a sheet of ordinary octavo; and the price is only twopence. The contents are of a varied and miscellaneous nature; but information on the cultivation and diseases of economic plants, and on the value and preparation of their products, largely predominates. It includes not only the results of local experience; the editor has also drawn upon the numerous sources open to him, thanks to the more intimate connection between similar establishments throughout the empire, due, to a large extent, to the efforts of the Director of Kew.

Among other things, there are lists of the economic plants, of plants yielding edible fruits, and of trees useful either for timber or shade, cultivated in the Jamaica botanic garden. Botanical and common names are given, as well as the native countries of the respective plants, together with the prices (of seeds or plants) at which they are offered to the inhabitants of the island. The prices, it may be mentioned, are ridiculously low; merely nominal, in fact. Free grants are also made; but in order to avoid waste of valuable plants, the conditions are somewhat stringent, though not more so than an intelligent and earnest cultivator would cheerfully submit to. Another interesting feature is Mr. Jenman's descriptive enumeration of the Ferns of Jamaica. This was commenced in 1890, and is still unfinished. It is to be hoped that this will some day be issued separately, as the Fern-vegetation of Jamaica is perhaps the richest in the world, comprising between 400 and 500 species.

Die Maschinellen Hilfsmittel der Chemischen Technik. Von A. Parnicke, Civil-ingenieur, vorm. Ober-ingenieur der Chemischen Fabrik Griesheim. (Frankfurt: H. Bechhold, 1894.)

WE are accustomed to hear little but praise of the German University system of education. There is, however, a reverse to the shield. While admitting the value of the training received by the University student in pure chemistry, the author of this work points out that only in a few of the higher technical schools is any systematic instruction given concerning the employment of machinery in manufacturing chemistry. The consequence is that many young chemists find, at the commencement of their practical career, that they have either to laboriously collect, from many scattered and not easily accessible sources, the information they require, or perforce remain mere copyists of the methods of others, for lack of the knowledge which might enable them to intelligently use the mechanical appliances best suited to attain their ends.

The work under review represents an endeavour to lessen the difficulties in this direction. In some 290 pages, a synopsis is presented of the principal mechanical arrangements with which the chemist may be concerned. A vast amount of information is set out in well-arranged sequence, and, though many of the descriptions are necessarily somewhat sketchy on account of the large number of appliances to be described, a study of the pages before us cannot fail to be of great use to the limited class for whom they were written. The book is well illustrated, having no fewer than 337 figures; these would have possessed a much greater value had dimensions been more generally given. From the point of view of the highly-trained chemist, it is perhaps to be regretted that valuable space is occupied by descriptions of certain machines of well-known types, such as common weighing machines. No doubt the volume is rendered more complete by the inclusion of such matter, yet it would seem of far greater importance that a chapter should have been added dealing with the many useful types of pressure and temperature regulators and their applications. It could hardly be expected that all parts of the book should be equally up to date; the account given of pyrometers is notably incomplete, no mention being made, for instance, of the now well-known instrument designed by Le Chatelier. English students may find in this compilation a useful index serving as a guide to direct their attention to the most important mechanical devices used in chemical operations; but we think that they will benefit more by undertaking the additional labour of unearthing details from the many admirable treatises and dictionaries already in existence in their own language. W. T.

Air, Water, and Disinfectants. (Manuals of Health Series.) By C. M. Aikman, M.A., D.Sc. Pp. 126. (London: S. P. C. K., 1895.)

THIS little book contrives to tell us a great many most interesting and instructive facts, without for one moment running the risk of boring us. It is written in an attractive style, and whilst popular, the author never forgets what is due to the subjects he is discussing.

Microbes, not perhaps, without reason, furnish material for a substantial portion of the text, and free use is made of "Our Secret Friends and Foes," which, however, Dr. Aikman amply acknowledges.

The little section on "Dust particles in the air" contains an interesting *résumé* of Dr. Aitken's investigations, and as they have been, we believe, chiefly published in Edinburgh scientific journals, will doubtless suggest much that is novel to the general reader. Many such will be astonished to learn "that a cigarette smoker sends 4,000,000,000 particles of dust, more or less, into the air with every puff he makes," and that one cubic inch of the air of a room at night, when the gas is burning, may contain as many dust particles as there are inhabitants of Great Britain!

We cordially recommend this little book to all those who wish to obtain an accurate, though popular, idea of the nature of air, water, and disinfectants.

An Elementary Text-book of Anatomy. By Prof. H. E. Clark. (London: Blackie and Son, 1895.)

A TEXT-BOOK of anatomy, suitable as an introduction to junior students of medicine, and simple enough to be understood by all who wish to read about the structure of their bodies. The book is limited to the anatomy of the human subject, and is divided into seven sections, dealing respectively with the tissues, bones, joints, muscles, vessels (the heart, blood-vessels, and lymphatic vessels), nervous system, and internal organs. It contains numerous instructive illustrations, as well as a useful glossary, and is altogether a serviceable elementary manual of anatomy.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Liquefaction of Gases.

IN a long letter which you published in NATURE of February 14, Mr. Pattison Muir charged me with appropriating the work of Olszewski and passing it off as my own. I replied at some length, not on account of the intrinsic importance of the attack, but because there are always persons ready to assume that a charge of this kind, by whomsoever made, must be unanswerable unless it is answered. But as I can conceive nothing more uninteresting to your readers or myself, than a mere dialectical controversy with Mr. Muir, my reply to his letter published on the 21st will be brief.

"A careful study" of my previous letter has not enabled Mr. Muir to substantiate his original charge of wilful piracy. On the contrary, he entirely shifts his ground. He extracts four clauses from my reply and proceeds to deal with them, ignoring altogether the only question of the smallest importance, namely, the *one claim made by himself* to have convicted me of dishonest appropriation of another man's work.

The third claim found in my reply by Mr. Muir, which is the all-important one, is, to use his own language, that in "1886 I liquefied oxygen by passing the gas through a long copper coil surrounded by liquid ethylene, and that my apparatus made it possible to transfer the liquid oxygen to a glass vessel wherein it could be used as a cooling agent." Well, the only question here is whether I did or did not do what I claim to have done in a public lecture delivered and published in the year 1886, and this question Mr. Muir shirks.

Until Mr. Pattison Muir can declare that after trial an apparatus constructed according to the plan given in 1886 is essentially defective, and will not deliver liquid oxygen in a manner at all comparable to the Olszewski steel cylinder, described in the Cracow *Bulletin* of 1890, let him acknowledge at least that the case of Prof. Olszewski, which he championed in his last letter, will have to be abandoned.

Having failed to overthrow a single one of the claims which he himself after "careful study" holds me to have made, Mr. Muir falls back upon a general attack upon the scientific work "that is attributed to the Fullerian Professor at the Royal Institution." With what is attributed to me by others, I have no concern. The low temperature work that has been commenced and so far developed in the laboratory of the Royal Institution comprises the following subjects: Construction of apparatus for the production of liquid air and other gases in quantity, improving high vacuum, vacuum vessels for storage and manipulation of liquid gases, solid air, radiation at low temperatures, thermal transparency of liquid gases, refractive indices of oxygen, nitrogen, and air; spectroscopy of liquid oxygen and air, thermo-electric inversions, latent and specific heats, chemical action, magnetic properties, breaking stress of metals, solid matter and argon in liquid air, phosphorescence and photographic action, liquefaction of hydrogen, &c. The abstracts of the results of these investigations have been published, and if Mr. Pattison Muir would only take a little trouble he could find them. In due course, and when I think proper, fuller details will be published. Mr. Muir's case is, however, that my intellectual pap comes from Cracow, and that I have followed in the wake of the researches of his client. On referring to Prof. Olszewski's record of work since his alleged invention of the way to use liquid oxygen as a cooling agent in 1890, I find that with the exception of the refractive index of oxygen, which was anticipated by Prof. Liveing and myself, and an attempt to confirm the late Prof. Wroblewski's critical constants of hydrogen, the work carried on at the Royal Institution and at Cracow have *had nothing in common*. It is not my business to inquire why Prof. Olszewski should take five years over this work, any more than it is legitimate for Mr. Muir to complain that I ought to have done more with my apparatus of 1886, than cool a piece of meteorite or expand liquid oxygen into a vacuum. No doubt by implication Mr. Muir intends to convey that any success at the Royal Institution was due to the use of a steel cylinder instead of the copper coil of 1886, and that suggestion I have to emphatically contradict, seeing that a steel cylinder never was used in any part of the apparatus employed for the liquefaction of gases. Under the circumstances it will be for Mr. Pattison Muir to explain what new information I could derive from Prof. Olszewski's alleged invention of 1890 which had not been already involved in the construction and use of my 1886 apparatus. All this, however, does not relieve Mr. Muir from his embarrassment. He charged me with having attributed to myself work done by other men, and to this charge I pin him. Having failed in his first attack, he has changed his ground, ignored the evidence of dates and facts which he cannot overthrow, and made a second attack in a form chosen by himself. This also has failed ignominiously. It is to be hoped that in future, when scientific investigators enter on priority discussions, the real combatants will be left to their polemics without the interference of third persons.

Royal Institution, February 26. JAMES DEWAR.

On Certain Questions of the Theory of Gases.

§ 1. I PROPOSE to answer two questions:—

(1) Is the Theory of Gases a true physical theory as valuable as any other physical theory?

(2) What can we demand from any physical theory?

The first question I answer in the affirmative, but the second belongs not so much to ordinary physics (let us call it orthophysics) as to what we call in Germany metaphysics. For a long time the celebrated theory of Boscovich was the ideal of physicists. According to his theory, bodies as well as the ether are aggregates of material points, acting together with forces, which are simple functions of their distances. If this theory were to hold good for all phenomena, we should be still a long way off what Faust's *famulus* hoped to attain, viz. to know everything. But the difficulty of enumerating all the material points of the universe, and of determining the law of mutual force for each pair, would be only a quantitative one; nature would be a difficult problem, but not a mystery for the human mind.

When Lord Salisbury says that nature is a mystery,[1] he means, it seems to me, that this simple conception of Boscovich is refuted almost in every branch of science, the Theory of Gases not excepted. The assumption that the gas-molecules are aggregates of material points, in the sense of Boscovich, does not agree with the facts. But what else are they? And what is the ether through which they move? Let us again hear Lord Salisbury. He says:

"What the atom of each element is, whether it is a movement, or a thing, or a vortex, or a point having inertia, all these questions are surrounded by profound darkness. I dare not use any less pedantic word than entity to designate the ether, for it would be a great exaggeration of our knowledge if I were to speak of it as a body, or even as a substance."

If this be so—and hardly any physicist will contradict this—then neither the Theory of Gases nor any other physical theory can be quite a congruent account of facts, and I cannot hope with Mr. Burbury, that Mr. Bryan will be able to deduce all the phenomena of spectroscopy from the electromagnetic theory of light. Certainly, therefore, Hertz is right when he says:[2] "The rigour of science requires, that we distinguish well the undraped figure of nature itself from the gay-coloured vesture with which we clothe it at our pleasure." But I think the predilection for nudity would be carried too far if we were to forego every hypothesis. Only we must not demand too much from hypotheses.

It is curious to see that in Germany, where till lately the theory of action at a distance was much more cultivated than in Newton's native land itself, where Maxwell's theory of electricity was not accepted, because it does not start from quite a precise hypothesis, at present every special theory is old-fashioned, while in England interest in the Theory of Gases is still active; *vide*, among others, the excellent papers of Mr. Tait, of whose ingenious results I cannot speak too highly, though I have been forced to oppose them in certain points.

Every hypothesis must derive indubitable results from mechanically well-defined assumptions by mathematically correct methods. If the results agree with a large series of facts, we must be content, even if the true nature of facts is not

[1] Presidential Address to the British Association at Oxford.

[2] Hertz, "Untersuchungen über die Ausbreitung der elektrischen Kraft," p. 31. (Barth, Leipzig, 1892.)

revealed in every respect. No one hypothesis has hitherto attained this last end, the Theory of Gases not excepted. But this theory agrees in so many respects with the facts, that we can hardly doubt that in gases certain entities, the number and size of which can roughly be determined, fly about pell-mell. Can it be seriously expected that they will behave exactly as aggregates of Newtonian centres of force, or as the rigid bodies of our Mechanics? And how awkward is the human mind in divining the nature of things, when forsaken by the analogy of what we see and touch directly?

The following assumptions, while not professing to explain the mysteries to which Lord Salisbury alluded, nevertheless show that it is possible to explain the spectra of gases while ascribing 5 degrees of freedom to the molecules, and without departing from Boscovich's standpoint.

Let the molecules of certain gases behave as rigid bodies. The molecules of the gas and of the enclosing vessel move through the ether without loss of energy as rigid bodies, or as Lord Kelvin's vortex rings move through a frictionless liquid in ordinary hydrodynamics. If we were to take a vessel filled with one gram of gas kept during an infinitely long time always at 0° C. and containing always the same portion of ether, every atom of ether and every atom of our gas molecules would reach the same average *vis viva*. If then we were to raise the temperature to 1° C. and to wait till every ponderable and every ether atom was in thermal equilibrium, the total energy would be augmented by what we may call the ideal specific heat. But in actually heating one gram of gas, the ether always flows freely through the walls of the vessel. It comes from the universe, and is not at all in thermal equilibrium with the molecules of the gas. It is true that it always carries off energy, if the outside space is colder than the gas; but this energy may be so small as to be quite negligible in comparison with the energy which the gas loses by heat-conduction, and which must be experimentally determined and subtracted in measuring the specific heat. Only certain transverse vibrations of the ether can transfer sensible energy from one ponderable body to another, and therefore a correction for radiant heat must be applied to observations of specific heats. These transverse vibrations are not produced (as in the older theories of light) by simple atomic vibrations, but their pitch depends on the shape of the hollow space which the molecule forms in the ether, just as Hertzian waves are not caused by vibrations of the ponderable matter of the brass balls, the form of which only determines the pitch. The unknown electric action accompanying a chemical process augments these transverse vibrations enormously. The generalised coordinates of the ether, on which these vibrations depend, have not the same *vis viva* as the coordinates which determine the position of a molecule, because the entire ether has not had time to come into thermal equilibrium with the gas molecules, and has in no respect attained the state which it would have if it were enclosed for an infinitely long time in the same vessel with the molecules of the gas.

But how can the molecules of a gas behave as rigid bodies? Are they not composed of smaller atoms? Probably they are; but the *vis viva* of their internal vibrations is transformed into progressive and rotatory motion so slowly, that when a gas is brought to a lower temperature the molecules may retain for days, or even for years, the higher *vis viva* of their internal vibrations corresponding to the original temperature. This transference of energy, in fact, takes place so slowly that it cannot be perceived amid the fluctuations of temperature of the surrounding bodies. The possibility of the transference of energy being so gradual cannot be denied, if we also attribute to the ether so little friction that the Earth is not sensibly retarded by moving through it for many hundreds of years.

If the ether be an external medium which flows freely through the gas, we might find a difficulty in explaining how it is that the source of radiant heat seems to be in the energy of the gas itself. But I still think it possible that the source of energy of the electric vibrations caused by the impact of two gas molecules in the surrounding ether, may be in the progressive and rotatory energy of the molecule. If the electric states of two molecules differ in their motions of approach and separation, the energy of progressive motion may be transformed into electric energy.

Moreover, it is doubtful whether emission of rays of visible light takes place in simple gases without chemical action. Certainly the light of sodium and that of Gassiot's tubes do not come from gases whose molecules are in thermal equilibrium.

It may be objected that the above is nothing more than a series of imperfectly proved hypotheses. But granting its improbability, it suffices that this explanation is not impossible. For then I have shown that the problem is not insoluble, and nature will have found a better solution than mine.

§ 2. Mr. Culverwell's objections against my Minimum Theorem bear the closest connection to what I pointed out in the second part of my paper, "Bemerkungen über einige Probleme der mechanischen Wärmetheorie," *Sitz. ber. der k. Wien. Acad.* vol. lxxv. 1877. There I pointed out that my Minimum Theorem, as well as the so-called Second Law of Thermodynamics, are only theorems of probability. The Second Law can never be proved mathematically by means of the equations of dynamics alone.

Let us compare two motions of a dynamical system. At the beginning of the second motion, let the coordinates specifying the position of every part of the moving system, and the magnitudes of all the corresponding velocities, be the same as they were at the end of the first motion, but let the direction of every velocity be exactly reversed. Then in the second motion the system moves exactly in the opposite way to what it does in the first; hence, if for the first motion we have

$$\int \frac{dQ}{T} < 0,$$

then for the second we must have

$$\int \frac{dQ}{T} > 0.$$

That is, if under certain conditions

$$\int \frac{dQ}{T} < 0,$$

we can always find other initial conditions which give for the same system with the same equations of motion,

$$\int \frac{dQ}{T} > 0.$$

In the same manner, Mr. Culverwell wishes to refute my Minimum Theorem. Mr. Culverwell's reasoning is suspicious, because by the same reasoning we could prove that oxygen and nitrogen do not diffuse. Suppose that initially one half of a closed vessel contains pure oxygen, and in the other half pure nitrogen; when the diffusion has advanced for a certain time, reverse the directions of all velocities, then the gases separate again, and, according to Mr. Culverwell's argument, we could believe that the probability that oxygen and nitrogen separate, is as great as the probability that they mix.

Though interesting and striking at the first moment, Mr. Culverwell's arguments rest, as I think, only upon a mistake of my assumptions. It can never be proved from the equations of motion alone, that the minimum function H must always decrease. It can only be deduced from the laws of probability, that if the initial state is not specially arranged for a certain purpose, but haphazard governs freely, the probability that H decreases is always greater than that it increases. It is well known that the theory of probability is as exact as any other mathematical theory, if properly understood. If we make 6000 throws with dice, we cannot prove that we shall throw any particular number exactly 1000 times; but we can prove that the ratio of the number of throws in which that number turns up to the whole number of throws, approaches the more to 1/6 the oftener we throw.

Let us now take a given rigid vessel with perfectly smooth and perfectly elastic walls containing a given number of gas-molecules moving for an indefinitely long time. All *regular* motions (*e.g.* one where all the molecules move in one plane) shall be excluded. During the greater part of this time H will be very nearly equal to its minimum value H (min.). Let us construct the H-curve, *i.e.* let us take the time as axis of abscissæ and draw the curve, whose ordinates are the corresponding values of H. The greater majority of the ordinates of this curve are very nearly equal to H (min.). But because greater values of H are not mathematically impossible, but only very improbable, the curve has certain, though very few, summits or maximum ordinates which rise to a greater height than H (min.).

We will now consider a certain ordinate $H_1 > H$ (min.). Two cases are possible. H_1 may be very near the top of a summit, so that H decreases if we go either in the positive or negative direction along the axis representing time. The second case is, that H_1 lies in a part of the curve ascending to or descending from a higher summit. Then the ordinates on the one side of H_1 will be greater, and on the other less than H_1. But because higher summits are so extremely improbable, the first case will be the most probable, and if we choose an ordinate of given magnitude H_1 guided by haphazard in the curve, it will be not certain, but very probable, that the ordinate decreases if we go in either direction.

We will now assume, with Mr. Culverwell, a gas in a given state. If in this state H is greater than H (min.) it will be not certain, but very probable, that H decreases and finally reaches not exactly but very nearly the value H (min.), and the same is true at all subsequent instants of time. If in an intermediate state we reverse all velocities, we get an exceptional case, where H increases for a certain time and then decreases again. But the existence of such cases does not disprove our theorem. On the contrary, the theory of probability itself shows that the probability of such cases is not mathematically zero, only extremely small.

Hence Mr. Burbury is wrong, if he concedes that H increases in as many cases as it decreases, and Mr. Culverwell is also wrong, if he says that all that any proof can show is, that taking all values of dH/dt got from taking all the configurations which approach towards a permanent state, and all the configurations which recede from it, and then striking some average, dH/dt would be negative. On the contrary, we have shown the possibility that H may have a tendency to decrease, whether we pass to the former or to the latter configurations. What I proved in my papers is as follows: It is extremely probable that H is very near to its minimum value; if it is greater, it may increase or decrease, but the probability that it decreases is always greater. Thus, if I obtain a certain value for dH/dt, this result does not hold for every time-element dt, but is only an average value. But the greater the number of molecules, the smaller is the time-interval dt for which the result holds good.

I will not here repeat the proofs given in my papers; I will only show that just the same takes place in the much simpler case of dice. We will make an indefinitely long series of throws with a die. Let A_1 be the number of times of throwing the number 1, among the first $6n$ throws, A_2 the number of times of throwing 1, among all the throws between the second and the $(6n+1)$th inclusive, and so on. Let us construct a series of points in a plane, the successive abscissæ of which are

$$0, \frac{1}{n}, \frac{2}{n}, \frac{3}{n}, \ldots,$$

the ordinates of which are

$$y_1 = \left(\frac{A_1}{n} - 1\right)^2, y_2 = \left(\frac{A_2}{n} - 1\right)^2 \ldots;$$

let us call this series of points the "P-curve." If n is a large number, the greater proportion of the ordinates of this new curve will be very small. But the P-curve (like the aforementioned H-curve) has summits which are higher than the ordinary course of the curve. Let us now consider all the points of the P-curve, whose ordinates are exactly $= 1$. We will call these points "the points B." Since for each point $y = (A/n - 1)^2$, therefore for the points B we have $A = 2n$; these points mark, therefore, the case where, by chance, we have thrown the number 1 in $2n$ out of $6n$ throws. If n is at all large, that is extremely improbable, but never absolutely impossible. Let v be a number much smaller than n, and let us go forward from the abscissa of each point B through a distance $= 6v/n$ in the direction of x positive. We shall probably meet a point, the ordinate of which < 1. The probability that we meet an ordinate > 1 is extremely small, but not zero. By reasoning in the same manner as Mr. Culverwell, we might believe that if we go backward (*i.e.* in the direction of x negative) from the abscissa of each point B through a distance $= 6v/n$, it would be probable that we should meet ordinates > 1. But this inference is not correct. Whether we go in the positive or in the negative direction the ordinates will probably decrease.

We can even calculate the probable diminution of y. We have seen that for every point B we have $A = 2n$ (*i.e.* $2n$ throws out of $6n$ turning up 1). If we move in the positive or negative direction along the axis of x through the distance $1/n$, we exclude one of the $6n$ throws, and we include a new one. When we move forward through the distance $6v/n$, we have excluded $6v$ of the original throws, and included $6v$ others. Among the excluded throws we have probably $2v$, among the included ones v throws of the number 1. Therefore the probable diminution of A is v, the probable diminution of y is $2v/n$ approximately. Because the variation of x was $6v/n$, we may write

$$\frac{dy}{dx} = -\frac{1}{3}.$$

But this is not an ordinary differential coefficient. It is only the average ratio of the increase of y to the corresponding increase of x for all points, whose ordinates are $= 1$. The P-curve belongs to the large class of curves which have nowhere a uniquely defined tangent. Even at the top of each summit the tangent is not parallel to the x-axis, but is undefined. In other words, the chord joining two points on the curve does not tend towards a definite limiting position when one of the two points approaches and ultimately coincides with the other.[1] The same applies to the H-curve in the Theory of Gases. If I find a certain negative value for dH/dt, that does not define the tangent of the curve in the ordinary sense, but it is only an average value.

§ 3. Mr. Culverwell says that my theorem cannot be true because if it were true every atom of the universe would have the same average *vis viva*, and all energy would be dissipated. I find, on the contrary, that this argument only tends to confirm my theorem, which requires only that in the course of time the universe must tend to a state where the average *vis viva* of every atom is the same and all energy is dissipated, and that is indeed the case. But if we ask why this state is not yet reached, we again come to a "Salisburian mystery."

I will conclude this paper with an idea of my old assistant, Dr. Schuetz.

We assume that the whole universe is, and rests for ever, in thermal equilibrium. The probability that one (only one) part of the universe is in a certain state, is the smaller the further this state is from thermal equilibrium; but this probability is greater, the greater is the universe itself. If we assume the universe great enough, we can make the probability of one relatively small part being in any given state (however far from the state of thermal equilibrium), as great as we please. We can also make the probability great that, though the whole universe is in thermal equilibrium, our world is in its present state. It may be said that the world is so far from thermal equilibrium that we cannot imagine the improbability of such a state. But can we imagine, on the other side, how small a part of the whole universe this world is? Assuming the universe great enough, the probability that such a small part of it as our world should be in its present state, is no longer small.

If this assumption were correct, our world would return more and more to thermal equilibrium; but because the whole universe is so great, it might be probable that at some future time some other world might deviate as far from thermal equilibrium as our world does at present. Then the afore-mentioned H-curve would form a representation of what takes place in the universe. The summits of the curve would represent the worlds where visible motion and life exist.

Oysters and Typhoid.

WITH reference to the article "Oysters and Typhoid," which appeared in your last issue, it may interest your readers to know that De Giaxa investigated some years ago the behaviour of the typhoid bacillus in sea-water, both in its natural and sterilised condition. He found that in ordinary sea-water the typhoid bacillus suffered very considerably in the competition with the numerous other water bacteria present, but it was still identified on the ninth day after it was first introduced. In sea-water in which all other bacteria had been destroyed, the typhoid bacillus was detected in very appreciable numbers on the twenty-fifth day. More recently, however, the existence of typhoid bacilli in sterilised sea-water has been examined by Cassedebat, and his results are not in accord with those obtained by Giaxa. Cassedebat found that whilst many pathogenic

[1] See Ulisse Dini, "Grundlagen für eine Theorie der Functionen einer reellen Veränderlichen" (Teubner, 1892, § 126), or Weierstrass, *Journal für die Mathematik*, Band 79, p. 29.

bacteria, amongst which were those of anthrax and cholera, lived for several days, in the case of the former twenty-one to twenty-four days, and in that of the latter thirty-five days and even longer, typhoid bacilli were destroyed already in the course of forty-eight hours in sterilised sea-water. These results tend to confirm those obtained by Prof. Percy Frankland, who, in his last report to the Royal Society Water Research Committee, states that the addition of 1 and 3 per cent. of common salt to ordinary Thames water into which typhoid bacilli were introduced, acted very prejudicially on the latter, although it stimulated the multiplication of many forms of water bacteria present in a most astonishing manner. Similar results were obtained with salted but sterilised Thames water infected with typhoid bacilli, and not only did the latter disappear very rapidly, but the typhoid colonies which were obtained on plate-cultures from this salt water exhibited in some cases a very abnormal appearance, attributable to the degeneration of the typhoid bacilli under these conditions, for on passing such colonies through a further process of plate-culture, they returned to their ordinary type.

Giaxa also experimented with fish, introducing pathogenic microbes *per os*. Unfortunately, he did not select the typhoid bacillus for these experiments, but took instead cultures of cholera and anthrax bacilli. He found that in both cases these micro-organisms were entirely destroyed in the course of a few hours. Experiments were also made with oysters and some varieties of mussel-fish. A small hole was bored in the shell, and vigorous broth cultures of anthrax and cholera bacilli were respectively introduced, after which the aperture was carefully closed with sealing-wax, and whilst some of the molluscs were replaced in sea-water, others were kept in glass dishes without any water. The latter lived for two days under these conditions. Six hours after the injection had taken place, and again at the end of twenty-four and forty-eight hours, the sealing-wax was removed and a small quantity of the fluid within the shell was taken out and plate-cultures made. In the majority of the experiments these pathogenic microbes had completely disappeared in six hours, whilst in only two instances were they detected in small numbers at the end of twenty-four hours, and in no case were they identified after forty-eight hours. These results were irrespective of whether the mollusc was kept in or out of water. In these investigations, therefore, there would appear to be no evidence that these pathogenic microbes (cholera and anthrax) were capable of being transmitted by means of these shell-fish. So far as I am aware, no one has followed up these interesting experiments, and in view of the serious allegations which have lately been made against oysters as transmitters of typhoid fever, it is a subject which might well claim re-investigation.

February 13. G. C. Frankland.

The Occurrence of very Cold Days.

It is usual to estimate cold by minima of temperature. But we may also consider it as expressed in maxima. A day may fairly be called "very cold" in which the maximum is not over freezing point. I propose to offer some account of the occurrence of such days at Greenwich in the fifty winter seasons (November to March) 1844–5 to 1893–4. (For brevity, I will designate each winter by the year in which it begins.)

These very cold days are not very frequent. In some winters there are none. The highest number is 27. The list is as follows :—

1844	13	1861	5	1878	18
45	—	62	—	79	10
46	11	63	4	80	12
47	4	64	5	81	—
48	2	65	—	82	2
49	7	66	12	83	—
50	—	67	6	84	1
51	—	68	1	85	3
52	—	69	8	86	5
53	4	70	10	87	5
54	15	71	1	88	2
55	4	72	1	89	1
56	3	73	3	90	27
57	2	74	5	91	5
58	1	75	4	92	9
59	6	76	—	93	5
60	9	77	—		
				Total	251

The total, 251, gives an average of 5·02 for each season. Ten of the winters had none of those days, and fifteen had numbers over the average.

The distribution in months was as follows :—

	November.	December.	January.	February.	March.
	6	96	111	34	4
Average	—	1·92	2·22	·68	—

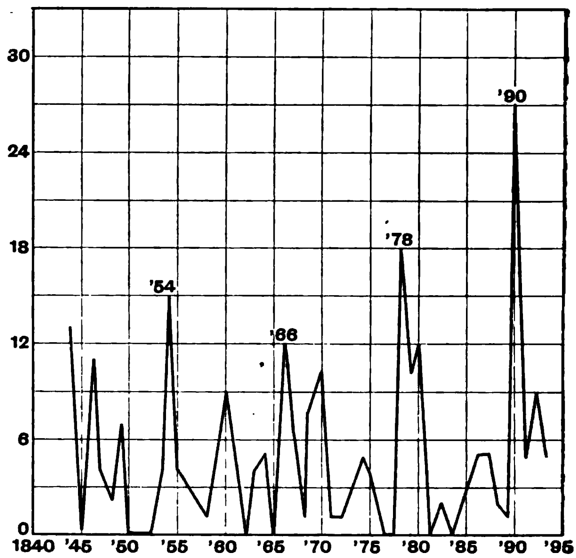
Such days are rare in November; and still more rare in March. The six cases in the former month were in 1849, 1858, 1861, 1887, and two in 1890; the earliest in the month being that in 1887 (16). The four cases in March were all in one year, 1845. January has most of such days (about 17 per cent. more than December).

The largest number in any one month was sixteen in December 1890; the next, twelve in January 1867 and January 1881.

We might perhaps note that relative maxima of the seasonal numbers occurred in 1854 (15), in 1866 (12), in 1878 (18), and in 1890 (27); giving three intervals of twelve years.

Measured by mean temperature of the three winter months, these winters were all severe (considerably under average) except 1866; in which, though January (1867) was very cold, December and February were both mild (the latter uncommonly so); thus the winter was above the average of mean temperature.

Days with Maxima not over 32° at Greenwich.



These very cold days most often come in groups (two or more in succession). The largest group was 10 in December '90; the next, 9 in January '81; then 6 in December '44, December '59, and January '93, &c.

Of the 251 days, 100 had maxima from 31° to 32°; 51 from 30° to 31°; 42 from 29° to 30°; 23 from 28° to 29°; 14 from 27° to 28°; and 21 under 27°, ranging down to 19°. The corresponding minima range from 29°·6 down to 7°·7, with greatest density about 22° to 24° (45 cases).

How are the maxima related to their respective minima? There is, of course, no rigorous proportionality; and we may often find high maxima with very low minima (*e.g.* December 29, '60, max. 31°·8, min. 10°·0), as also low maxima with relatively high minima (*e g.* January 15, '50, max. 26°·9, min. 25°·9). On an average, however, high minima go with high maxima, and low with low. Take the following:

I selected the cases in which the maxima was under 27°; there are 21. Of the corresponding minima only four were *over* 20°. On the other hand, taking the last 21 (of 46) cases in which the maximum was over 31°·5, one finds only four minima *under* 20°. The average minimum in the former case was 16°·4; in the latter 24°·4. The average difference of maxima and minima was in both cases about 8°.

It may be useful to put down a number of the coldest of these days (reckoned by maxima). Here are 12:

	Max.		Min.		Diff.
1. Jan. 5, '94 ...	19°·0	...	12°·8	...	6°·2
2. Jan. 4, '67 ...	21·2	...	7·7	...	13·5
3. Dec. 21, '55 ...	23·2	...	17·0	...	6·2
4. Dec. 22, '90 ...	23·7	...	13·4	...	10·3
5. Dec. 22, '55 ...	24·2	...	16·9	...	7·3
6. Jan. 10, '91 ...	24·4	...	12·0	...	12·4
7. Dec. 31, '74 ...	24·5	...	18·5	...	6·0
8. Jan. 7, '94 ...	24·5	...	18·1	...	6·4
9. Jan. 16, '81 ...	24·6	...	17·7	...	6.9
10. Jan. 15, '81 ...	24·8	...	14·0	...	10·8
11. Mar. 13, '45 ...	24·8	...	13·1	...	11·7
12. Jan. 14, '67 ...	24·9	...	13·9	...	11·0

These minima, it will be seen, range from 7°·7 to 18°·5. I do not enter on the question as to the coldest days measured by minima; but from a table by Mr. Charles Harding, giving the minimum at Greenwich in each winter, 1841–89 (*Quart. Journ. of R. Met. S.* vol. xvi. p. 165), extended to '93, I take the following cases (adding the maxima since '44):

	Min.		Max.		Diff.
(Jan. 9, '41 ...	4°·0)				
1. Jan. 5, '67 ...	6·6	...	32°·5	...	25°·9
2. Feb. 12, '45 ...	7·7	...	29·3	...	21·6
3. Dec. 25, '60 ...	8·0	...	30·0	...	22·0
4. Dec. 25, '70 ...	9·8	...	28·2	...	18·4
5. Feb. 19, '55 ...	11·1	...	33·4	...	22·3
6. Feb. 12, '47 ...	11·2	...	39·6	...	28·4

The lowest (4°·0) was in '41, and so beyond our fifty years' limit. It will be observed that those six maxima are all higher than any in our first list, exhibiting a wide range in the temperature of the very cold days thus measured.

In the present remarkable season, there have been, up to February 27, 17 of our "very cold" days, viz. 6 in January, and 11 in February (an unprecedented case). The lowest maximum is 27°·0, occurring on February 6, 7, and 9; the respective minima, 15°·1, 9°·6, and 10°·2. A. B. M.

Hesper and Phosphor.

IN his "History of the Inductive Sciences" (vol. i. p. 149, London, 1847), Whewell says:—"Pythagoras is said to have maintained that the evening and morning stars are the same body, which certainly must have been one of the earliest discoveries on this subject; and indeed, we can hardly conceive men noticing the stars for a year or two without coming to this conclusion" (*cf.* "The Planet Venus," by W. J. L., in NATURE, vol. xlix. p. 413). Now, what Whewell deemed so hardly conceivable appears to have actually occurred in old China. Wang Chung, the philosopher (*circa* 27–97 A.D.), in his work, renowned for its total repudiation of the then current errors, writes as follows:—"In the 'Book of Poems' it is said, '*Ki-ming* (Phosphor) exists in the east, and *Chang-kang* (Hesper) in the west.' In fact, however, they are but the phases of Jupiter and Venus, which, appearing now in the east, now in the west, received such distinct names from the ignorant bards" ("Lun-hang," Miura's edition, Kyôto, 1748, tom. xvii. pp. 12–13). Two facts are manifested in this passage. First, it shows that, celebrated for their astronomical acquirements in very archaic ages, as they are, the fact that the evening and morning stars are the same body, was not known to the Chinese of the eighth century B.C., when the poem entitled "Ta-tung" was composed, comprising the above-quoted line. Secondly, it shows that, even after the identity was established of the evening and morning stars, some Chinese, so well learned as Wang Chung, were ignorant of their own error: affirming that Jupiter as well as Venus appears now as Phosphor, now as Hesper, they have admitted the existence of two distinct Phosphori and two distinct Hesperi, and of a Phosphor essentially different from a Hesper. It is probable that some later scholars have tried to evade this intricacy by arbitrarily apportioning the two phases between the two planets; thus, Minamoto-no-Shita-zau, the Japanese poet and glossarist (909–983 A.D.), referring to a Chinese work "Kien-ming-yuen," which is perhaps lost now, identifies Jupiter (in Chinese: Sui-sing) with Phosphor (in Japanese: Aka-boshi), and Venus (in Chinese: Tai-peh) with Hesper (in Japanese: Yûtsutsu) ("Wamyô Ruijushô," Nawa's edition, Kyôto, 1667, tom. i. p. 1).

February 22. KUMAGUSU MINAKATA.

The Recent Storm in the United States.

THE storm of February 4–9 in the United States was notable for its extent and severity, recalling the memorable blizzard of March 1888. The Government Weather Bureau gives the following comparison of the two:—

	1888.	1895.
Snow	2 feet	5½ inches
Wind	50 miles	60 miles
Temperature at New York	4·8 above	3 below
Area	400 miles radius	1600 miles radius

It will be seen that the recent storm was more severe in everything except the amount of snow, and far more extensive. The entire southern portion of the country experienced severe cold, destroying fruits and vegetables to the value of 15,000,000 dols. in Florida alone. The zero line extended below the middle of Arkansas, and well down into Texas.

The storm reached New York on Thursday, February 7. On the previous afternoon, at about four o'clock, I observed at Brooklyn the unusual phenomenon of a double rainbow.

Brooklyn, February 11. WM. H. HALE.

SOME SUGGESTIONS ON THE ORIGIN AND EVOLUTION OF WEB-SPINNING IN SPIDERS.

IT cannot be reasonably doubted that one of the most interesting features connected with the natural history of spiders, is their habit of gaining a livelihood by spreading nets for the capture of prey. It may be that the large share of the attention of naturalists that this habit has attracted, is to be attributed to the fact that it appears to be confined in the animal world to spiders and men. This circumstance is of itself sufficiently remarkable to call for special comment; but its interest is not a little enhanced by the reflection, that since spiders made their appearance in the history of animal life vast ages before man came upon the scene, none of us can justly claim that any member of our own kind was the first in the field in the invention of the art of netting. Possibly, indeed, the oft-repeated and unavoidable observation of the efficacy of a spider's web for the purpose of catching otherwise unobtainable prey, may have roused in the brain of some intelligent hunter amongst our ancestors, the idea of the practical utility of a similar instrument for the capture of fish or other eatable forms of life. But if this be so, civilised man has long forgotten the debt of gratitude he owes to spiders. For, to the average individual amongst us, a spider is a thing to be looked upon and spoken of with fear and dislike amounting to loathing, and to be ruthlessly destroyed when a safe chance of destruction is afforded.

It is, perhaps, on account of this widespread repugnance that the science of arachnology has claimed within the last century far fewer students than many another less instructive branch of zoology. Moreover, such attention as it has received, is no doubt largely due, as suggested above, to the wonderful web-building powers that spiders possess. But those who have devoted their time to the study of webs, have, for the most part, contented themselves with observing and recording the structure and method of formation of the various types of nests and snares, and in claiming or disputing their value as a basis for a natural classification of the animals that make them. This has resulted, if in nothing else, at least in the accumulation of an array of facts sufficiently vast to make it possible to attempt to weave them into a coherent and intelligible whole, by trying to trace the origin and evolution of the habit of net-spinning. It is strange that but a small number of students seem to have occupied themselves with this most attractive aspect of the subject. With the exception, indeed, of a few authors who have here and there thrown out stray suggestions upon particular points, no one appears to have seriously set himself to the elucidation of the whole problem. It is true that in the second volume of his work upon the American orb-weaving spiders, Dr. McCook devotes a chapter to the "genesis of snares"; but since he does not appear to be able to attach great importance to the evidence in favour of evolution, his treatise on the subject practically resolves itself into a demonstration of the fact that, by starting at any point you please, in what is called "aranead spinning work," a series of gradations may be traced from one modification of architecture to another, from the simplest to the most complex, or from the most complex to the simplest. He thus succeeds in leaving his readers completely in doubt as to whether or not he intends one or all of his attempts at tracing the "genesis" of snares to represent what has actually occurred in the course of nature; and one closes the chapter without satisfactorily ascertaining if its writer has any definite views respecting a primitive form of spinning work. Yet, at the same time, it must be admitted, an impression remains that the suggestions that are put forward, based as they are upon an extensive knowledge of the subject, point in more than one instance to the true lines along which the web-spinning habits have been evolved.

In attempting to arrive at an understanding of the origin of any structure or instinct in an animal, one nowadays naturally refers for an explanation to what is hypothetically its ancestor, or, failing this, its ancestor's nearest ally. If this method of research be adopted in connection with the spinning powers of spiders, it is found that silken threads are fabricated by two allied groups of animals, both of which are believed by some students to stand, in many respects, nearer than spiders do to the ancestor of the class to which spiders, scorpions, mites, &c., belong. In one of these—the Chelifers, or book-scorpions—the presence of silk glands has long been known. In the other—the *Phrynidæ*—their existence is now, for the first time, I believe, pointed out. The function of the silk in the Chelifer is cocoon-spinning; and that it is materially the same in the *Phrynidæ* is shown by the easily verified fact, that the egg-case of the mother is secured to the lower surface of her abdomen by fine silk-like threads. One of the chief interests of this discovery lies in the circumstance, that of existing animals the *Phrynidæ* appear to be most nearly allied to the immediate ancestor of the spiders. We are, therefore, justified in concluding that originally the silk in spiders was utilised for the purpose of making a case for the eggs.

If, however, we consider the question from the standpoint of spiders alone, it seems to me that we should naturally arrive at the same result. For it is, *à priori*, probable that the primitive form of spinning industry was that particular kind which is now common to all groups. But when we pass in review the spinning work of the various tribes of spiders, we find that the habits of utilising the silk for constructing a snare, or drag-lines, for enswathing captured prey, or for purposes of locomotion, do not occur, by any means, invariably throughout the class. In fact, we cannot say of any one of them that it is characteristic of spiders. Not so, however, is it with cocoon-spinning. For, however different from each other in structure spiders may be, and however dissimilar in habits and mode of life, we yet find that the instinct of the mother to spin a cocoon for the protection of her eggs is never wanting.

Granting, then, the possession of silk-glands inherited from an ancestor, we may conclude that the first step in the development of web-spinning was the formation of the cocoon. What was the second? We know that a spider's care for her eggs does not, as a rule, cease with the completion of the cocoon: some species carry it about with them; others mount guard in its vicinity. Possibly the former was the original method of disposing of it. But if so, since such a habit must more or less impair the mother's activity and must render her a conspicuous object of attack, we can understand why it has been abandoned for the latter method by the great majority of spiders, and is now almost confined to those species in which the nomadic mode of life reaches its highest development. If, on the other hand, as seems more likely, the primitive habit was that of watching by the cocoon, we can understand that during the temporary period of quiescence thus enforced, the mother would naturally seek concealment and protection for herself; and since she possessed the instinct and material for constructing a receptacle for her eggs, it is possible to see how a slight modification of intelligence might have led her to extend the same protection to herself by weaving a covering over and around the retreat in which she had sought refuge. Then if an aperture for ingress and egress, for purposes of feeding, were left at any spot in the wall of such a protective domicile, there would arise, in a rudimentary form, what is known as the tubular nest or web. And the next simple but important step would doubtless be the adoption of the silken tube as a permanent abode for the mother after the dispersal of the young to shift for themselves.

As a matter of fact, some spiders have advanced no further than this stage. The females of some *Drassidæ*, for instance, spin a temporary retreat for themselves and their young at the breeding season; while others utilise the retreat as a permanent dwelling-place. Lastly, the view that the formation of a tubular retreat was in reality the second stage in the evolution of web-spinning, seems supported by the circumstance that the tube, whether accompanied or not by accessory developments, is, with the exception of the cocoon, the most constant feature in the spinning industry of spiders.

Adopting then, for these reasons, the conclusion that a simple tube was the primitive form of nest, it seems that the evolution of web-spinning has been carried out along two main lines. Along one there is a gradual elaboration of the tube until it culminates, so far as structural complexity is concerned, in the trap-door nest with which everyone is familiar; along the other, the tubular nest either ultimately disappears, or, retaining its primitive simplicity, it is to a greater or less extent superseded by the formation of a new structure—namely, the net for ensnaring prey.

It will not here be necessary to enter upon a discussion concerning the various forms of tubular nests that are constructed; but a few words respecting the probable origin of the door-making habit may prove of interest.

In the first place, it is important to note that the remarkable instinct to close the aperture of a tubular nest with a movable lid is possessed by spiders belonging to two groups. These are the *Lycosidæ*, or wolf-spiders, of which the South European *Tarantula* is a historical example, and the gigantic *Aviculariidæ*, which have won such a bad name for their alleged bird-catching propensities. But although there is no direct genetic affinity between the species composing these two families, it is nevertheless highly interesting to note that they present a close parallelism in nest architecture. In both there are species which form no nest, others which construct a simple silken tube, and others which close the aperture of the tube with a hinged-door. Yet it is certain that the last-named instinct has been independently acquired in the two cases. Moreover, it is probable, as will presently be explained, that in both cases it has been brought to its present state of perfection under stress of the same adverse conditions of life. As is well known, Mr. Moggridge long ago suggested that the instinct to construct the door may have arisen from the habit of closing the aperture of the tube in the winter and opening it again in the spring. This idea, in substance, has been adopted and further developed by Dr. McCook, who states, upon the authority of Mrs. Treat, that a North American species of wolf-spider (*Lycosa tigrina*) has acquired the instinct of sealing up the aperture of her nest during the breeding season of the Mason-wasps; for at this period these insects scour the country for spiders, in order that they may lay up a store of food for their young. When the wasps have disappeared with the close of their hunting and breeding season, the spiders venture again to remove the covering of their nests; but Mrs. Treat has made the further important observation, that some examples leave the covering attached at one point. Thus a genuine, though roughly-formed, trap-door nest is produced. In view of this circumstance, there cannot be much doubt that the permanent and highly-finished trap-door nest of the Russian *Lycosa opifex* has been similarly brought about, as M. Wagner, the discoverer of the species, has suggested, under the stress of the dire persecution from wasps to which spiders in general are subjected.

Being thus able to trace with some degree of certainty the steps by which the trap-door nest has been evolved in one group of spiders, namely, the *Lycosidæ*, we are justified in concluding, at all events until evidence to the contrary is forthcoming, that it has been evolved in the same way in the case of the *Aviculariidæ*—the trap-door spiders *par excellence*.

The primary influence, then, that has been at work in guiding the evolution of the architecture of the tunnel-making species, has apparently been that great necessity for the preservation of life, the avoidance of enemies. But if we turn to the other line, along which the web-building instinct has been developed, we find that the primary guiding influence has been that second great vital necessity, the acquisition of food.

As has been already stated, the origin of the webs which function as snares seems to be referable to a simple silken tent or tube, similar to that from which all the more or less complicated forms of tubular nests appear to have been developed. Perhaps the most rudimentary form of snare arose, as Dr. McCook has suggested, from the chance spinning of a few stray threads about the mouth of the tubular retreat; or, perhaps, an irregular network of threads spun around the aperture to interfere with the entry of such enemies as wasps, was the first step in the evolution of net-spinning; or even lines anchoring the tube securely in its site might have first served the purpose of catching prey. But, however this may be, it is clear, as Dr. Romanes[1] has poin ed out, that "there is much potential service to which the power [of net-spinning] may be put with reference to the voracious habits of the animal." Taking this into consideration with the variation in structure presented by different species of spiders, it is not surprising that there are many modifications of the net. Sometimes it is a thick, closely-woven horizontal sheet, which is continuous at one extremity with a tubular retreat, as in the case of one of our commonest house-spiders, *Tegenaria*; or, as in the equally common *Amaurobius*, the net is less regular in shape and less thickly woven, but is still continuous, with a silk-lined hole, in which the spider lurks; or again, the web, as in *Pholcus* or *Theridium*, may be composed of an irregular mesh-work of interlacing threads, without any such tubular retreat as that constructed by *Tegenaria* or *Amaurobius*; or, lastly, it may be composed of radiating and concentric lines, like that of our garden spider, *Epeira*: and it seems to be generally admitted that this orbicular web of *Epeira* manifests the greatest perfection of instinct, and is therefore to be regarded as the highest form of this kind of spinning-work. Consequently, the question concerning the possible steps by which such a structure has been evolved cannot fail to be of interest.

[1] "Animal Intelligence," p. 208.

In the first place, if all snares are traceable back to a common tubular origin, it may be taken for granted that those that are still associated with a tubular retreat are, *cæteris paribus*, of a more primitive type than those in which the tube has been abandoned. Furthermore, it may be confidently assumed that the habit of weaving the lines of the snare radially and concentrically in a definite and elaborate pattern, was preceded by the habit of arranging them irregularly and without order. Looked at from this point of view, the web of a *Tegenaria* or *Amaurobius* is a much less specialised structure than that of an *Epeira*. It may consequently be concluded that the complete orbicular snare of the latter animal, and of orb-weavers in general, has been derived from one which, like that of the tunnel-weavers, was composed of irregularly crossing threads, and was continuous at one extremity with a tubular domicile. Having arrived at this conclusion, we naturally appeal to nature for corroboration, and search for connecting links. Nor need we look far. For, taking first the tunnel-weavers, we find that a species of *Dictyna*, a spider nearly allied to our common *Amaurobius*, constructs a snare of which the threads are arranged radially and concentrically, but so roughly that the resemblance to the finished structure with which we are familiar in our garden-spiders is only remote. Nevertheless, one cannot avoid the conclusion that it represents an initial stage in the development of the perfect orb.

Turning, in the next place, to the orb-weavers, we naturally look out for snares constructed upon a more primitive plan than that which is typical of our English species of *Epeira*. But if there be any such in existence, we should reasonably expect, in accordance with our hypothesis, to find these simpler kinds associated with a tubular retreat. And our expectation would be justified by facts. For the large and handsome tropical genus *Nephilengys* spins a web which is structurally intermediate in character between that of *Epeira diademata* (our garden-spider) and that of the tunnel-weaver, *Dictyna*.[1] This web resembles that of *Tegenaria* and *Dictyna*, in consisting of a long silken tube, with an expanded funnel-shaped mouth opening directly upon an extended network of threads. But the latter, instead of being fashioned like that of the majority of tunnel-weavers, consists of a scanty mesh-work of lines arranged radially and concentrically with respect to the mouth of the funnel. In this particular it is similar to the net of our garden-spider, *Epeira*; but its area, instead of forming a complete circle, extends over only about one-third of this figure. The importance, however, of this distinction breaks down when the webs of other species of orb-weavers are taken into consideraton. For it is found that those of the Malaysian *Epeira beccarii*, as figured by Mr. Workman, and of the North American *Epeira labyrinthea* of Hentz, are completely circular, and yet the radial threads at the centre of the web spring from the mouth of a long silk tube, in which the spider lurks.

To all intents and purposes, therefore, there are not many links missing in the chain which starts with the web of a tunnel-weaver, like our house-spider *Tegenaria*, and terminates with that of our garden-spider *Epeira*. Furthermore, from the web of *Tegenaria* gradations may be traced backwards to the simple tubular retreat

[1] I have to thank my friend Mr. H. A. Spencer for sketches of the web of a species of this spider, and also for a living example of the animal which he kindly brought to me from Durban, while acting as medical officer on board the s.s. *Mexican*. I was fortunate enough to keep this spider alive for several months, and was thus enabled by personal observation to satisfy myself of the accuracy of Mr. Spencer's representation of the web.

of some of the tunnel-weavers belonging to the family *Drassidæ*, which merely construct a web to serve as a nest during the breeding season.

But to strengthen the probability that such an evolution of webs has ever occurred, it is necessary to be able to show in what respects a snare composed of radiating and concentric lines may excel in efficacy the sheet-like web of a *Tegenaria* or the tangled mass of threads of a *Phalcus*.

Firstly, it seems clear that threads which radiate directly from the spot where the spider is stationed, must more rapidly and more certainly inform her of the position of a struggling insect than irregularly crossing threads, which must spread the vibration indiscriminately in all directions; and the advantage of there being as little delay as possible on the spider's part, between her perception of the vibration and her arrival at the spot, where it originates, will be readily understood by those who have observed powerful insects break loose from the web before being seized by the spider. Secondly, the object of the concentric lines is evidently to support the radii and to fill up the spaces between them. It may perhaps be urged, however, that these two ends would be apparently more satisfactorily attained if the inter-radial areas were filled in by a complete sheeting of web, or, at all events, by a larger number of threads than is used by an *Epeira* for this purpose. But it must be remembered, in the first place, that in proportion as the mesh of the web becomes closer, the whole structure is rendered more and more liable to be beaten down by the rain, or blown into shreds by the wind, unless its supports are correspondingly multiplied; and in the second place, that every thread of white silk that is added to the web, tends to make it more and more conspicuous, and so to convert it into a visible object, which will serve as a warning to wary flies, and as an attraction to marauding wasps. And these are the two ends which it is particularly the spider's interest to avoid, inasmuch as they are alike detrimental to its chances of life.

It is legitimate, therefore, to conclude that the principal, if not the sole factor that has guided the evolution of the orb-web, has been the advantage gained by a delicacy of construction, involving comparative invisibility. But the making for invisibility has been kept in check, and has not been permitted to go to the length of interfering with the efficacy of the web as a net, for which a closeness of mesh and strength of thread sufficient to intercept and hold insects is a vital necessity for the spider.

Seeing, then, the advantage of the radiating threads as rapid and sure transmitters of vibration, and the necessity for a net as inconspicuous and delicate, and yet as strong as possible, we are led to inquire if the method of filling up the inter-radial spaces with concentric lines is not calculated to afford the greatest possible support to the radii. This inquiry must, I think, be answered in the affirmative. For if, as is the case here, the threads be drawn from points on one radius to points on another, so as to make the two interior angles on either side of them equal, these threads are the shortest that can be made; and the shorter the threads, the less their elasticity, and the greater the support they supply to the radii. This fact alone has been, one would think, of sufficient importance to bring about the concentric arrangement of the supporting lines. But more than all this, it is also to be borne in mind that the shortest threads utilise the smallest quantity of silk, and take the shortest time to spin. So that, in constructing a net of radiating and concentric threads, it appears to me that an *Epeira* economises both time and silk, and in addition renders her snare as strong and as serviceable, and yet as delicate and invisible, as possible.

R. I. POCOCK.

NEW METRIC STANDARDS.

THE President of the Royal Society, with Sir John Evans, and the following members of the Council—Dr. A. A. Common, Mr. W. Crookes, Dr. A. R. Forsyth, Prof. H. Lamb, Prof. J. H. Poynting—visited the Standards Department of the Board of Trade on Thursday, the 21st inst., for the purpose of inspecting the new metric standards which have been recently deposited with the Department. The President and Council were received by Sir Courtenay Boyle, K.C.B., the Secretary of the Board of Trade, and Mr. H. J. Chaney, Superintendent.

Two new metric standards, of length and mass respectively (*des prototopes nationaux*), were delivered to the Board of Trade by the International Committee of Weights and Measures at Paris on September 28, 1889, and the third and final standard was received from the Committee in December last. All three standards are deposited at the Standards Office, 7, Old Palace Yard, Westminster, and are available for use in the verification of metric standards for the purposes of science.

The two standards received in 1889 include a "line" standard metre measure (*mètre-à-traits*) and a kilogramme weight. The standard received last year is an "end" standard metre (*mètre-à-bouts*). These three standards, together with other similar standards supplied to twenty-one different States, are, *inter alia*, the outcome of the results of the labours of the International Committee for more than twenty years; and Great Britain is the first country which has received all three of such standards.

The standards were verified at the Bureau International des Poids et Mesure (*Pavillon de Breteuil, Sèvres, près Paris*), which bureau was established under a Metric Convention, dated May 20, 1875, signed by twenty different High Contracting States, exclusive of Great Britain, who finally joined the Convention in September 1884. The Committee is a self-elected body, and is founded and maintained by common contribution from all countries who are parties to the Convention of 1875. The bureau of the Committee is required to be near Paris, and has been declared to be internationally neuter. The Committee was charged in 1875 with the construction, restoration, and verification of new metric standards (*des prototypes internationaux*) to replace the ancient standards of France (*mètre et kilogramme des archives*), and with the verification of copies of the new standards for all the contracting States. By such means the international accuracy of metric standards is now assured throughout the world.

The Committee, which includes thirteen members, undertakes also the verification of standards for scientific authorities or persons.

The Mètre.

The two metric standards above referred to are made of iridio-platinum, or an alloy of 90 per cent. of platinum and 10 per cent. of iridium. The metres are in transverse sections, nearly of the form of the letter X, known as the Tresca form, and selected as being not merely as the most economical (iridio-platinum being a costly metal), but as being less affected by heat, practically non-oxidisable, and well adapted for receiving finely engraved lines. This alloy appears to be of all substances the least likely to be affected by time or circumstance, and has been preferred for standards purposes to rock-crystal, gold, &c. The lines on the *mètre-à-traits* are fine, and are barely visible to the naked eye.

The actual relation of our prototype metre No. 16 is as follows:—

At 0° C.

$$\text{No. } 16 = 1 \text{ metre} - 0{\cdot}6\,\mu \pm 0{\cdot}1\,\mu \text{ at } 0^\circ \text{ C.}$$

Here μ means one micron, or one-thousandth of a millimetre (or nearly 0·00004 inch), so that metre 16 may be said to have been verified with an accuracy of one part in a million.

The certificate of the verification of the end standard, or *mètre-à-bout* (étalon No. 6), will not be issued by the Committee until their general conference in September next; but this standard has been verified also with great accuracy, with a probable error of $\pm 0 \cdot 3 \mu$. In the verification of the end standard (*mètre-à-bout*) MM. Cornu and Benôit have introduced a method of reflection, by means of which it is unnecessary to bring the ends of the metre bar into contact with any touching surfaces, and thus the measuring ends of the bar may be carefully preserved and used. Only Austro-Hungary, Germany, Great Britain, and Russia have at present applied to the International Committee to be supplied with *end* standard metres.

Experiments with reference to light-wave analysis, which have been carried out under the directions of the International Committee by Dr. Michelson during 1893, with the view to the discovery of a radiation of light of sufficient homogeneity to serve as an ultimate standard of length, appear to show that it is possible within certain limits to reproduce the length of the metre by reference to such physical constant.

The Kilogramme.

The unit of mass of the kilogramme is determined by a piece of iridio-platinum in the form of a cylinder, the height and diameter of which are equal (thirty-nine millimetres). The kilogramme, No. 18, supplied to Great Britain has no distinguishing marks, and is highly polished. On analysis it showed very faint traces of ruthenium, rhodium, and iron. Its volume was found to be at 0° C.

Prototype 18 = 46·414 millilitres,

corresponding to a density of—

21·5454.

After its final adjustment it was found to be *in vacuo* at 0° C.

Prototype 18 = 1 kg. + 0·070 ± 0·002 milligramme.

So that it may be said that the kilogramme (kg.) has been verified with a probable accuracy of 0·002 parts in a million.

NOTES.

THE Committee of the Athenæum Club, acting under the Rule which provides for the annual election of persons "of distinguished eminence in science, literature, the arts, or for public services," have admitted to membership Prof. Bayley Balfour, F.R.S., and Sir W. H. White, K.C.B., F.R.S.

DR. F. J. LAUTH, the eminent Egyptologist, died at Munich on the 11th inst., at the age of seventy-three. He was Honorary Professor of Egyptology at the University of Munich, and Keeper of the Egyptian Collections. His writings on the antiquities of Egypt are numerous and important.

WE regret to announce the death of Prof. Heinrich Wild, of St. Petersburg. He was a Swiss by birth, and his work in magnetism and optics, as well as the magnetometer, polaristrobometer, and other instruments devised by him, are well known to students of physics.

IT is reported from Athens that the architect who has examined a number of the ancient monuments in Athens, states that the majority of them, and particularly the Parthenon and the Temple of Theseus, are in a dangerous state. The work of rendering them secure would cost a million drachmas. The Archæological Society intends to make an appeal to all countries for a portion of the money required to restore these wonderful monuments to a sound condition.

GENERAL ANNENKOFF, constructor of the Russian Central Asian Railway, has been appointed one of the vice-presidents of the International Congress of Geography to be held in London in July next. Russia will further be represented on that occasion by nine or ten other well-known men, including Senator Semenoff (vice-president of the Imperial Russian Geographical Society), M. Grigorieff (secretary of the same society), and Baron Wrangel (director of the Imperial Lyceum).

A REUTER telegram from St. Petersburg reports that a scientific expedition, organised by the French Minister of Public Works, has just arrived at Samarcand. The head of the expedition is M. Jean Chaffanjon, who has previously made a journey in South America, and he is accompanied by two naturalists, MM. Henri Mangine and Louis Gay. From Samarcand the expedition will proceed to Tashkend, and after completing all the necessary preparations there, will start on a journey of exploration in Tibet and other countries.

WE are informed by the trustees of the Australian Museum, Sydney, that Dr. E. P. Ramsay, after twenty years' service as Curator of this Museum, has retired, owing to ill-health. Dr. Ramsay's official connection with the Museum as Curator ceased from December 31, 1894. The trustees have appointed as his successor Mr. R. Etheridge, jun., formerly of the British Museum, and lately Palæontologist to this Museum, and to the Department of Mines of New South Wales, and who has on several occasions temporarily acted as Curator. Mr. Etheridge has entered on the duties of Curator.

DR. A. R. WILLIS will commence a course of six lectures to working men at the Museum of Practical Geology, Jermyn Street, on Monday, March 4. The subject of the course is "Heat Engines."

THE weather over these islands has been comparatively mild during the past week, and the higher temperatures which set in at the end of the prolonged frost were maintained for some days; subsequently there was a slight return of cold, with high barometric pressure, accompanied by strong north-easterly winds, and snow showers in various places. Frost occurred on Sunday and following nights, the lowest shade temperatures being 22° in the central parts of Ireland, while in the south-eastern and midland portions of England the readings were several degrees below the freezing point.

AT a recent meeting of the Vienna Academy of Sciences, the President announced that the late Herr Joseph Treith, director of the First Austrian Savings Bank, had bequeathed the whole of his considerable fortune to the Academy for the purpose of the advancement of science. The grants are to be apportioned by a committee of five, three of whom are to be appointed by the Academy, and two by the Minister of Education, the Academy to decide all doubtful questions. The branches of science to be encouraged are those for which there is no other official provision made. Among the subjects suggested are the physical structure of the earth and of the heavenly bodies. The income is to be divided every year into several grants, but if some great enterprise is to be undertaken, it shall be permitted to let the funds accumulate for not more than three years. The extension of higher instruction among all classes fitted for it by education, the strengthening of moral character, the advancement of technical education, the simplification of medical practice, and the furtherance of the material prosperity of the human race by invention and discovery, are the guiding principles indicated by the donor for the administration of his generous gift.

AT the last meeting of the Société Française de Navigation Aërienne, M. de Fonvielle gave an account of a paper by M. Andrée, the chief engineer of the Swedish Patent Office, read on the 14th inst. before the Stockholm Academy of Sciences. In that paper the Swedish aëronaut described a scheme to go to the North Pole in a balloon, and, to carry out his plans, he asked for a sum equivalent to about £7220. Although M. Fonvielle opposed a similar scheme put forward about seven years ago by two of his countrymen, he expressed himself favourable to the new undertaking, and his opinion seemed to have been shared by the Society. M. Andrée has already executed a number of ascents in very difficult circumstances. He is well acquainted with all the peculiarities of Arctic climates, having been one of the meteorologists of the Swedish 1882-83 expedition for observing the transit of Venus from Cape Thorsden. He hopes to start from this station in the month of July, 1896, as it appears that there are no great variations of temperature at that time of year. The balloon is to contain 186,000 cubic feet of gas, and the inflation process is to be carried out at Cape Thorsden by means of compressed hydrogen.

THE Select Committee of the House of Commons appointed to inquire into the existing systems of weights and measures in this country had a meeting on Tuesday, under the presidency of Sir Henry Roscoe. Evidence was given by Mr. H. J. Chaney, Superintendent of the Standards Department of the Board of Trade, who described the system under which the verification of legal standards is carried on at the Board of Trade by experts appointed for the purpose, and also gave an account of the different systems of weights and measures now in use in the United Kingdom. He stated that the Imperial and the metric systems were the only ones with which the Department had to do in England, but there were other local customary weights and measures in use. There were many weights and measures in use which were not legally recognised. Among these he mentioned the carat, the boll (used in Scotland), the ell, the coomb (used for measuring corn), the Winchester bushel, the butchers' stone of 8 lb., the miners' dish (used for weighing ore in Derbyshire), and the gauge (used in measuring plates) as examples of weights and measures which were not recognised by law. A number of anomalies which formerly existed—*e.g.* a ton of stone being different from a ton of other materials, &c.—had disappeared to a great extent under the operation of the Weights and Measures Acts of 1878 and 1889. The Scotch and Irish mile were still locally recognised, but for all statutory purposes a mile was 1760 yards. Practically the only two countries of any importance in Europe in which the metric system was not adopted were Great Britain and Russia. In Germany, Austria, France, Italy, Spain, and Portugal the metric system was the only system in use.

DURING recent years the advantages of work at biological stations have been recognised at various Universities. The Indiana University has lately shown its appreciation of the need for such research by deciding upon the establishment of an inland biological station on one of the lakes of Northern Indiana, probably Maxinkuckee. To begin with, the main object of the Station will be the study of variation. For this purpose it was thought that a small lake would present a limited, well circumscribed locality, within which the differences of environmental influences would be reduced to a minimum. The study will consist in the determination of the extent of variation in the non-migratory vertebrates, the kind of variation whether continuous or discontinuous, the quantitative variation, and the direction of variation. In this way it is hoped to survey a base line which can be utilised in studying the variation of the same species throughout their distribution. This study should be carried on for a series of years, or at least be repeated at definite intervals to determine the annual or periodic variation from the mean. A comparison of this variation in the same animals in other similarly limited and well-circumscribed areas, and the correlation of the variation of a number of species in these areas, will demonstrate the influence of the changed environment, and will be a simple, inexpensive substitute for much expensive experimental work. In connection with this study of the developed forms the variation in the development itself will receive attention; for instance, the variation in segmentation, the frequency of such variation, and the relation of such variation in the development to the variation in the adult, and the mechanical causes affecting variation. Admirable courses of instruction have been drawn up by Prof. Carl H. Eigenmann, the Director of the Station, to lead to the special investigations, and there is every indication that useful work will be accomplished.

DR. A. PETER gives, in the *Nachrichten von der Königlichen Gesellschaft der Wissenschaften zu Göttingen*, the results of a second series of cultural experiments with dormant seeds, taken from various depths in the soil of woodlands or forest. The forest in question of the present day is the site of villages and cultivation that disappeared several centuries ago; and some of the samples were taken from dense forest, 100 to 150 years old, under the shade of which there has been no surface vegetation for years. The principal point to investigate was the probable existence of seeds of cornfield weeds still possessing the power of germinating and developing into reproductive plants. Dr. Peters succeeded in raising a large number of plants belonging to about fifty different species, including some that are essentially weeds of cultivation; and he believes he has good grounds for supposing that the buried seeds of many pasture plants and cornfield weeds retain the vitality much more than half a century; that is, under the conditions he describes.

THE hundreds of Gulls that have lately come up the Thames in search of food seem only matched by a remarkable invasion of the north and north-east coasts, by the Little Auk (*Mergulus alle*) during January. Writing in the *Zoologist*, Mr. J. E. Harting says that on the 21st of that month, great numbers were observed passing south, both at sea and along the coast, and many were cast ashore in a helpless condition, exhausted in their attempts to withstand the stormy weather which has recently prevailed. In the neighbourhood of Redcar, as many as two hundred and fifty of these little birds have been counted; at Scarborough they were also numerous, and on the Norfolk coast one hundred and twenty have been captured. Another result of the severe weather and snow during the third week in January, was that the Grouse in Yorkshire left the moors in packs, and migrated to the lower grounds in search of food and shelter. It is pointed out that an exodus of this kind is of extremely rare occurrence; the last one being during the severe winter of 1886.

IN the *Meteorologische Zeitschrift* for December last, Prof. G. Hellmann gives a very interesting account of the invention of the barometer which has now been in use 250 years. Torricelli, who died at the early age of thirty-nine years, was too busily engaged in mathematical studies to publish an account of his discovery, but on June 11, 1644, he wrote a description of it to his friend Ricci. This letter, and Ricci's objections to the experiment, were published in 1663 by C. Dati, a friend of Torricelli's, and as this work is now exceedingly scarce, Prof. Hellmann has reprinted the correspondence, in the original Italian, in the above-mentioned journal. Some of the paragraphs are noteworthy, especially those in which Torricelli states that it was not merely a question of producing a vacuum, but of making an instrument which would indicate the changes of the atmosphere. The first continuous barometrical observations appear to have been made in France. In England they were first taken by Robert Boyle, about the year 1659, to whom we owe the invention of the word "barometer."

SOME time ago we gave an account of the considerable extension of the ultra-violet photographic spectrum obtained by Dr. Victor Schumann, of Leipzig, by eliminating the air between the source and the sensitive plate, which was found to exert a strong absorption upon the rays of shortest wave-length. This work has been carried on since with great success. At a recent meeting of the Vienna Academy, Dr. Schumann announced that he had improved his plates and his "vacuum spectrograph" so as to obtain results in a few minutes which used to take as many hours. The hydrogen spectrum shows a further lengthening, and the spectra of cobalt, iron, aluminium, zinc, and cadmium have also been considerably extended beyond 170 $\mu\mu$. This limit, although far beyond the ordinary limits of the photographic spectrum, was due to a residue of air and electrode vapour. The absorptive effect of air upon the most refrangible rays was traced down to thicknesses below 0·01 mm. Hydrogen also shows a strong absorption for these extreme rays, especially if insufficiently dried.

HERR K. MACK, working in the Hohenheim Physical Institute, has succeeded in demonstrating the occurrence of double refraction of electric waves in wood. That electric waves, unlike light waves, are capable of penetrating wood, was already found by Hertz. "It is not without surprise," he says in his classical work on the "Propagation of Electric Force," "that one sees the sparks appear inside a closed room." But the fact that waves of electric force are transmitted in a different manner accordingly as they vibrate across or along the fibre of the wood, has only just been proved by Herr Mack, who gives a full description of his method in the current number of *Wiedemann's Annalen*. It is well known that two Nicoll prisms transmit no light when their principal planes are crossed, but that light may be made to appear by inserting a doubly-refracting substance between them. For the Nicoll prisms substitute Hertzian concave mirrors with their focal lines crossed, and, instead of the tourmaline or other doubly-refracting substance, insert a plate of wood 10 inches thick, with its fibre at 45° to each of the focal lines, and you have Mack's apparatus. The sparks, which are extinguished on crossing the two focal lines, reappear on inserting the wood in the manner indicated. This striking experiment forms another important link in the chain connecting the domain of light with that of electricity.

IN an admirable paper on the after-shocks of earthquakes (*Journal* of the College of Science, Imperial University of Japan, vol. vii. part ii.), Mr. F. Omori has attacked a somewhat neglected branch of seismology. In three recent Japanese earthquakes, those of Kumamoto in 1889, Mino-Owari in 1891, and Kagoshima in 1893, the after-shocks have been carefully recorded, and are here specially studied from the frequency point of view. Numerous tables are given, and also many curves showing the way in which the number of after-shocks varies with the time at different places. When their inequalities are smoothed away, these curves differ little from rectangular hyperbolas. At the same time, they show periodic fluctuations in the decrease of frequency of after-shocks. Besides the diurnal and annual fluctuations, six different periods have been ascertained, whose lengths range from a few hours to several months. In the case of the great Mino-Owari earthquake of 1891, the after-shocks were most numerous some distance to the south of the principal epicentral tract, which lay in the Neo valley. They also occurred more frequently along four axial lines, radiating from the vicinity of Kori, than in the neighbouring districts. Mr. Omori suggests that the principal earthquake was caused by the formation of some great fractures beneath the Neo valley, and that the axial lines indicate the positions of four weaker or deeper fractures, along which the crust is not yet in the way of steadily settling into equilibrium.

IN a paper recently published (*Journal of Geology*, May-June 1894; *Johns Hopkins University Circular*, January 1895), Prof. W. K. Brooks discusses from the zoological point of view a problem familiar to the geologist—the sudden appearance in the Lower Cambrian of a rich fauna in which most of the great classes of animals are represented by unmistakable forms. His conclusion is that early Cambrian times and those immediately preceding them formed a period of rapid modification induced by the first colonisation of the sea-bottom. His arguments may be briefly summarised thus:—Embryology indicates simple pelagic forms, as the ancestors of all the great animal stems. The existing pelagic fauna consists in part of small and primitive forms, and in part of the specialised descendants of shore or bottom forms. The fact that the latter are almost exclusively carnivorous indicates the enormous wealth of plant-life, mostly of minute forms, on which ultimately the existence of all the fauna depends, and shows the extremely favourable character of the conditions of pelagic life to simple organisms. The supply of these simple organisms is inexhaustible, and on them the bottom-fauna also depends for food. It is suggested that the evolution of all the main stems of animal life took place at the surface of the ocean, but that when their descendants had colonised the bottom the crowding that soon ensued there led to fierce competition, especially between nearly related forms, and to the specialisation of the types already established, but not the production of new types. The development of hard skeletons was an early result of these conditions. Geologists will certainly find many points to criticise in Prof. Brooks's suggestions, but they constitute an important addition to the discussion of faunal origins.

ONE of the many botanic stations the advancement of which has been promoted by the Director of the Royal Gardens at Kew, is that at Aburi on the Gold Coast. A few interesting facts referring to the establishment and present condition of this station are given in the *Kew Bulletin* for January, from which the following information has been gathered. The site is in the hills, at an elevation of about 1400 feet, overlooking the sea-board, near Accra and Pram Pram. In addition to its suitability for the growth of economic plants, Aburi is a valuable resort for European invalids. The locality has been greatly improved of late years, and it promises to become the centre of activity for many cultural industries started by the Botanic Station. During the winter of 1893–94 Mr. William Crowther, the curator (appointed in 1890), was deputed to visit the West Indies "to observe the system pursued there in the cultivation of economic plants, and to bring back such useful seeds and plants as might with advantage be introduced to the Gold Coast." Mr. Crowther very successfully carried out the object of his mission, and published a detailed report. Since then the work of the Aburi Station has made excellent progress. The inception, as well as the actual work, so far accomplished in botanical enterprise at the Gold Coast, is entirely due to the Governor, Sir W. B. Griffith. He has given warm and consistent support to the station, and personally encouraged in every way the efforts of the curator.

THE *Forschungsberichte* (Theil 3, 1895) of the biological station at Plön, recently published, contains a number of interesting papers on the flora and fauna and on the biological phenomena of the lakes adjoining the station. Among the contents may be mentioned the copious reports on the flora by Drs. Klebahn and Lemmermann, the faunistic contributions of Dr. Zacharias, and the memoirs of Drs. Zacharias and Strodtmann on the Plankton of the lakes. The investigation of the movements, periodicity, and changing quantity of floating organisms in inland waters can be pursued with such ease and completeness, as compared with marine phenomena, that biologists may look forward to the early achievement of valuable results by Dr. Zacharias and his assistants. The present report goes far to justify this expectation.

THE history of the Royal Microscopical Society, as told by Mr. A. D. Michael in his presidential address last month, is contained in the February *Journal* of the Society.

A BOOK of gummed labels, for the chemical laboratory, having the names of 750 special reagents, &c., printed upon them, has been compiled by Mr. W. H. Symons, and published by Messrs. A. Gallenkamp and Co.

WE are always glad to see the Reports of the Natural Science Societies of our Public Schools. The twenty-fifth annual report of the Wellington College Society has just come to hand, and the abstracts of the lectures delivered under the auspices of the Society, as well as the records of observations in various branches of science, show that excellent work is being done in creating and fostering interest in natural knowledge.

MR. H. WARINGTON SMYTH'S "Notes of a Journey on the Upper Mekong, Siam," read before the Royal Geographical Society just a year ago, have been published in a handy and attractive form, for the Society, by Mr. John Murray. Siamese and Laos life are vividly described in the volume, and interesting information is given with regard to the geographical and general features of the country traversed.

THE Society for the Protection of Birds was called into existence to protest against the slaughter of birds for decorative purposes. It now numbers more than eleven thousand members, and the fourth annual report shows that it plays an important part in preventing the extermination of our rarer species of birds. Owing to the Society's efforts, that remnant of primitive ornamentation—the bird-wearing fashion—is on the decline. The Bill passed last July, to amend the Wild Birds' Protection Act of 1880, is given at length in an appendix to the report.

A HANDY work of reference, occupying an intermediate position between a mere school dictionary and a bulky lexicon, is Ogilvie's "Student's English Dictionary," a new edition of which, edited by Dr. C. Annandale, has been published by Messrs. Blackie and Son. The new issue has been so greatly changed and augmented, that it is practically a fresh work. A large number of scientific and technical terms, many of them recently introduced, as well as thousands of other words, have been added. The woodcut illustrations have been more than doubled, there being now nearly eight hundred of them. Experience has taught us that the "Students' Dictionary" rarely disappoints the inquirer; in its improved and enlarged form, it will be even more useful.

MESSRS. MACMILLAN AND CO. will shortly publish an important work on "Meteorology," by Mr. T. Russell. The book has for its main object the explanation of the use of weather-maps for the purpose of making forecasts. The various forms of meteorological instruments are described, and a general view is taken of all knowledge connected with the science of meteorology, and of interest in relation to weather changes. To a large extent, the volume refers to weather prediction in the United States, and to the use of weather-maps in the prediction of floods along the lower Ohio and Mississippi Rivers. It will, however, also appeal to European meteorologists, as well as assist in the development of scientific weather observation and prediction. Another work which will very soon be published by the same firm, is a translation of the late Prof. A. de Quatrefages' "Les Pygmées." This volume, which is the second in the Anthropological Series, has been translated by the editor of the series, Prof. F. Starr, of the University of Chicago.

THE atomic weight of tungsten has been subjected to a careful revision by Prof. E.F. Smith, of the Pennsylvania University, and the specific heat of the pure metal again determined. Two independent series of atomic weight determinations have been carried out, in which Prof. Smith has been assisted, respectively, by Miss M. E. Pennington and Mr. E. D. Desi, and accounts of the work are contributed to the current issue of the *Zeitschrift für Anorganische Chemie*. In the first series the method employed consisted in the reduction of pure tungstic acid to metal in a stream of pure hydrogen, and then determining the amount of oxygen absorbed by the metal upon conversion of the latter into tungstic anhydride by ignition in contact with the air. The mean value of the atomic weight derived from nine such determinations, taking oxygen as 16, is 184·92. The highest and lowest values obtained differed by only 0·02 from this mean value. The second series of determinations were based upon the estimation of the amount of water produced during the reduction of tungstic acid by hydrogen. Exceptional precautions were taken with the purification of the latter, in order to exclude error from this source. The mean of six experiments affords the value 184·70 for the atomic weight of tungsten, the greatest difference between the individual values being only 0·07. The slight difference of 0·2 between the results derived from the two methods of work is probably to be ascribed partly to the difference in the methods, and partly to the different personal factors involved. The mean of the two series, 184·8, may therefore be taken as representing a close approximation to the true atomic weight of tungsten. This value is considerably higher than the currently accepted one, 184·02, the number afforded by Clarke and Becker's recalculation of the experimental results of older determinations. The increase is in all probability due to the great pains which have been taken to remove the last traces of the lighter molybdenum from the tungstic acid employed, a task which is particularly difficult, and which most likely has never previously been so completely achieved.

THE specific heat of the pure tungsten obtained during the course of the atomic weight determinations has been ascertained by Prof. Smith in conjunction with Mr. Grodspeed The method adopted was that described by Joly in 1886, involving the use of the "gravimetric calorimeter." The final mean value arrived at for the specific heat of tungsten 0·0338, a result closely agreeing with former determinations o this constant. The atomic heat obtained by multiplying the new value for the atomic weight by this number expressing the specific heat is 6·25, a value in fairly close accordance with that usually accepted as representing the constant of Dulong and Petit for the truly metallic elements.

The additions to the Zoological Society's Gardens during the past week include a Lion (*Felis leo*, ♂) from India, presented by Her Majesty the Queen; a Black-striped Wallaby (*Halmaturus dorsalis*, ♂) from New South Wales, presented by Miss H. W. Howes; a Hairy-rumped Agouti (*Dasyprocta prymnolopha* from Guiana, presented by Miss W. B. Jackson; a Roseate Cockatoo (*Cacatua roseicopilla*) from Australia, presented by Mr. A. Reynart; four Triangular-spotted Pigeons (*Columba guinea*), two spotted Eagle Owls (*Bubo maculosa*) from South Africa, presented by Mr. J. E. Matcham; a Fieldfare (*Turdus pilaris*) British, presented by Mr. Gervase F. Mathew; two Lions (*Felis leo*, ♂ ♀) from India, deposited; an Eland (*Oreas canna*, ♀), two Collared Fruit Bats (*Cynonycteris collaris*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ORIGIN OF THE LUNAR FORMATIONS.—The experiments by which Scrope attempted to reproduce the characteristic features of the moon's surface have been repeated with slight modifications by M. Stanislas Meunier, and the results which he has obtained are certainly very suggestive, if, indeed, they do not furnish the key to the origin of the various formations which the moon presents to us. (*Comptes rendus*, January 28.) Plaster is mixed with water in which a little glue has been dissolved to prevent too rapid setting, and the mixture is heated in a frying-pan over a gas-burner until ebullition commences; the gas is suddenly turned off at an opportune moment, and the mass is left to cool undisturbed. Experimenting in this way, and by varying the consistency of the paste, M. Meunier has obtained many features besides the intermingling circular cavities produced by Scrope. The central peaks which are so frequently noticed in lunar craters are reproduced perfectly, being formed at exactly the same time as the circular borders, and even resembling their lunar prototypes in being generally somewhat lower than the edges of the craters. Further, the artificial craters tend to form in groups of two or three, or even more, and sometimes one ring will envelope several; some parts may be covered with cavities, with or without central peaks, and relatively large smooth areas at once recall the lunar "seas." If the experiment be carried on until nearly the whole of the water is evaporated, fissures also make their appearance.

By covering the paste with fine grey sand at the moment it begins to boil, the results are said to be still more striking, and better adapted for photography.

M. Meunier expresses the opinion that the moon has failed to pass through all the planetary stages, in consequence of the original relative scarcity of fluids, and he believes this conception to be confirmed to some extent by another modification of the experiment, in which the paste is covered with a rather thick layer of sand, representing the rocks forming the earth's epidermis; the "volcanic" manifestations then change character, and more nearly approach terrestrial types.

γ CASSIOPEIÆ.—This star has always possessed a special interest to spectroscopic observers since the discovery of bright lines in its spectrum by Secchi. Continued observations seemed to suggest a periodicity in the visibility of the bright lines, but this question can now be attacked more completely by the photographic method. Fifty-three photographs, extending over a period of six years, have been taken at South Kensington, and a first examination of the negatives has led to several important conclusions (*Roy. Soc. Proc.* vol. lvii. p. 173). The lines of hydrogen were constantly bright in the period covered by the photographs, and other bright lines were also seen in all good photographs. Further, the lines of hydrogen are double in all the photographs taken with sufficient dispersion, and the distance between the components is constant within the limits of error in measurement. Other conclusions are that the bright lines of hydrogen are superposed on broad dark bands, and that there are also other ill-defined dark lines in various parts of the spectrum; these dark lines correspond very closely with the lines seen in the spectra of ζ Orionis and Bellatrix. "This at once contradicts Prof. Scheiner's recent statement that he does not believe it possible that dark lines can exist in the spectrum." Dark lines have also been observed and photographed by Keeler.

It will be seen that the spectrum presents numerous peculiarities, and an explanation of the physical condition of the star or stars which produce the different appearances is by no means simple.

THE IDENTITY OF DENNING'S AND BRORSEN'S COMETS.—It was pointed out in the *Astronomische Nachrichten*, No. 3271, that the orbits of the comet 1894 I (Denning), and Brorsen's comet, intersect in heliocentric longitude 285°, and that early in 1881 the two objects must have been close to one another near the point of intersection (see NATURE, January 24, p. 302). The elements used for the comparison were, in the case of Denning's comet, due to M. Schulhof. This computor gives new elements for the comet, in *Astr. Nachr.* No. 3276, and expresses an opinion upon the suggested connection. He thinks that the elements compared, with the exception of inclination, certainly present some points of resemblance. More important, perhaps, is the fact that the point of intersection of the two orbits is nearly their point of nearest approach to the orbit of Jupiter. Applying M. Tisserand's criterion for the connection between two orbits, the value 0·47 was found for Brorsen's comet, and 0·50 for Denning's. It is therefore concluded that the two comets formed at one time a single body, and that after their separation their orbits were more and more modified by Jupiter.

THE ANTITOXIC SERUM TREATMENT OF DIPHTHERIA.[1]

II.

The Treatment.

ASSUMING now that the antitoxic serum is available, how is it to be used? It has been strongly recommended that it should be used not only as a curative or direct therapeutic agent, but that it should also be used as a prophylactic—that is, as a protective agent against possible infection, especially during those periods when diphtheria is rife. It is almost too soon to consider this prophylactic property of antitoxic serum, as for some time to come the energy of those engaged in the preparation and use of this serum must be directed towards obtaining a sufficient supply for the treatment of cases of developed diphtheria.

Results of this Method of Treatment.

It may be well to consider what have been the results obtained up to the present, and for this purpose the statistical method will probably carry most conviction, especially if it is possible to give full and accurate detail; and now that these statistics have been criticised not only by those who have used this treatment, but also by those who oppose it because it runs counter to their feelings and ideas, they are every day more and more trustworthy, much fuller, and more valuable.

It is first necessary to determine the average case mortality in diphtheria for some considerable period before the antitoxic treatment was introduced; then to see what has been the lowest case mortality during an equal and similar period for which we have any statistics; and lastly, to compare these with the case mortality of the period during which the antitoxic serum has been used.

In Table I. are given the mean annual death rates from diphtheria per million living in England and Wales and in London, in four periods of three years each.

TABLE I.

	1881-3	1884-6	1887-9	1890-2
England and Wales	144	166	173	192
London	213	227	315	377

Dr. Sykes gives the following statistics:—During the year 1892 there were 1962 deaths from diphtheria in London, whilst in 1893 there were 3265, or nearly twice as many deaths.

Now let us see what has been the case mortality. Statistics after correction give the following results. During 1893 there were 13,694 cases of diphtheria notified in London. The mortality amongst these cases was 3195 (*Lancet* statistics corrected), or 23·3 per cent.

Table II. gives further information, and enables us to see what is the diphtheria case mortality in large well-found hospitals.

TABLE II.—*Metropolitan Asylums Board: Admissions and Case Mortality, Diphtheria*, 1888–93.

Year.	No. of admissions.	No. of deaths.	Percentage of case mortality.
1888	99	46	46·4
1889	722	275	38·0
1890	942	316	33·5
1891	1312	397	30·2
1892	2009	583	29·0
1893	2848	865	30·3

Note.—Diphtheria cases have only been admitted into the Hospitals since October 23, 1888.

In Table III. are given statistics dealing with the diphtheria case mortality where the serum treatment has been used. Wherever possible, the case mortality over a considerable period is given in the last column of the table, for purposes of comparison.

[1] A lecture delivered at the Royal Institution, on Friday, February 8 by Dr. G. Sims Woodhead. (Continued from page 406.)

It is objected, however, that general statistics of this kind are of comparatively little value unless the age of the patient treated is given. In order to determine the foundation upon which this certainly very legitimate objection is based, I have taken four series of cases as reported, and have placed them side by side. The percentages of deaths at certain ages in the London Asylums Board hospitals before the serum treatment are given in Table IV., the percentages of deaths of four observers who have used the serum, in Tables V. and VI.

[1] There is probably some overlapping, especially in the Berlin figures. This fact must be taken into account in dealing with this table as a whole.

It is very important, however, that the period of the disease at which the treatment is commenced should be taken into account, for, as already indicated, experience has taught that the later the stages of the disease at which this serum is injected, the stronger must be the dose given. It is necessary, therefore, to separate the cases in which the treatment is commenced at an early period from those in which it is commenced only when the poison has had time to disorganise the tissues, and to render them incapable of reacting to the antitoxic serum.

The following table (VII.), given by Kossel, brings out the great importance of this element in keeping down the case mortality. In the first column is given the day of the illness on which antitoxic serum was first injected:—

TABLE VII.

Day of illness.	Treated.	Died.	Percentage.

	117	13	11·1

For statistical purposes, too, only those cases which have been bacteriologically examined and found to be due to the action of Loeffler's diphtheria bacillus should be accepted as being cases of true diphtheria. As most of the cases in which the diphtheria bacilli are absent run a much milder course, and are much more amenable to general treatment, and as many of these have been included under diphtheria in the old statistics, such elimination will necessarily make the record tell rather against the antitoxic serum treatment than in its favour.

From a somewhat extended experience (although condensed into a very short period of time) I am satisfied that this question of the Loeffler bacillus is most important, and that every case in which the serum is used should be bacteriologically examined.

It has been said, however, and said very truly, that statistics may be made to prove anything, and I have heard it said that the observation of a few cases of diphtheria under the antitoxic treatment is worth all the statistics that could be brought together for convincing a man of the value of the antitoxic serum treatment.

A distinguished physician, who has had charge of diphtheria wards for some time, informs me that the patients he sees now wear an entirely different aspect from those he saw before the serum treatment was adopted. Instead of being struck by the stupor, the pain, the difficulty of breathing, and the other distressing symptoms that so frequently manifest themselves during the course of this treacherous disease, he observes children with patches of membrane in the throat sitting up and playing with their toys. There is little of that distress of breathing, very little of the anxious look, and the wards altogether present a much more pleasant and genial appearance than he has ever before noticed. The other day I received a short note from another colleague, who has been going over the German hospitals to study this question, in view of taking out with him to the colonies a supply of antitoxic serum; he also states that this difference in the appearance of the diphtheria wards has impressed him far more than any statistics he has yet come across.

The alleged Ill-effects of the Use of the Serum.

It has been said that most unfavourable symptoms have followed the exhibition of this serum. There can be no doubt of the fact; but after a careful study of the cases reported, I am thoroughly convinced that a very large proportion of them, at any rate, are merely *post hoc*, and not *propter hoc*. There can be no doubt that a kind of nettle-rash makes its appearance during the course of treatment, and that this may be accompanied by pains in the joints. Both these conditions, however, are usually quite transient, and seldom give rise to permanent ill effects. Albuminuria has also been ascribed to this treatment; but any one who has had to deal with children not only suffering from diphtheria, but from any form of disease, and even from none at all, will bear witness that albuminuria in children is of comparatively frequent occurrence. It is not striking, therefore, that those who have hitherto paid little attention to this subject should, when they come to make a careful examination of children affected with diphtheria, find a considerable number of cases in which transient albuminuria is a prominent symptom. More than this, however, it has been my duty to examine a large number of cases in which diphtheria has proved fatal, and in these cases there were certain lesions in the kidney, so distinct and so frequently present, that in describing them I used to note simply "diphtheritic condition," and then describe in detail only those features in which the appearances differed from the type that I had in my mind. This will indicate to you that alterations in the internal organs, especially in the kidneys, such as would lead to marked interference with the performance of their proper functions, were present, and had been noted long before the antitoxic serum method of treatment came into use. I may give an example of what, under certain circumstances, might have been used as a powerful argument against the use of antitoxic serum. In the *Deutsche Medizinischer Wochenschrift* for December 20 of last year is reported a case of acute hæmorrhagic nephritis coming on after the use of Behring's curative serum. The patient recovered. But a similar case of acute hæmorrhagic nephritis in diphtheria, in which, however, the curative serum was not used, is reported in the same number of the same journal. The author of the second paper quotes some interesting statistics to show that albuminuria is of frequent occurrence in cases of diphtheria not treated with antitoxic serum. One observer found it in 131 out of 279 cases; another in 16 out of 53; another in 60 per cent. of all his cases; another in 227 out of 470. Suppression of urine has also been ascribed to the action of this agent; but here again, if a careful search be made of the records of diphtheria cases treated under the old method, it will be found that just as in scarlatina and acute specific infective diseases generally, but especially in those associated with rapidly supervening toxic symptoms, suppression of the urine is of common occurrence; and until we have statistics on these several points, which can be compared with those above mentioned, it will be impossible and unjust to ascribe conditions to the therapeutic agent which, so far as those best able to judge can see, are to be ascribed to the disease itself.

It has been held by some that the paralysis which is so common a sequel of diphtheria should disappear entirely under the use of what they are pleased to call a specific cure for the disease. It should be remembered that the antitoxic serum cannot make good any organic damage that has been caused by the action of the toxic products of the diphtheria bacillus. It may stop their action on the tissues, and it may stimulate the tissues to react against the poison, but to the tissues themselves must be left the process of repair; the *vis medicatrix naturæ* is alone responsible for the making good of damage already done. This damage may be done at a very early stage of the disease, and if the nerves or the muscles are attacked before the antitoxine is injected, then we must expect to find degenerations and evidence of these degenerations in the various forms of post-diphtheritic paralysis; but of this we may be sure, the sooner the poison is antagonised the less will be the risk of permanent damage to the tissues. It is for this reason, I believe, that the antitoxic serum treatment of diphtheria has been so much more successful than the antitoxic serum treatment of tetanus.

Conclusion.

The hope of success in diphtheria depends upon the early application of the remedy. One word of warning. It should not be accepted that this agent can reduce the cure of diphtheria to a mere process of injection. Everything must be done to improve the conditions under which the patients are treated, to maintain their strength, to give them fresh air, cleanly surroundings and good general hygienic conditions. It will be found withal that a certain number of deaths from rapid poisoning will take place, while a number of others will succumb in the later stages of the disease. This serum can no more act as a specific in every case than can quinine cure every case of malaria; but if properly used, we believe it will reduce the mortality in a very marked degree, and if at the same time those practical sanitary reforms and improvements for which our country is so justly renowned are carried out, we may expect that diphtheria as a scourge may gradually die out from our midst. As Dr. Seaton pointed out at Buda-Pesth, we have done more in this country to improve the conditions associated with most specific infective diseases than any other nation in the world. If, now, we can graft on to our system what is best in Behring's treatment, I am convinced that we shall soon have diphtheria statistics which will compare very favourably with any that have yet been presented. The antitoxic serum treatment is only one of our lines of defence against this disease; but so much progress has already been made along this line, that within a few years, or even months, we may fairly anticipate the announcement of still greater advances and successes.

DR. DUBOIS' SO-CALLED MISSING LINK.[1]

AT a meeting of the Royal Dublin Society, held on Wednesday, January 23, Dr. D. J. Cunningham, F.R.S., Professor of Anatomy in the University of Dublin, and Hon. Secretary of the Society, read a paper upon the characters presented by the fossil remains recently described by Dr. Eugene Dubois. (See NATURE, January 24, p. 291.) The following is an abstract of this communication.

The fossil remains are three in number, viz.: the upper part of a cranium, a right-upper wisdom tooth, and a left femur. These are believed to belong to the Pleistocene period, and, according to Dubois, present characters which justify him in placing the animal to which they belonged in a new family which stands midway between man and the apes. The specimens were found in Java, on the left bank of the Bengawan River, in the neighbourhood of Trinil. Each was exhumed at a different time, but all at the same level, viz. 1 m. below the dry-season level of the river, and from 12 to 15 m. below the level of the plain through which the stream has cut its way.

The characters assigned to the new family proposed by Dubois are the following: "Cranium absolutely and relatively to body-size, much more roomy than in simiidæ, but less roomy than in hominidæ; cranial capacity about two-thirds of the average capacity of the human cranium. The inclination of the cervical surface of the occiput distinctly stronger than in simiidæ. Dentition after the type of the simiidæ. Femur similar in its dimensions to that of man, and designed for the upright walk and attitude."

The leading peculiarities of the cranium of the so-called Pithecanthropus are: (1) the low depressed character of the cranial arch; (2) the extreme narrowness of the frontal region;

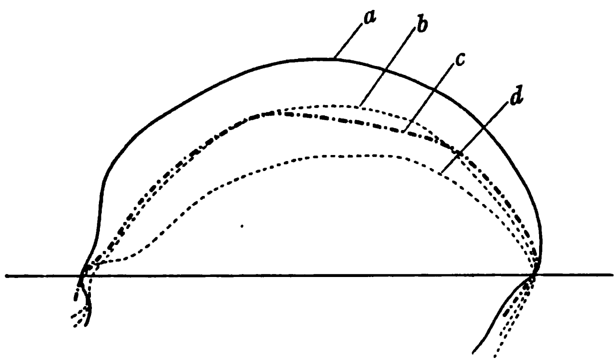

FIG. 1.—Outlines of the cranial arch of: *a*, ordinary Irish skull; *b*, skull of a microcephalic idiot; *c*, the fossil cranium described by Dubois; *d*, skull of a gorilla. The base-line is one which passes through the external occipital protuberance behind, and the centre of the glabella in front.

and (3) the striking development of the superciliary ridges. These are all to some extent simian features: and when outlines of the antero-posterior cranial arch of an ordinary Irish skull, of the skull of a microcephalic idiot (the brain of which presented many atavistic characters), of the fossil cranium, and of the skull of a young female gorilla, are reduced to the same size and superimposed over each other, it is seen that the idiot cranium and the fossil cranium present almost identically the same curvature; further, these two outlines occupy a place almost exactly midway betweeen the Irish cranial outline and that of the gorilla. (Fig. 1.)

Another combination, equally interesting and equally instructive, is one in which the outlines of the antero-posterior cranial arch of the fossil form, of the Neanderthal skull, of the Spy cranium No. 2, and of the ordinary Irish skull, are superimposed over each other. (Fig. 2.) In this the Neanderthal arch is seen to present almost exactly the same characters as those of the fossil form, and, further, to lie nearer to it than to the outline of the arch of the modern Irish skull. The Spy cranium No. 2 takes its place between the normal skull and the Neanderthal cranium, so that by a series of easy and nearly equal gradations we are led from the fossil form up through the Neanderthal and Spy forms to the modern cranial arch.

The heavy, strongly marked superciliary ridges constitute another Neanderthaloid feature of the fossil form, but the transverse frontal diameter is very much less than that of the Neanderthal or Spy crania. In this respect the fossil cranium closely approaches the microcephalic skull referred to above, and also the skull of the gorilla.

When the measurements of the fossil cranium are compared with those of the Neanderthal and Spy skulls, other striking resemblances become manifest.

—	Maximum antero-posterior diameter.	Maximum transverse diameter.	Cephalic index.	Cranial capacity
Fossil cranium	185	130	70	1000(?)
Neanderthal cranium ...	200	144	72	1200(?)
Spy cranium No. 1 ...	200	140	70	—
Cranium of intelligent adult woman measured in the Anthropometric Laboratory of Trinity College	167	139	83·2	—

The fossil cranium is thus only 15 m.m. shorter and 10 m.m. narrower than the Spy cranium No. 1. In every anthropo-

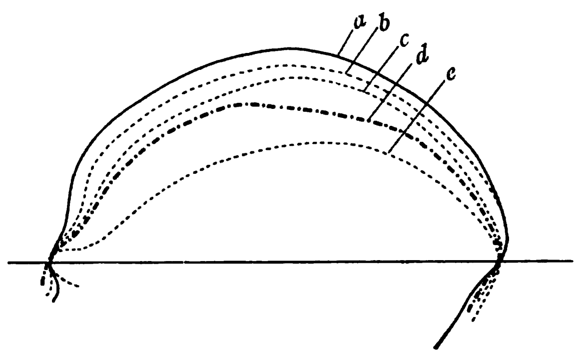

FIG. 2.—Outlines of the antero-posterior cranial arch of: *a*, ordinary Irish skull; *b*, Spy cranium No. 2; *c*, Neanderthal cranium; *d*, the fossil cranium described by Dubois; *e*, the skull of a gorilla. Base-line the same as in Fig 1.

metric laboratory intelligent individuals are occasionally measured who possess an antero-posterior cranial diameter very much less than that of the fossil cranium. In these cases, however, the head is usually brachycephalic, and presents a high and full cranial arch. In the above table the diameters of one of the smallest heads measured in the Dublin University Laboratory are given.[1]

Dubois calculates, from a comparison with ape crania, that the fossil specimen had originally a capacity of at least 1000. The average capacity of the European skull may be said to range from 1400 to 1500 (Welcker), and the Neanderthal cranium has been computed to have had a capacity of 1200. In this respect, therefore, the Neanderthal skull takes an intermediate place between that of the fossil form and of the European. Further, it should be borne in mind that a capacity of 1000 is usually regarded (as indeed Dubois points out) as being the physiological minimum for the human cranium.

From these considerations the fossil cranium described by Dubois is unquestionably to be regarded as human. It is the

[1] "Pithecanthropus erectus, eine menschaenliche Ubergangsform aus Java." By Eugene Dubois. (Batavia, 1894.)

[1] A female cranium from the Island of Inishboffin on the west coast of Ireland presents an antero-posterior diameter of 178 m.m., and a transverse diameter of 129 m.m. In both of these diameters, therefore, it is smaller than the Java fossil cranium. It differs from the latter, however, in possessing a very lofty antero-posterior cranial arch.

lowest human cranium which has yet been described. It presents many Neanderthaloid characters, but stands very nearly as much below the Neanderthal skull as the latter does below the ordinary European skull. The similarity in form which it presents to the microcephalic cranium, with which it has been compared, is undoubtedly interesting, but on this account we are not to conclude that it belonged to a person of feebler intellect than others of the same race. The Neanderthal skull was supposed by certain observers at one time to have been that of an idiot, but this idea was disposed of when other crania, presumably belonging to the same geological period, and possessing similar characters, were discovered. That the fossil cranium should in many respects resemble certain microcephalic skulls, is not surprising: indeed, to some extent it was to have been expected, seeing that a considerable number of this class of idiots present undoubted atavistic characters in so far as brain and cranium are concerned.

Dubois, in his description of the fossil cranium, institutes a close comparison between it and the crania of the higher apes, and only incidentally touches upon its relationship with the human cranium. He asserts that no good could arise from a comparison between it and the Neanderthal and Spy remains, seeing that the latter are pathological. It is not within the scope of an abstract, such as this, to take up the gauntlet on a question of this kind. It will be sufficient to assert an entire accordance with the views so ably advocated by Prof. Huxley, viz. that the Neanderthal and Spy crania are typical of the earliest human race with which we are acquainted.

It is not necessary to delay over the femur. That it is human in every respect, no one could for a single moment doubt. Further, it is curious to note that its form and proportions are more those of a modern than of a prehistoric thigh-bone. It presents none of the characters which distinguish the Spy femora. Its length is 455 m.m., therefore the height of the individual to whom it belonged must have been 1654 m.m., or, in other words, about the same as that of an average Frenchman.[1] From the fact of the femur being found at a distance of from 12 to 15 m. from the place where the cranium was discovered, as well as from other considerations, it is very unlikely that the two specimens belonged to the same individual.

The tooth is undoubtedly a very remarkable specimen. Its great size and strong divergent fangs are characters which at first sight appear to separate it widely from an ordinary human upper wisdom tooth. But we know that in low races, such as the Australian and the Negro, and also in the ancient Neanderthaloid race, the wisdom tooth has not undergone the same retrograde changes which we observe in the European and other mesognathic or orthognathic people. If we take the mean of the antero-posterior and the transverse diameters of the crown of the fossil tooth, we get a result of 13·3. A right upper third molar extracted from the jaw of a negro, treated in the same way, yields a result of 11·5, whilst three Irish upper wisdom teeth, selected at random, give an average of 9. The negro tooth is thus seen, in point of size, to be as far removed from the European tooth as the fossil tooth is from it, and the same may be said for the condition of the fangs. The fossil tooth, so far as one can judge from the figure, is fashioned more after the human model than the simian. The variability of an upper wisdom tooth in man is very remarkable, not only in regard to size, but also in the disposition of its cusps and fangs.[2]

From what has been said, it will be seen that the skull and the tooth, even granting that they are from the same individual, present no such characters as would warrant the formation of a new family. The cranium at least is undoubtedly human. Most certainly they are not derived from a transition form between any of the existing anthropoid apes and man; such a form does not and cannot exist, seeing that the divarication of the ape and man has taken place low down in the genealogical tree, and each has followed, for good or bad, its own path. The so-called Pithecanthropus is in the direct human line, although it occupies a place on this considerably lower than any human form at present known.

[1] Topinard gives the average height of the French as 1650 m.m.

[2] In the museum of the Dublin School of Dental Anatomy there is an upper wisdom tooth extracted from the maxilla of an Irishman, the crown of which presents a transverse diameter of 13 m.m., and an antero-posterior diameter of 12 m.m. (mean result 12·5); which possesses seven cusps and four stout fangs; two of the latter being partially fused. This tooth is very little smaller than the wisdom tooth of the fossil form, and is more remarkable in the way of cusps and fangs.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Biological Club held its jubilee meeting on Saturday last, when the professors of the biological faculties in the University were entertained to a commemorative dinner given in Merton College. The ravages of influenza unfortunately deprived the Club of the presence of several familiar members and of more than one expected guest; but the presence in Oxford of Prof. Bayley Balfour gave the Club an opportunity of extending its welcome to an old friend and an additional distinguished visitor. In the absence of Mr. G. C. Bourne, the presidential chair was taken by Mr. Henry Balfour, of Trinity. Profs. Bayley Balfour and Lankester replied for the guests.

In accordance with a recommendation from the Board of Faculty of Natural Science, the Council has approved of the subject of Astronomy being added to the list of subjects which may be offered in she Honour School of Natural Science. For a reason which is not very obvious at first sight, a candidate who offers Astronomy as a final subject must have obtained honours in the first or second public examination, but need not have passed any of the preliminary science examinations; and a candidate who has passed the science preliminaries is not eligible to compete in the Honour School of Astronomy unless he has obtained honours in the first or second public examination. The object of this rule, which places the School of Astronomy in a position different to that of any other science school, is to compel candidates to take Honours either in Mathematical Moderations or Finals before entering on Astronomy. But the object is not attained, for as the statute now runs, a man who has taken honours in Classical Moderations or in any Final Honour School may enter for the Astronomical School, whilst a man scientifically trained cannot. It may be hoped that the rule, which as it stands is absurd, may soon be rectified. The subject of Astronomy has long been an optional or additional subject in the Honour School of Natural Science, but like other additional subjects, has not attracted students. Astronomy having asserted its claims to recognition, Anthropology has followed its lead, and the Faculty of Natural Science has by a large majority sent up a recommendation to Council that the subject of Anthropology should be added to the Final School. The answer of Council has not yet been received.

In a Congregation held last week, the Curators of the University Chest were empowered to make sundry payments to the Curators of the Botanic Garden, to bring up the whole income of the Garden during each of the next four years to a sum sufficient to defray its expenses.

Mr. G. C. Bourne, Fellow of New College, has been elected a Delegate of the University Museum, in place of Mr. E. Chapman, Fellow of Magdalen College, resigned.

CAMBRIDGE.—The vacancy in the Sadlerian Professorship, caused by the death of Dr. Cayley, has been filled up by the election of Dr. A. R. Forsyth, F.R.S., University Lecturer in Pure Mathematics. Dr. Forsyth is well known as the author of standard text-books on Differential Equations and the Theory of Functions, and of many papers on the higher branches of pure mathematics. He is a Fellow of Trinity, and a member of the Council of the Senate.

Dr. Charles Waldstein, Reader in Classical Archæology, has been elected to the Slade Professorship of Fine Art, vacant by the retirement of Prof. Middleton.

A shower of "fly-sheets" has fallen on the University on the question of requiring further evidence of power to write essays in the various degree examinations. The questions will be decided by the vote of the Senate on Thursday afternoon.

SINCE 1892 there has been a decrease in the number of candidates for entrance into the Central Technical College at South Kensington. But though fewer candidates have presented themselves, the number admitted is about the same, indicating either that the examiners lowered the matriculation standard, or that candidates were better prepared for the examination. In the report of the work of the College during the session 1893–94, various causes are given to account for the diminution of candidates. One is the great increase of facilities for obtaining technical education in London and in the provinces since the College opened. To what extent this increase of schools for technical education may help or hinder the development of the Central Technical College remains to be seen. If to some extent it increases the competition for students, on the other hand it may, in the long run, more than compensate for this by increasing the public appreciation of the value of technical education. It is also suggested that probably the falling off in the number of candidates for admission is chiefly due to the continued commercial depression, and happily this is a disadvantageous condition which may be expected to pass away.

A copy of the programme of the College, received at the same time as the report, shows that the College is far and away in advance of similar institutions in London, and is in the highest degree competent to provide "for the higher technical education, in which advanced instruction shall be provided in those kinds of knowledge which bear upon the different branches of productive industry, whether manufactures or arts."

SCIENTIFIC SERIALS.

American Journal of Science, February.—On the relation of gravity to continental elevation, by T. C. Mendenhall. Determinations of the intensity of gravitation made by the Coast and Geodetic Survey, and by Commander Defforges, and extending across the North American continent, bring out the fact that the deviations from the values of gravitation as deduced from the theoretical shape of the earth's spheroid, are in a direct relation to the elevation of the observing station above sea-level. An explanation based upon differences in the density of the surface layers is difficult to find, but the fact is undoubted.—Glacial phenomena of Newfoundland, Labrador, and Southern Greenland, by G. F. Wright. The ice-sheet of Southern Greenland formerly sent glaciers down through all the fiords, filling them to a height of about 2000 feet, and pushing even to the very margin of the continent. Greenland, therefore, like the rest of the world, has had its ice age, which has already partially passed away. During the maximum of the ice extension, the mountains bordering the sea in Southern Greenland formed innumerable "nunataks." The ice was not thick enough to cover them in solid mass, and there is no probability that the ice extended far out into Davis Straits. In Labrador and Newfoundland, on the other hand, all the mountains were completely covered with glacial ice, which extended far out over the bordering continental plateau. The facts point to considerable preglacial elevations of land, followed in Labrador, at least, by a period of extensive depression below the present level, and subsequent gradual elevation. There is evidence of the recent date of the glacial period, while the indications of recent changes of level point to terrestrial rather than astronomical causes to account for the vicissitudes of the glacial period.—The *Pithecanthropus erectus*, Dubois, from Java, by O. C. Marsh (see pp. 428-29).

Bulletin of the American Mathematical Society, vol. i. 4 (New York, January 1895)—A pathetic interest is attached to the second article, "Note on a memoir in Smith's collected papers," as it must have been amongst the last pieces of work done by Prof. Cayley. The memoir is that on the Theta and Omega Functions (Smith papers, vol. ii. pp. 415-623). The notice is a very slight one, and gives an abstract of the contents of the memoir.—The opening paper is a presidential address, delivered before the American Mathematical Society at its annual meeting, December 28, 1894, of which the title is, "The Past and Future of the Society." Dr. McClintock traces the growth of the Society from its origin in 1888 as a small mathematical club, meeting at Columbia College, whose first meeting was called by a circular signed by three young men, up to its present membership of 251. A paragraph points out that the pioneer of all these mathematical societies which have subsequently sprung up was the London Mathematical Society. "There had been no previous example of a similar organisation, and fears were felt and expressed that its management might naturally drift into the hands of a few having time and energy to give to its affairs, and that there might thus be serious danger of its falling into the control of a clique. The lapse of time has developed the fact that the leading members of that Society have been men of broad views, unusually free from personal prejudice, and quick to recognise talent wherever displayed. We may almost conclude from the history of that Society that proficiency in the science of mathematics is distinct evidence of a well-balanced mind." We repeat the wish we have previously expressed for the continued success of this flourishing young branch. In the Notes the new officers and Council are given, the new President being Dr. George W. Hill.—A long list of new publications closes the number.

IN the numbers of the *Journal of Botany* for January and February, new plants are described by Mr. A. Fryer from Scotland (a new hybrid *Potamogeton*); by Mr. R. P. Murray, from Teneriffe; by Mr. W. Fawcett, from Jamaica; and by Mr. H. N. Ridley, from the Malay Peninsula. Mr. A. Bennett discusses the claims of *Juncus tenuis* to rank as a British species.

SOCIETIES AND ACADEMIES.

LONDON

Chemical Society, February 7.—Dr. H. E. Armstrong, President, in the chair.—The following papers were read: The action of heat on ethylic β-amidocrotonate; Part ii., by J. N. Collie. During the destructive distillation of this salt, $\alpha\gamma$-dimethyl-α^1-ethoxypyridine, a dimethylpyrrol and a pyridine derivative, $C_6H_8N_2O$, are produced together with ethylic lutidonemonocarboxylate.—The acidimetry of hydrogen fluoride, by T. Haga and Y. Osaka. Phenolphthaleïn is the best indicator to use in the titration of hydrofluoric acid. The authors' experiments with litmus suggest that the molecular composition of hydrogen fluoride is H_3F_3 or H_4F_4.—Composition of ancient silver ornaments from Peru, by Miss C. Walker.—Molecular change in a silver amalgam, by Miss F. T. Littleton.—On heating silver amalgam, preferably of the composition $Ag\,Hg_4$, considerable swelling occurs; this can only be attributed to molecular change, inasmuch as gas is not evolved.—Sulphocamphylic acid II., by W. H. Perkin, jun. Further evidence has been obtained indicating that this acid has the composition $C_8H_{12}(SO_3H).COOH$; the acid yields two isomeric acids $C_8H_{11}.COOH$ on fusion with potash. Other new derivatives have been obtained.—Derivatives of ethylorthotoluidine, by W. MacCallum, jun.—Acetyl derivatives of benzaconine and aconitine, by W. R. Dunstan and F. H. Carr. A number of unsuccessful attempts have been made to convert benzaconine into aconitine by introducing an acetyl group; two isomeric triacetylbenzaconines and a tetracetylbenzaconine are obtained on acetylation. The authors have also prepared di- and tri-acetylaconitine and triacetylpyraconitine.—Aconitine aurichlorides, by W. R. Dunstan and H. A. D. Jowett. A new examination of the three modifications of aconitine aurichloride confirms the authors' previous assertions as to the existence and nature of these compounds. The alcoholate of aconitine aurichloride described by Freund and Beck is the β-aurichloride containing a little alcohol.

Entomological Society, February 6.—Prof. Raphael Meldola, F.R.S., President, in the chair.—The President announced that he had nominated the Right Hon. Lord Walsingham, F.R.S., Mr. Henry John Elwes, and Prof. Edward B. Poulton, F.R.S., Vice-Presidents of the Society for the Session 1895-96.—Mr. W. F. H. Blandford made some remarks regarding Mons. Brongniart's donation to the library, of his monograph entitled "Recherches pour servir a l'histoire des Insectes Fossiles des Temps Primaires." Mr. Blandford also called attention to figures of pupæ of species of *Spalgis* (Lycænidæ), in the *Journal* of the Bombay Natural History Society. A discussion followed, in which Mr. Hampson and Mr. McLachlan took part.—Canon Fowler exhibited, on behalf of Mr. C. A. Myers, an unusually fine specimen of *Sphæria robertsi*, growing from the prothorax of an underground larva of a Hepialus, supposed to be *H. virescens*, from New Zealand. Mr. McLachlan said that there was a doubt whether the caterpillar should be referred to this species. Mr. Blandford stated that the French Government had set aside a section of the Pasteur Institute at Paris for the study of entomophagous fungi.—Prof. L. C. Miall, F.R.S., and Mr. N. Walker, communicated a paper entitled "On the Life History of *Pericoma canescens* (Psychodidæ)," with an Appendix by Baron Osten-Sacken.—Herr Jacoby read a paper entitled "Contributions to our Knowledge of African Phytophagous Coleoptera." Dr. D. Sharp, F.R.S., remarked that Erichsen began the "Insekten Deutschlands" some sixteen years ago, and as he was engaged on a classification of the Coleoptera of the world, he included a considerable number of these exotic species in his work.—Mr. G. F. Hampson read a paper entitled "Descriptions of New Heterocera from India."

Mineralogical Society, February 5.—Dr. Hugo Müller, F.R.S., in the chair.—Prof. Judd read a paper on some simple crys'alline rocks (massive minerals) from India and Australia. From specimens supplied by Mr. T. H. Holland, of the Geological Survey of India, Mr. P. Bosworth Smith, late Government Mineralogist at Madras, and Mr. C. Barrington Brown, the author was able to make known some new types of rocks. Two remarkable forms of corundum-rock were noticed, one from Pipra, S. Rewah, first brought to the knowledge of mineralogists by Mr. F. R. Mallet, and the other from Hunsúr Talug, in the Mysore State. A fibrolite-rock, derived from the same district as the last, was also noticed. A new variety of tourmaline (schorl)-rock with a fibrous texture, having a wide distribution in India, was likewise described, and an analysis, together with a description of the optical properties of the mineral, was given. From the Bingera district in New South Wales, two dykes were described as traversing masses of serpentine, one being composed of a green garnet-rock (grossularite?) yielding gold, and the other of picotite, the chrome-spinel.—The Earl of Berkeley read a paper on an accurate method of determining the densities of solids, in the course of which it was shown that by taking suitable precautions with a pyknometer having a thermometer stopper and a capillary at the side, results accurate to 0·03 per cent. could be obtained. The actual values for different crops of rubidium alum were 1·8884, 1·8885, 1·8885 and 1·8889. The chief point of the communication was that the evaporation of the liquid used in the observations (CCl_4) from the film formed between the stopper and the neck of the pyknometer, instead of being a source of error, is utilised to bring the level of the liquid into coincidence with the mark on the capillary.—Prof. Church made a communication on the derermination of mineral densities. Three points were specially referred to: The employment of dilute alcohol instead of water was recommended as enabling full advantage to be taken of the sensitiveness of an assay balance; the results quoted for specimens under two grams in weight were probably correct to ·003. A method of removing interstitial air by first replacing it with carbon dioxide, and then absorbing this gas by an alkaline solution or by boiled water was described. An account was next given of a method of determining relative densities by means of mercury, the volume of mercury displaced by the mineral being weighed. Although no novelty was claimed for these methods, special precautions in their conduct were named, and illustrations adduced of their application to the determination of mineralogical problems.

CAMBRIDGE.

Philosophical Society, February 11.—Prof. J. J. Thomson, President, in the chair.—On a method of determining the conductivities of badly conducting substances, by Prof. J. J. Thomson. A sphere of the substance the conductivity of which is to be determined is placed inside a coil A through which very rapidly alternating currents are passing. The currents induced on the sphere react on those in the coil. A small coil B placed in series with A contains a highly exhausted bulb in which a ring discharge is produced by the alternating currents. Any change in the intensity of the currents through A produces a change in the brightness of the discharge through the bulb inside B. The effect produced by the sphere inside A is measured by the change in the brightness of the discharge within B, and as the effect produced by the sphere depends on its conductivity, the observation of changes in the brightness of the discharge makes it possible to compare the conductivities of different substances. The paper contains applications of this method to the study of the conductivity of electrolytes under very rapidly alternating currents, of rarefied gases, of gases when entering into chemical combination, of flames, and of the effect of the formation of drops of water from aqueous vapour.—Note on the calibration of the wire of a Wheatstone bridge, by Mr. E. H. Griffiths.

BERLIN.

Physiological Society, January 4.—Prof. du Bois Reymond, President, in the chair.—In the discussion on Prof. Waldeyer's discourse (of December 21, 1894), Dr. Benda and Dr. Rawitz laid stress on the anatomical difficulties which stand in the way of the generalisations of Golgi's school, and Prof. Gad made his protest from the physiological point of view. Prof. Waldeyer recognised the propriety of the objections made against the newer views as to the minute anatomy of the nervous system, views due to those recent methods of research which have led to a very distinct advance in knowledge. Dr. Ziegenhagen communicated the results of his researches on the development of the blood-vessels in trout-embryos, based on observation of the living object, on injections by Wertheim's method, and on photographs.

January 18.—Prof. du Bois Reymond, President, in the chair.—Dr. Benda explained the preparations he exhibited of nerve-endings in muscles made by Prof. Sihler, of Cleveland.—Dr. Rawitz described a new method of staining cells with aniline dyes, which consists in first mordanting the tissues, hardened in Flemming's fluid, with tannin and tartar-emetic, and then treating them with the dye. By this method of "adjective" staining, only the protoplasm of the cell is coloured, not the nucleus. The same speaker next described some results of his method as applied to resting-cells of salamander testis. The nucleus shows the brown-coloured chromatin filaments; the linin network and the distinct nuclear membrane are of a pale red colour. In the middle of the protoplasm, at some distance from the nucleus, is the dark-red attraction sphere with the centrosome in its midst. Close-set meshes of the network of red fibrils, which permeate the protoplasm, and are in other parts less close-set, join on to the periphery of the sphere, and are in direct communication with the nuclear membrane and the linin filaments. Occasionally the attraction spheres of two neighbouring cells are joined together by a dark-red filament.—Dr. Cohnstein described experiments on the action of intravenous injections of sodium chloride on the composition of lymph and blood, and showed that the observed variations of quantity and of the amount of water and salt in the lymph, as also the changes in the amount of salt in, and concentration of the blood, could be adequately explained by the purely physical processes of diffusion and filtration.

Meteorological Society, January 8.—Prof. Hellmann, President, in the chair.—Dr. L. A. Bauer discoursed on the secular changes of terrestrial magnetism. From the observations available at an extended series of stations he had determined the declination and dip of a magnetised needle freely suspended at its centre of gravity, and had compared the curves of secular change thus obtained with the corresponding formulæ. Taking older compass-charts additionally into consideration, he found that the curves of secular change must contain loops. If one imagines a magnetised needle, freely suspended at its centre of gravity, to be carried round the earth along a given parallel, one obtains the momentary curve of terrestrial magnetism for that parallel, and this curve corresponds to the curve of secular variation. This curve further shows a distinct loop, as, for example, for the parallel 40° N. In the discussion which followed, the President drew attention to the fact that the statements of the older travellers as to compass bearings cannot well be used for determining the components of terrestrial magnetism, since each compass was specially arranged in order to show the astronomical north-pole, and hence it is necessary, first of all, to know what this special arrangement was before their indications can be used.—Dr. Kassner described a "föhn" wind in the Riesengebirge, which was very marked on November 1 and 2 last, on the north fall of the mountain, and caused by the high temperature and excessive dryness. The dryness and great transparency of the air was observed as far as Breslau, a distance of 100 kilometres.

Physical Society, January 11.—Prof. du Bois Reymond, President, in the chair.—Dr. Altschul made communications from the Raoul Pictet Institution, dealing first with the influence of intense cold (−70° to −200° C.) on a long series of chemical processes, and in the next place on physical processes, such as phosphoresence, &c. He then reported upon experiments on the behaviour of bodies at the critical temperature. The disappearance and reappearance of the meniscus was found to take place always at the same temperature as long as the warming of the substance was uniform. It was found that the critical temperature is a better criterion of the chemical purity of a liquid than are its melting point and boiling point, and a number of instances were cited where minute impurities altered the critical temperature by many degrees. Solutions of solids when heated above the critical temperature gave no precipitate, the solid remaining dissolved in the gaseous vapours. Solutions of colouring matter behaved similarly.

January 25.—Prof. du Bois Reymond, President, in the chair.—Mr. Archenhold discussed the principles and advantages of two recently projected telescopes, of which one with a 44-inch object-glass and short focal length is to be set up in the Berlin Industrial Exhibition in May 1896, while the second, with a 50-inch object-glass, is to be taken in hand later on. The glass for the first of the two is already cast by Dr. Schott, of Jena, and is to be ground according to scientific principles by Dr. Steinheil. The speaker further discussed a series of fundamental novelties in the mounting of the telescopes, by which the cost of the same would be materially reduced. The discussion, which was then opened by Prof. von Bezold, on behalf of Profs. Auwers and Vogel, and continued by Prof. Lummer, was adjourned to the next meeting.

[*Notice.*—In the report of the meeting of the Physiological Society of December 7, 1894, NATURE, vol. li. p. 288, for "Dr. G. Joachim," read "Dr. G. Joachimstal."]

PARIS.

Academy of Sciences, February 18.—M. Marey in the chair.—On Neumann's method and Dirichlet's problem, by M. H. Poincaré.—On the form of the intrados of arches, by M. H. Resal.—On the kinds of chlorophyll; remarks *à propos* of the note by M. Étard, by M. Arm. Gautier. The author claims priority for the proof that several chlorophylls exist, and that chlorophyll contains no iron, but contains organic phosphorus.—On the agricultural value of aluminium phosphates; remarks *à propos* of M. Andouard's note, by M. Arm. Gautier. In 1893 the author showed that amorphous aluminium phosphate was of value in agriculture owing to its solubility in the products of decomposition present in soils. This does not extend to crystallised phosphates of aluminium or of aluminium and calcium.—On the estimation of tannic compounds, by M. Aimé Girard.—Remarks on atomic weights, by M. Lecoq de Boisbaudran. The author mentions a method of classification of the elements which enables him to calculate their atomic weights as well as predict their properties; this system has not yet been published. According to it, argon belongs to a group of elements of which no other members are yet known. They should be octads of atomic weights as follows: $20{\cdot}0945$, $36{\cdot}40 \pm 0{\cdot}08$, $84{\cdot}01 \pm 0{\cdot}20$, $132{\cdot}71 \pm 0{\cdot}15$; $(O = 16)$. They should be metalloids, the first two members relatively abundant, the others rare. Taken in order, they should respectively be more volatile than oxygen, sulphur, selenium, and tellurium.—The scope and method of a work on the "theory of algebraical functions and their integrals," by M. Appell and M. Édouard Goursat, is explained in a short note by the former.—On the astronomical inscription of Keskinto, by M. Paul Tannery. The author draws conclusions with regard to the state of knowledge of planetary periods about 150-50 B.C.—On a surface of the sixth order, allied to abelian functions of the third type, by M. G. Humbert.—On the properties of amorphous silicon, by M. Vigouroux. These properties are very fully given. Speaking generally, amorphous silicon prepared by reduction with magnesium somewhat resembles crystalline silicon in properties. Though somewhat inert at lower temperatures,, at high temperatures it is chemically very active.—On the oxidation of the tannin of the cider apple, by M. L. Lindet. This oxidation appears to be due to the action of a ferment of the *laccose* type.—On the composition and analysis of eaux-de-vie, by M. X. Rocques.—On the seeds of the Moâbi, by MM. H. Lecomte and A. Hébert. An account of a tree found in French Congo, and of a fat produced from its seeds.—On ferrocyanide, rutheniocyanide, and osmiocyanide of potassium, by M. A. Dufet. A crystallographical paper giving measurements of axial ratios, angles, and optical constants of (1) $K_4FeCy_6.3H_2O$, (2) $K_4RuCy_6.3H_2O$, (3) $K_4OsCy_6.3H_2O$. A remarkable similarity is shown by these compounds throughout the extensive series of measurements given.—On modifications of the blood, brought about by the thermal treatment with Bourboule water from the spring Choussy-Perrière. by M. Ph. Lafon. Conclusions from results of many analyses (quoted): (1) In cases of chloro-anæmia there is generally a notable increase of red corpuscles and oxyhæmoglobin in the blood of patients, due to the treatment. (2) In cases of leucocytæmia the treatment produces a diminution of the numbers of white corpuscles.—On the nucleus and nuclear division in the *Benedenia*, by M. Alphonse Labbé.—On egg-deposition of *Vespa crabro*, L.; conservation of heat in the nest, by M. Charles Janet.—Observations on the upper Tongrian or *Stampien* strata in the Chalosse, by M. L. Reyt.—Considerations on contact-metamorphism, derived from a study of the contact phenomena of lherzolite in the Pyrenees, by M. A. Lacroix.—Mineralogical composition and structure of the *silex* of the Paris gypsum, by M. L. Cayeux. Conclusions: (1) The siliceous nodules from gypsum, known as *silex*, have an essentially different microstructure and mineralogical composition from *silex* properly so called. (2) They result from a substitution of silica for gypsum. (3) The silicification of gypsum causes the production of some one of the arrangements of which quartz is capable. (4) The ultimate term of the series of transformations of saccharoidal gypsum, under the action of silica, is the production of wholly quartzose plates, having the same structure as quartzites.—Earthquake recorded at Grenoble, a note by M. Kilian, February 3, 6h. 2m. 40s. morning.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Introduction to Physiological Psychology: Dr. Th. Ziehen, translated, 2nd edition (Sonnenschein).—An Elementary Text-Book of Anatomy: Prof. H. E. Clark (Blackie).—Report of Observations of Injurious Insects, &c., 1894: E. A. Ormerod (Simpkin).—Economic Classics—David Ricardo (Macmillan).—Economic Classics—Adam Smith (Macmillan).—A Course of Elementary Practical Bacteriology: Drs. Kanthack and Drysdale (Macmillan).—The Pathology of Mind: Dr. H. Maudsley (Macmillan).—Notes on a Journey on the Upper Mekong, Siam: H. W. Smyth (Murray).—Das System der Übergewalt oder das Analytisch-Synthetische Princip der Natur: K. Beyrich (Berlin, Oppenheim).

PAMPHLETS.—Revue de l'Aéronautique, 1893, 3[e] Livr.: Le Travail Intérieur du Vent: S. P. Langley (Paris, Masson).—Tableau Oeconomique: F. Quesnay (Macmillan).—Philosophical Transactions of the Royal Society of London, Vol. 185 (1894) A, pp. 93-121: Propagation of Magnetisation of Iron as affected by the Electric Currents in the Iron: J. Hopkinson and E. Wilson (Dulau).

CONTENTS. PAGE

THURSDAY, MARCH 7, 1895.

THE ANCESTRY OF THE VERTEBRATES.

Amphioxus and the Ancestry of the Vertebrates. By Arthur Willey, B.Sc., Tutor in Biology, Columbia College; Balfour Student of the University of Cambridge. With a preface by Henry Fairfield Osborn. (Columbia University Biological Series, II.) (New York and London: Macmillan and Co., 1894.)

THE observations on Amphioxus made before the second half of the present century, amongst which those of Johannes Müller take a foremost place, showed that this remarkable animal bears certain resemblances to Vertebrates; and since then its interest in this respect has gradually become more apparent. The extent to which our knowledge of its structure and development has recently increased, is indicated by the fact that about two-thirds of the papers dealing with Amphioxus quoted by Mr. Willey have appeared during the last ten years. With the exception of the admirable account given by the late Prof. Milnes Marshall, last year, in his "Vertebrate Embryology," most of the works relating to this form are of a special nature, and to many not easily accessible. A consecutive history of the more recent observations was, therefore, greatly needed by those whose opportunities did not permit them to follow out the matter for themselves, and who will welcome a book written in an extremely lucid style by a naturalist who can speak with authority on the subject.

After giving an excellent description of the habits, anatomy, and development of Amphioxus, Mr. Willey devotes a special section to the Ascidians. Then follows a section on "the Protochordata in their relation to the problem of Vertebrate descent," which includes an account of the so-called "Hemichorda," together with a number of details relating to larval forms, Nemertines, and Vertebrates. On the basis of the facts stated, there is a considerable amount of theoretical matter dealing with the complex question included in the title of the book, in the discussion of which the author is not dogmatic, and makes the distinction between fact and theory clear to the reader. Of the very few inaccuracies we have noticed, mention need only be made of the statements with regard to the cilia on the ectoderm of craniate Vertebrates, on p. 176, and to the distribution of the ganglion-cells in the nerve-cord of Annulates, on p. 260, both of which require modification. The figures, which are 135 in number, are extremely good and clear, not a few of them being taken from the author's original papers; and a good bibliography is given at the end. Altogether we congratulate Prof. Osborn on the publication of the second of the series which is appearing under his editorship.

The problem of the ancestry of the Vertebrates has been approached from many different points of view, and some of the various theories advanced—such as the well-known "Annelid theory" of Semper and Dohrn—have been supported by so many facts and arguments as to gain for them many adherents. Others, again, were less fortunate, and cannot be said to have held the field at all. In all such phylogenetic speculations, as Mr. Willey points out, mere parallelisms are often difficult to distinguish from true affinities; and even with the increase in our knowledge during the past few years, we are stil so much in the dark that it is hardly possible to do more than accept provisionally any particular theory which appears to be supported by the greatest number of facts.

Although Amphioxus and the Ascidians have long been recognised as of extreme importance in helping to throw light on the question of Vertebrate ancestry, their many peculiarities are so difficult to explain that by many zoologists they have been attributed to degeneration—more especially in the case of the Ascidians—and on this supposition these animals can be of little use in helping us to any sound view as to the form and structure of the proximate ancestor of the Vertebrates.

The more recent researches on the structure and development of Amphioxus have, however, shown that, specialised as this animal undoubtedly is, it can no longer be so easily put on one side, and that it, at any rate, almost certainly represents an extremely archaic form. The general lines of its early development, for the knowledge of which we are mainly indebted to Kowalewsky and Hatschek, are now a matter of every-day knowledge, and are almost universally accepted as the best possible starting-point for the study of Embryology generally. In the present notice we can only refer to some of the more recent discoveries and theories as stated by Mr. Willey.

The curious tongue-bars in the gill-slits, which are only known to be represented elsewhere in Balanoglossus, are supposed by Mr Willey to be the "functionally active organs, of which the thymus of the higher forms is a metamorphosed derivative." This view is supported by reference to Dohrn's account of the development of the thymus in Selachisms. In a note on p. 42, the metapleural folds of Amphioxus and the evolution of the lateral fin-folds and lateral line of Vertebrates are made the subject of a hypothesis which cannot be done justice to in a few lines. The discovery of the excretory tubules by Boveri and Weiss, is one of the most interesting points which have recently come to light with regard to Amphioxus; and Mr. Willey supports Boveri's view that, in spite of their special peculiarities, they represent the pronephric system of Vertebrates, and that the pronephric ducts of the latter are partially homologous with the atrial chamber of Amphioxus. This conclusion is especially important as furnishing another argument against the Annelid theory, to which, moreover, the nervous system of Amphioxus lends no support, although its peripheral portion "can only be compared definitely, at present, in its broader features, with that of the higher Vertebrates."

The remarkable asymmetry of the larvæ of Amphioxus has probably no ancestral significance, and Mr. Willey concludes that it "is of no specific advantage whatever to the larvæ, but is merely a stage, which has been preserved in the ontogeny, of a topographical readjustment of parts necessitated by the removal of the mouth from its primitive mid-dorsal position in consequence of the secondary forward extension of the notochord, which has thus caused a virtual semi-rotation of the pharyngeal region of the body. On the other hand, the forward extension of the notochord is a distinct advantage in later life, since by giving resistancy to the snout, it enables the animal to burrow its way into the sand with such astonishing facility, while the fact that it grows to the front end of the body at a very early stage in the embryonic development, long before it comes to be put to this definite use, must be regarded as an instance of *precocious* development, of which there are numerous and otherwise inexplicable examples in the field of comparative embryology." The author regards it as probable that the proximate common ancestor of Amphioxus and the higher Vertebrates was characterised by the possession of from nine to fourteen pairs of gill-slits, counting the "club-shaped gland" as representing the antimere of the first primary slit.

After an account of the structure of the Ascidians, these animals are compared with Amphioxus, and are defined as "more or less *Amphioxus-like* creatures which have become adapted to a sessile habit of existence." Their embryology is then described, and it is pointed out that development proceeds along parallel lines in them and Amphioxus "up to a certain point, and then at the time of the outgrowth of the tail in the embryo of the former, and the hatching of the embryo of the latter, divergences set in." The precocious formation of the larval tail in Ascidians is shown to be one of the chief evidences of the abbreviation which has occurred in the development of this group.

Metamerism—"that fetish of the morphologists," as Brooks calls it—may, as this author points out in his monograph on Salpa, "have been acquired by the ancestors of the Vertebrates after the divergence of the Tunicates"; and consequently, even if the supposed metamerism of the tail in Appendicularia had not now been definitely shown by Seeliger and Lefevre to be artificial, it could hardly have been considered of ancestral significance. Mr. Willey recognises the secondary nature of the "so-called metamerism" of the tail in this animal, and is inclined to conclude that "the Appendicularïæ represent Ascidian larvæ which have become secondarily adapted to a pelagic life, and have acquired the faculty of attaining sexual maturity." We feel, however, that the arguments brought forward are hardly sufficient to balance those in favour of the view held by Brooks and many others, that Appendicularia is the more primitive type, though until the development of this form is known we cannot, as Mr. Willey points out, decide definitely between these two views.

As already indicated, Bateson's grouping of Balanoglossus, Cephalodiscus, and Rhabdopleura into the division *Hemichorda* of the group *Protochordata*, is accepted by the author, and these forms are described and compared, and an account of the development of Tornaria and of Echinoderm larvæ given. Although we fully appreciate the general force of the quotation from Weismann, given at the head of Section V., the perusal of the following pages will not, we fear, be convincing to everyone that it applies in this particular instance. Such arguments as those brought forward by Spengel in his great monograph on the Enteropneusta cannot easily be put on one side, and we must make allowance for the principle of parallelism in evolution quite as much in this case as in that of the Annelid theory. Nevertheless, whether the Hemichorda hypothesis proves to be true or falls to the ground, it will have had its value in stimulating inquiry.

So many other points of theoretical interest naturally appear in considering the problem of Vertebrate ancestry, that one is tempted to discuss each as it arises. We must, however, content ourselves with a bare statement of certain only of these, and the conclusions at which Mr. Willey has arrived with regard to them.

It is concluded "that the ventral mouth of the craniate Vertebrates is the homologue of the dorsal mouth as we find it in the Protochordates, and that its direction of evolution has been, as was so ably maintained by Balfour, from the cyclostomatous to the gnathostomatous condition." The hypophysis is supposed to have arisen "in connection with a functional neuropore; when the neuropore ceased to be functional, there was no longer any bond of union between its inner portion, which opened into the cerebral cavity, and its outer portion, which opened into the buccal cavity; and these two portions became separated by differential growth of the cerebral and body-walls." Much stress—we are inclined to think too much—is laid on the pre-oral lobe, which is supposed to be "represented in the craniate Vertebrates by the *præmandibular head-cavities*."

In conclusion, we cannot do better than quote the last paragraph of Mr. Willey's useful and suggestive book, which is dedicated to Prof. Lankester:—

"For the present we may conclude that the proximate ancestor of the Vertebrates was a free-swimming animal intermediate in organisation between an Ascidian tadpole and Amphioxus, possessing the dorsal mouth, hypophysis, and restricted notochord of the former; and the myotomes, cœlomic epithelium, and straight alimentary canal of the latter. The ultimate or primordial ancestor of the Vertebrates would, on the contrary, be a worm-like animal whose organisation was approximately on a level with that of the bilateral ancestors of the Echinoderms."

W. N. P.

A CYCLOPÆDIA OF NAMES.

The Cyclopædia of Names. Edited by Benjamin E. Smith, A.M. Pp. 1085. (London: Fisher Unwin, 1894.)

THE production of a pronouncing and etymological dictionary of proper names, encyclopædic in its scope and fulness, must have involved an immense amount of care and industry. The ponderous tome which represents the result of such labour comprises —to quote from the Editor's introductory remarks— "not only names in biography and geography, but also names of races and tribes, mythological and legendary persons and places, characters and objects in fiction, stars and constellations, notable buildings and archæological monuments, works of art, institutions (academies, universities, societies, legislative bodies, orders, clubs, &c.), historical events (wars, battles, treaties, conventions, &c.), sects, parties, noted streets and squares, books, plays, operas, celebrated gems, vessels (warships, yachts, &c.), and horses. Pseudonyms, also, which have literary importance, are included. The only condition of insertion has been that the name should be one about which information would be likely to be sought."

The condition expressed in the last sentence is one that may be regarded as essential, and only by adopting it as a guiding principle can any dictionary or cyclopædia worthy of the name be constructed. It follows from this that the various groups of subjects could not be presented with equal fulness; accordingly we find that persons and places are given a much greater amount of space than any other class. The personal names included in the volume embrace not only actual biography, but also mythology, legend, and fiction. We are chiefly concerned with the names of men of science, and, so far as can be judged from test references, few names of importance have been omitted. But even if a few omissions have been committed, it would be ungracious to condemn the work on that score; rather let us marvel at the number of names that have not been overlooked, and at the care which must have been expended in bringing so much accurate information together. Who but those that have had to investigate biographical details can understand the difficulties which crop up in the matter of dates, due to different styles of reckoning, and the differences between various authorities? It cannot be laid down that in every case the most trustworthy authority has been selected; nevertheless, there is ample evidence in the volume to show that judicious discrimination has been used.

The geographical names given include every town, place, or locality likely to be looked for by the average man; physical and political divisions of the earth; rivers, lakes, seas, &c.; and natural curiosities. In the spelling of place-names, the established usage in the language from which the name is taken has generally been accepted. In many cases, however, where the established English usage differs more or less from the native form, no general considerations can be applied. Instances of this are: Munich for the German München, Flushing for the Dutch Vlissingen, Hanover for the German Hannover. Having regard to the fact that there is a tendency to return to the native form of spelling place-names, where the difference between this form and the Anglicised orthography is slight (as in Hannover), the former has usually been taken. This seems to be a common-sense rule to follow, and it enforces the opinion of many geographers that the correct spelling of a place-name is the local one.

The general plan of the dictionary will be understood from the foregoing brief description. It only remains to be said that, as a collection of proper names, the work is the most complete one-volume cyclopædia that has ever come under our notice. No scientific society should be without the volume, and every reference library ought to have a copy on its shelves.

OUR BOOK SHELF.

Varied Occupations in Weaving. By Louisa Walker. Pp. 224. (London: Macmillan and Co., 1895.)

THERE is a scientific and an artistic side to the kindergarten system of education. Froebel's graduated sets of simple apparatus, known as "gifts," are most valuable in training a child to observe and think. The first of the gifts, consisting of six wool balls, coloured respectively violet, blue, green, yellow, orange, and red, serve to teach elementary colours; the second, consisting of a wooden cube, a sphere, and a cylinder, is used to familiarise children with geometrical forms, and with the figures presented when the objects are rotated around different axes. A number of other gifts follow these, each calculated to develop the minds of the infants for whom they are intended. So much cannot be said, however, for all the "varied occupations" which are carried on in many elementary schools. The educational value of an occupation such as that described in the book before us, lies not in the development of the mind, but in the training of the hand and eye. If the elements of kindergarten knowledge have been previously acquired by the young students, there is no harm in teaching how to weave paper mats, and to do macramé work, though our opinion is that the child might be better employed in object-lessons, which naturally follow a scientifically arranged kindergarten course. For this playing at making things is often carried too far, and leads to technical instruction being given before instruction in the broad principles inculcated by means of Froebel's early gifts. Possibly we do not fully appreciate the value of hand and eye training for children. The greatest benefit to be derived from such training seems to be the cultivation of the imitative and inventive faculties. Addition and multiplication can be taught by the weaving occupations described by Mrs. Walker, but they can be taught just as well by means of Froebel's gifts. However, the book is the outcome of twenty years' experience in kindergarten methods of teaching, and therefore should be of great service to teachers of children, even though its value, when viewed from a scientific point of view, is but little.

Horse Breeding for Farmers. By Alfred E. Pease. (London: Macmillan and Co., 1894.)

THE aim and object of this little work is to impress upon the impecunious present-day farmer the pecuniary profit which is to be derived from horse-breeding; and if the balance-sheets which Mr. Pease produces are to be relied upon, it undoubtedly constitutes a profitable pursuit. Unfortunately, however, so much depends upon the judgment, care, and skill bestowed by the individual in the purchase of suitable mares, the selection of proper sires, as well as upon the business capacity of the breeder, when the time arrives for placing the produce upon the market, that a profit on paper may readily be converted into a loss in practice. More particularly is this so in the case of the lighter breeds, such as the hunter and high-class carriage horse, whose value is largely dependent upon the thoroughness with which they have been trained and schooled. Mainly for these reasons we believe that the average farmer will be best advised to confine his horse-breeding operations to the heavier or agricultural breeds. They possess the additional advantage of being more docile, less trouble to break in, more useful to the farmer whilst young, and, finally, are more readily disposed of. The other breeds are best left to the landowners and so-called gentleman-farmer. Holding these views, we regret Mr. Pease should devote twenty pages to tracing the origin and history of the English thoroughbred, the Arab, the Barb, and other Oriental breeds.

For the rest, the book is replete with valuable information on the subject it professes to deal with, and may be cordially and unreservedly recommended to those who are inclined to try their luck in horse-breeding. To our minds, the final chapter, which treats of the ailments which horseflesh is heir to, is the least satisfactory. This is hardly to be wondered at, when we bear in mind how wide a subject is veterinary science, and how small a space Mr. Pease has devoted to its consideration.

W. F. G.

Preparatory Physics. By William J. Hopkins. (London: Longmans, Green, and Co., 1894.)

THE course here presented is the outgrowth of needs of the classes beginning the study of physics in the Drexel Institute, Philadelphia. It is arranged strictly for laboratory work, and although the ground covered is not very extensive, yet sufficient has been selected for a first course, and that expounded to a very full extent. Mechanics has been chiefly taken in hand, and the numerous problems have been so arranged that the student is able to investigate them experimentally for himself. A glance at the instructions and explanations shows one that the author wishes at every step to instil into the beginner the idea that habits of accurate and thorough observation must be developed, and, further, that students must be careful, complete, and orderly in recording and arranging his results. With this intention most of the experiments are accompanied with printed forms illustrating concise methods of recording the observations. The apparatus alluded to in the text is of a simple nature, and quite sufficient for those beginning the subject. As an introduction, a few pages are devoted to such fundamental points as units, errors and sources of error, coordinates, plotting of curves, &c. Altogether, the book will be found a serviceable and able help to all wishing to take part in the more simple laboratory work.

The Story of the Stars. By George F. Chambers, F.R.A.S. Pp. 192. (London: George Newnes, Limited, 1895.)

ONE or both of two qualifications are essential in a book designed for general readers: the text must be attractively written, or the illustrations must please the eye. This book has neither of these claims to public favour: the text is stodgy and the illustrations are the very worst that we have seen disfiguring a volume on astronomy. The former defect is due to the author's attempt to say something about the whole of sidereal astronomy in less than two hundred small pages; the wretched illustrations cannot be due to his inability to find others, so this fault must lie at the publisher's door. And yet we cannot understand why the publisher of the *Strand Magazine* and other pictorial papers could not give the same care to the illustration of a book on astronomy as he does to the description of the home of some celebrity. Only in regard to quantity of information are we able to say a favourable word for this book. Mr. Chambers is thoroughly competent to collect the facts belonging to the old astronomy, and to condense them. He may be able to compress a mass of knowledge into a small compass, but his latest production shows that he has not the touch *simplex munditiis* of a writer for the popular mind.

Aërial Navigation: Proceedings of the International Conference held at Chicago, August 1893. Pp. 429. (New York: *American Engineer* Office. London: Sampson Low, Marston, & Co., 1894.)

AN International Conference on aërial navigation formed one of the series of Congresses which were held in Chicago during the summer of 1893. The meetings proved to be successful, and the volume in which the proceedings are recorded shows that facts and positive knowledge, rather than speculations or descriptions of things "in the air," were the order of the day. Some thirty-five papers were presented, each containing an account of observations and results of experiments carried out by scientific men or experienced engineers. These papers and the discussions upon them are now published in a volume uniform with Mr. Chanute's treatise on "Flying Machines," previously noticed in NATURE (vol. l. p. 569, 1894). Both show that many of the problems of aeronautics and aviation are being treated scientifically. The present volume is of special interest to meteorologists, for it contains several papers on the exploration of the upper atmosphere.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Liquefaction of Gases.

I DECLINE to follow Prof. Dewar into the fresh crop of irrelevant side issues raised by his letter in NATURE of February 28. The charge brought against Prof. Dewar, which I think I have amply substantiated, is that he has allowed the impression to go abroad that he has carried out much original research into the methods of liquefying the more permanent gases, and the properties of the liquids produced; whereas his experiments have been mainly repetitions of work done by others.

Prof. Dewar has not met this accusation. He has not proved that his methods for liquefying the more permanent gases are original methods, he has not even shown that for scientific purposes they are good methods; he has not proved that his experiments on the liquefied gases are either original or valuable; he has no attempted to rebut the actual facts, or to deal with the actual dates, brought forward by Prof. Olszewski and myself.

In his last letter Prof. Dewar gives a list of work "commenced and so far developed in the laboratory of the Royal Institution." The list might, however, have been made a little less grotesque by the omission of such things as "argon in liquid air," and the "liquefaction of hydrogen," and the substitution in place of these of a double &c.

When Prof. Dewar quits the region of romance, and tries to meet the definite statements I have made, and the evidence afforded by the dates I have quoted, I shall be ready to deal with his arguments to the best of my ability.

Cambridge, March 2. M. M. PATTISON MUIR.

Eleven-year Sun-spot Weather Period and its Multiples.

MANY years ago, investigations in regard to the existence of a period of about eleven years in the weather corresponding with the eleven-year sun-spot period were actively carried out in various parts of the world. Much data was accumulated in support of such a period, a large part of which was published in the earlier volumes of NATURE. But the investigations, as a whole, showed that the period was less marked or more complex than at first anticipated, so that recently less interest has been manifested in the subject, and indeed many express their doubts as to the existence of such a period.

One of the complexities which has helped to obscure the eleven-year period is the existence of what may perhaps be called weather harmonics, on account of the resemblance to harmonics in sound—that is, the existence of other periods related to the length of the first as 2, 3, 4, &c. Thus the existence of the eleven-year period is obscured by the existence of other periods of 22, 33, 44, &c., years.

If the reader will turn to the letter "On Some Temperature Variations in France and Greenland," in NATURE of October 11, 1894, he will find plotted the smoothed number of frost days and mean July temperatures at Paris for a large part of the present century. These curves show three marked waves in the temperature with the crests about 1825, 1848, and 1869, that is, almost exactly 22 years apart. If the dates of the chief maxima and minima of the individual curves are arranged under dates 22 years apart, as shown below, it will be seen that the dates closely approximate, thus:—

Mean dates of maxima	... 1825	... 1847	... 1869	... 1891
Frost days, Paris—minima	... 1824	... 1848	... 1868	... 1883
July temp. Paris—maxima	... 1826–34	... 1848	... 1870	... 1885
Mean dates of minima	... 1815	... 1837	... 1859	... 1881
Frost day, Paris—maxima	... 1814	... 1839	... 1856	... 1878–89
July temp. Paris—minima	1815	... 1842	... 1862	... 1881–90

If only the two highest maxima are considered, they occurred about 1826 and 1870, or 44 years apart; but if all the secondary and chief maxima are considered, there are indications of an 11-year period, thus :—

Mean dates of minima—
1814 ... 1825 ... 1836 ... 1847 ... 1858 .. 1869 ... 1880 ... 1891
Frost days, Paris—maxima—
1814 ... 1830 ... 1839 ... — ... 1856 ... — ... 1878 ... 1889
July temp. Paris, minima—
1815 ... 1830 ... 1842 ... — ... 1862 ... — ... 1881 ... 1890

In the *Annals* of the Astronomical Observatory of Harvard College, vol. xxxi. part 1, p. 103, is given the average temperature for each five years, observed at a large number of stations in New England. The three stations having the longest records, namely, New Haven, Connecticut, Cambridge, Massachusetts, and New Bedford, Massachusetts, are given below :—

Year.	1781-85.	1786-90.	1791-95.	1796-00.	1801-05.	1806-10.	1811-15.	1816-20.	1821-25.	1826-30.	1831-35.
Cambridge			50·4	48·0	49·4	47·4					
New Bedford ...								48·1	49·5	49·6	48·2
New Haven	49·0	49·8	49·8	50·0	51·2	49·3	47·8	46·9	49·2	49·8	48·1

Year.	1836-40.	1841-45.	1846-50.	1851-55.	1856-60.	1861-65.	1866-70.	1871-75	1876-80.	1881-85.	1886-90.
Cambridge		46·6	47·7	47·4	47·1	48·1	47·1	46·4	48·5	48·5	49·0
New Bedford ...	47·0	47·8	48·8	48·6	47·9	49·9	48·3	47·1	49·1	48·1	47·9
New Haven	47·5	49·4	49·1	48·6	48·9	50·6			51·7	48·4	48·6

These records show that maxima occurred in New England about 1803, 1828, 1848, 1863, 1876, and 1889, and minima about 1818, 1838, 1858, and 1873. If these are arranged according to intervals of 22 years, as before, the following results are obtained :—

Mean dates of
maxima ... ... 1803 ... 1825 ... 1847 ... 1869 ... 1891
Observed max. temp.
New England ... 1803 .. 1828 ... 1848 ... 1863 ... 1889
Minima ... ... 1814 ... 1836 ... 1858 ... 1880
Observed ... ... 1818 ... 1838 ... 1858 ... 1873

It will be seen that the dates of maximum and minimum temperature correspond almost exactly with those observed in Paris, showing how general were the forces acting to produce them.

That there exists all over the world a tendency to a period of about 33 years, is so well worked out by Brückner, that it is only necessary to refer the reader to his treatise on "Klimaschwankungen seit 1700," to find exhaustive data on this subject.

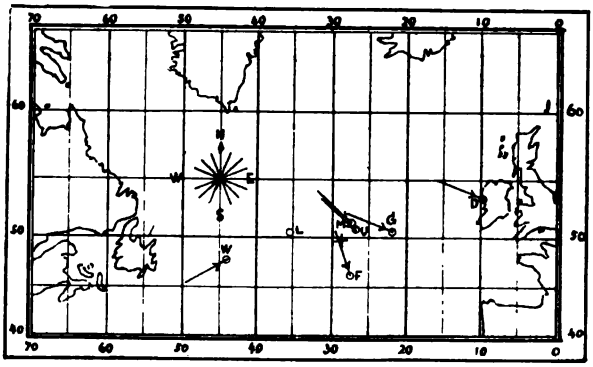
This harmonic tendency of multiplication in weather periods has been extensively worked out by the writer in shorter periods, and the evidence of its existence appears conclusive, based in that case on a very large mass of data. It is desired to call attention to it here, that those making future inquiries concerning sun-spot periodicity and the weather may bear the possibility of this phenomenon in mind. H. HELM CLAYTON.

Blue Hill Meteorological Observatory, Readville, Mass.

Abnormal Atlantic Waves.

In 1887 (NATURE, vol. xxxvii. p. 151) you kindly published a few remarks from me on the possible volcanic origin of the two waves which swept the decks of the steamers *Umbria* and *Faraday*, and which, from the data then available, seemed to have originated at a point in the Atlantic known as the "Faraday Reef," and marked with a cross (+) on the accompanying chart. I am now able to send you the details of a few similar cases which I have collected since then. The exact positions of the vessels, and the directions from which these solitary waves seemed to come, being also marked on the chart. In the case of H.M.S. *Orontes* the ship's course was not stated, and on account of darkness and other causes the directions from which some of the other waves came are not to be depended upon. None of these encounters would have been reported had they not caused much damage—masts and funnels going by the board, and bulwarks, deckhouses, and lifeboats being smashed; but many seafaring men can recall solitary and abnormally high waves having struck their vessels, although the sea was otherwise quiet. Amongst the strange results which these blows have produced, may be mentioned that the magnetism of the steamship *Energia* was thus suddenly altered sufficiently to introduce an error of 18° into the compass readings. The full details about this and a few other vessels have not been obtained.

North Atlantic.



Initial.	Ship's name.	Local time.	Date.	Latitude. North. °	′	Longitude. West. °	′	Speed.	Ship's course.	Wave's course.
								Knots.		
F	*Faraday*	6 45 a.m.	14/2/84	46	11	27	53	6	N. 72° E.	Port beam.
W	*Westernland* ...	2.45 a.m.	27/11/86	47	59	43	57	7	S. 60° W.	Bow.
G	*Germanic*	9.40 a.m.	5/5/87	50	36	22	8	4	N. 68° W.	Bow.
U	*Umbria*	4.40 a.m.	26/7/87	50	50	27	8	16	S. nearly W.	3 points on starboard bow.
	H.M.S. *Orontes*..	5 p.m.	18/2/91	36	12	32	50	9	?	Bow.
L	*Festina Lente* ...	noon.	16/11/94	50	12	35	23	?	S.E. by S.	?
M	*Manhattan*	2 a.m.	17/11/94	51	26	27	31	?	S. 86° W.	N.W.
D	*Diamond*	10 p.m.	21/11/94	53	9	9	52	Lying to	W.N.W.	W.N.W.

The following are short summaries of each case:

S.s. Faraday.—The wave was visible like a line of high land on the horizon about five minutes before it struck the vessel.

S.s. Westernland.—A huge wave rose to a great height just in advance of the ship. No other similar waves were met with. About noon the wind had changed from S.W. to W.N.W.

S.s. Germanic.—Wind W.N.W. with terrific squalls. Shipped a tremendous sea over bow.

S.s. Umbria.—The disturbance came from N.W. and consisted of two waves. The first one was broken, the second one green. The wind had previously changed from S.W. to N.W.

H.M.S. Orontes.—While steaming in smooth water a huge wave broke over the vessel forward.

S. Festina Lente.—A steep sea fell on board from both sides.

S.s. Manhattan. The sea was high, but fairly true until a mountainous wave broke on board from N.W.

S.s. Diamond.—Lying to, awaiting daylight to enter port. The wave was heard some time before it was seen, and then seemed to be about 40 feet high. The vessel never rose to it, but was literally submerged for a time.

An examination of the chart will show that with the exception of the *Westernland* each wave may have originated at a common centre, and might therefore be due to subaqueous volcanic activity. However, as the solitary waves which strike the west coast of South America and the so-called Death Waves on the west coast of Ireland are said to be regarded as precursors of storms, it is possible that these solitary Atlantic waves may be due to a similar cause; but even then it is inexplicable how a number of comparatively small and regular waves can be converted into one abnormal one, or how the reported changes of wind and consequent confused sea could produce such a wave. It will be noticed that the dates for the *Festina Lente*, *Manhattan*, and *Diamond* are very close together, and therefore there is a possibility that they were struck by the same wave. C. E. STROMEYER.

Glasgow, February 18.

The Presence of a Stridulating Organ in a Spider.

WHILST spending a short time at Alice Springs, in Central Australia, during the course of last year, in connection with the Horn Scientific Expedition, I found that it was firmly believed by a considerable number of people, white men and natives alike, that a spider existed in Central Australia which made a booming noise at night. Thanks to the assistance of the blacks, the spider itself was easily captured, but I could detect no organ capable of producing a booming sound. The animal forms a tubular burrow, about three-quarters of, or an inch, in diameter, which passes down for some eighteen to twenty-four inches in a slightly slanting direction until it terminates in a small chamber capable of holding the animal comfortably. In this chamber are found fragments of beetles upon which the animal has preyed, and a certain amount of web material; but there is no regular lining to the tube or chamber. The spider, which may reach a length of two and a half inches, and a span across the legs of five inches, proves to be *Phrictis crassipes*, belonging to the tribe *Territelariæ*, to which also belongs the well-known *Mygale*.

After listening carefully for the noise, and spending with a friend a night out in the open, in a spot where the booming could be heard, we came to the conclusion that the noise attributed to the spider was, in reality, made by a quail.

However, we kept some dozen specimens under observation in tin and wooden boxes, and after a few days in captivity, during which time they were very sluggish, one or two of them began to be more active, and on irritating one of the livelier ones (a large female) with a straw, I was pleased to see her rise on her hinder legs, and to hear her make a low whistling noise, moving alternately the palps up and down on the chelicerae as she did so. Whilst doing this she would make short angry darts at the straw.

On examination it was seen that the surface of the basal joint of the palp was provided with a somewhat oval-shaped comb-like structure composed of hard chitinous rods of various lengths, each ending in a club-shaped head. The comb is so placed that when the palp is moved up and down it rubs against a special part of the chelicera, which is provided with several rows of strong, sharply-tapering spines, and the sound produced can be heard, when the spider is in a box in a quiet room, at a distance of, at any rate, six or eight feet.

I was not at the time aware of the fact that, in the *Transactions* of the Entomological Society for 1877, Mr. Wood Mason had described a very similar stridulating organ in another ground-spider, *Mygale stridulans*, and it is interesting to note the close resemblance between, as well as the presence of, the organs in these two genera, both of which belong to the tribe *Territelariæ*. The figure given by Mr. Wood Mason admirably illustrates the position of the spider when it stridulates.

I hope to publish a full description of the organ in the volume dealing with the work of the Horn Expedition.

BALDWIN SPENCER.

Biological Laboratory, Melbourne University, January 24.

The Spectrum Top.

PERHAPS some of your readers may be glad to learn that the curious phenomena of the spectrum top can be shown on a screen to a large audience. It is only necessary to paint the usual black lines and sector on a suitable disc of glass, and then to mount it in a revolving stage which can be rotated in a lantern by means of a multiplying wheel. The projected disc of light must not be too large; if the lime-light be used the disc may be about 2 feet in diameter, and about double that size with the electric arc. A great variety of effects can be obtained by interposing coloured glasses in the path of the beam; *e.g.* with a green glass, and in diffused gas-light, the dark sector and lines appear to be mauve-coloured when suddenly stopped after rapid rotation, or when very slowly rotated, but become of a dark blue when the gas is turned off. On rotating the disc in the usual way the lines appear to be blue, green, and violet.

With a blue glass in gas-light the dark sector and lines appear to be yellow when suddenly stopped, but a fine purple without diffused light. The colours given by the lines at a moderate rate of rotation are red, grey, green, and blue. With a monochromatic red glass, the lines appear to be blue, grey, red, and dark red.

Is it not somewhat extraordinary that a rich blue colour can be obtained when dealing only with monochromatic red light? With whatever coloured light the disc is fed, the characteristic red lines at the centre, and blue at the periphery, or *vice versa*, seem almost invariably to appear. Altogether the phenomenon is worthy of further study by physiologists and physicists; the lantern appears to throw, in a double sense, new light upon this interesting problem. The idea of employing transmitted instead of reflected light for producing the phenomena of the spectrum top is partly the suggestion of Mr. T. J. Walls, instrument maker, Edinburgh, who constructed the disc for me. DAWSON TURNER.

Edinburgh, March 4.

THE AGE OF THE EARTH.

PROF. PERRY and I had not to wait long after the publication of his article "On the Age of the Earth" (NATURE, January 3, 1895, pp. 224-227) to learn that there was no ground for the assumption of greater conductivity of rock at higher temperatures, on which his effort to find that the consolidation of the earth took place far earlier than 400 million years ago, is chiefly founded. In a letter of date January 13, most courteously written to me by Dr. Robert Weber in consequence of his having seen by my letter to Prof. Perry of December 13, that we were anxious to find how far his experimental results regarding differences of thermal conductivity and specific heat at different temperatures could be accepted as trustworthy, he tells me that he had made farther experiments on an improved plan, and that on the whole his investigations do not seem to prove augmentation of conductivity with temperature; and he kindly gives me, with permission to communicate to NATURE, the following results, hitherto unpublished, of experiments which he made in t e years 1885 and 1886 on the thermal conductivities (k) and specific heats (c) of five rocks.

	Density	
Basalt	3·0144 ...	$c=0.1763+0.000296t$ [between 0° and 60°] $c=0.1946+0.000575(t-60)$ [between 60° and 110°] $k=0.00317\{1+0.00001t\}$
Marble ...	2·7036 ...	$c=0.20279+0.000466.t$ $k=0.00540\{1-0.000005.t\}$
Rock salt ...	2·161 ...	$c=0.2146+0.00017t$ $k=0.0137\{1-.0044t\}$
Anhydrite of Jura ...	2·892 ...	$c=0.1802+0.0003.t$ $k=0.0123\{1-0.0024.t\}$
Quartz ...	2·638 ...	$c=0.1754+0.0004.t$ $k=0.01576\{1-0.0019.t\}$

These results show practically no change of thermal conductivity with temperature for Basalt and Marble. For Rock Salt, Anhydrite of Jura, and Quartz, they show diminutions of thermal conductivity amounting per 100° C. to 44 per cent., 24 per cent., and 19 per cent. respectively. They contrast curiously with the 75 per cent. *augmentation* of thermal conductivity per 100° C. (NATURE, January 3, p. 226), used by Prof. Perry in his estimate of the age of the earth, and they form a practical comment on his statement (NATURE, January 3, p. 226):—"From the analogies with electric conduction, one would say, without any experimenting, that as "a metal diminishes in conductivity with increase of "temperature, so a salt, a mixture of salts, a rock, may "be expected to increase in conductivity with increase of "temperature."

Since the beginning of January I have myself been endeavouring to find by experiment the proportionate differences of thermal conductivity of rocks at different temperatures; and before the end of January I had made some preliminary experiments on slate and sandstone, from which I was able to tell Prof. Perry that the thermal conductivity of each of these two rocks is probably less at higher temperatures than at lower. Since that time I have been arranging for experiments on granite, in which as rapid progress as I would have liked has been impossible for many reasons, including the necessity of standardising a Kew certificated thermometer of 1886, now for the first time being compared with an air thermometer in my laboratory. Unless its differences from the air thermometer are much larger than can be expected from what we know of the behaviour of mercury-in-glass thermometers generally, it is already almost proved that the thermal conductivity of granite is *less* between 150° C. and 250° than between 50° and 150°.

As to specific heats there can be little doubt but that *they* increase with temperature up to the melting point of rock, but the rate of augmentation assumed by Prof. Perry is about five times as much as that determined up to 1200° by the experiments of Rücker and Roberts-Austen (*Phil. Mag.*, 1891, second half-year, p. 353) for Basalt, and of Carl Barus (*Phil. Mag.*, 1893, first half-year, pp. 301–303) for Diabase; these being apparently the only experiments hitherto made on specific heats of rock at temperatures beyond the range of the mercury-in-glass thermometer.

Taking the primitive temperature as 4000° C. and the thermal conductivity and the specific heat at this temperature respectively 30 times and 14½ times their values at the surface, and throwing in a factor 3 for three-fold density at the greater depths (though the average density of the *whole* earth is scarcely double that of the upper crust) Perry takes the product of three factors $30 \times 14\frac{1}{2} \times 3$ and so finds in round numbers 1300 times my estimate as his corrected estimate of the age of the earth!! (NATURE, January 3, p. 227.)

But even if the ratios of thermal conductivities and of specific heats at the higher and lower temperatures were as assumed, Prof. Perry's product of the two corresponding factors vastly over-estimates the age. Of this I thought I had given a sufficient warning when I wrote to him (December 13), "But your solution on the supposition of an upper stratum of *constant* thickness, having smaller conductivity and smaller thermal capacity than the strata below it, is very far from being applicable to the true case in which the qualities depend on the temperature." (NATURE, January 3, p. 227.) It is obvious that the supposed higher thermal conductivity and the higher specific heat, if beginning suddenly at a short distance below the surface, and continuing constant to the great depth, would greatly prolong the time of cooling to the same surface-gradient, beyond what it would be with these qualities increasing continuously with temperature. For the simple case of conductivity assumed to increase in the same proportion as specific heat, Prof. Perry has himself since given in a later communication (NATURE, February 7, pp. 341–342) the necessary correction of his previous mathematics: and in an example of his own choosing (50 per cent. augmentation of each quality per 100° elevation of temperature), he now finds 121 times my estimate for the age of the earth, instead of 441 times as by the formula which he used in his first article.

When the ratio of thermal conductivity to specific heat per unit bulk varies with the temperature, the problem of secular cooling presents mathematical difficulties which, so far as I know, have not been hitherto attacked; but I find it quite amenable to analytical treatment, and I hope before long to be able to offer a paper to the Royal Society of Edinburgh on the subject, as an appendix to my original paper "On the Secular Cooling of the Earth," published in its *Transactions* (1862). I have already worked out numerically two cases, in one of which both conductivity and specific heat increase with temperature, and in the other the specific heat increases with the temperature but the conductivity is constant. The first of these is at present only interesting as a mathematical exercise because, according to present knowledge, it is more probable that the thermal conductivity decreases than increases with increasing temperature. To the results of the second I shall refer later as substantially helping us towards a revised estimate of the time which has elapsed since the consolidation of the earth.

Twelve years ago, in a laboratory established by Mr. Clarence King in connection with the United States Geological Survey, a very important series of experimental researches on the physical properties of rocks at high temperatures was commenced by Dr. Carl Barus for the purpose of supplying trustworthy data for geological theory. Mr. Clarence King, in an article "On the Age of the Earth" published in the *American Journal of Science* (vol. xlv., Jan. 1893), used data thus supplied, to estimate the age of the earth more definitely than was possible for me in 1862 with the very meagre information then available as to specific heats, thermal conductivities, and temperatures of fusion. I had taken 7000° F. (3871° C.) as a high estimate of the temperature of melting rock. Even then I might have taken something between 1000° C. and 2000° C. as more probable, but I was most anxious not to *under*-estimate the age of the earth, and so I founded my primary calculation on the 7000° F. for the temperature of melting rock. Now we know from the work of Carl Barus (*Phil. Mag.* 1893, first half-year, pp. 186, 187, 301–305) that Diabase, a typical Basalt of very primitive character, melts between 1100° C. and 1170° and is thoroughly liquid at 1200°. The correction from 3871° C. to 1200° or $1/3.22$ of that value, for the temperature of solidification, would, with no other change of assumptions, reduce my estimate of 100 million to $1/(3.22)^2$ of its amount or a little less than ten million years; but the effect of pressure on the temperature of solidification must also be taken into account, and Mr. Clarence King, after a careful scrutiny of all the data given to him for this purpose by Dr. Barus, concludes that without farther experimental data "we have no "warrant for extending the earth's age beyond 24 millions "of years."

By the solution of the conductivity problem to which I have referred above, with specific heat increasing up to the melting point, as found by Rücker and Roberts-Austen and by Barus, but with the conductivity assumed constant, and by taking into account the augmentation of melting temperature with pressure in a somewhat more complete manner than that adopted by Mr. Clarence King, I am not led to differ much from his estimate of 24 million years. But, until we know something more than we know at present as to the probable diminution, or still conceivably possible augmentation, of thermal conductivity with increasing temperature, it would be quite uninteresting to publish any closer estimate.

In the latter part of Mr. Clarence King's paper on the "Age of the Earth" the estimates of the age of the sun's heat by Helmholtz, Newcomb, and myself, are carefully considered, and the following sentences with which the paper is brought to a conclusion will, I am sure, be interesting to readers of NATURE:—"From this point of "view the conclusions of the earlier part of this paper "become of interest. The earth's age, about twenty-four "millions of years, accords with the fifteen or twenty "millions found for the sun.

"In so far as future investigation shall prove a secular "augmentation of the sun's emission from early to pre-"sent time in conformity with Lane's law, his age may "be lengthened, and further study of terrestrial conduc-"tivity will probably extend that of the earth.

"Yet the concordance of results between the ages of "sun and earth, certainly strengthens the physical case "and throws the burden of proof upon those who hold "to the vaguely vast age, derived from sedimentary "geology."

KELVIN.

NOTES.

IN addition to Lord Aberdare, the Royal Society has to mourn the loss of two more of its Fellows. Sir Henry Rawlinson, the distinguished Orientalist, died on Tuesday, in his eighty-fifth year. He was elected into the Society so long ago as 1850. Sir William Savory, who died on Monday, at the age of sixty-nine, was admitted eight years later.

WE have also to announce the death of Dr. D. H. Tuke, well known for his works on psychological medicine.

IT is announced in the *British Medical Journal* that Dr. Armand Ruffer has tendered his resignation of the post of Director of the British Institution of Preventive Medicine.

WHEN the news of Prof. Cayley's death reached America, American mathematicians were not slow in expressing sympathy with their English brethren. We are informed that—"In that great American University, the Johns Hopkins, in which, not many years ago, Prof. Sylvester and Prof. Cayley, at the same time, gave instruction in advanced mathematics, the death of Prof. Cayley was the occasion of universal mourning, and all was appropriately draped with black."

IT appears from a correspondence between the Board of Trade and the Electric Lighting Committee of the St. Pancras Vestry, that Major Cardew, the electrical adviser of this department, has discovered, during his investigations into the recent explosions in the street boxes used for electrical supply in St. Pancras, that a remarkable deposit on some of the insulators contained a considerable quantity of the metal sodium. The presence of this metal appears to be so grave a source of danger, and to afford so reasonable an explanation, in connection with the accumulation of escaped coal-gas, of the several explosions which have recently occurred, that the Board of Trade intends to investigate the causes of the deposit of this substance with a view to its prevention, and in this investigation they have asked for the assistance of the Royal Society and of the Institution of Electrical Engineers.

PROF. CHARLES STEWART will deliver a course of six lectures on "The Internal Framework of Plants and Animals," at the Royal College of Surgeons, Lincoln's Inn Fields, on March 11, 13, 15, 18, 20, and 22, at five o'clock. Admission to the lectures can be obtained on presentation of visiting card.

A CORRESPONDENT, writing from Brooklyn on February 16, says:—The severity of the weather and depth of snowfall throughout the southern United States for the past few days are unparalleled. On the 14th inst. the temperature at Abilene, Texas, was 15°, and in the State of Georgia it ranged about 9° lower than in New York city. Yesterday there was snow five inches deep in Atlanta, four inches at Darien, three inches at Thomasville, and two inches at Savannah, all in Georgia; two feet at Birmingham, Alabama; eight inches at New Orleans, Louisiana; six inches at Galveston, Texas, with snow falling as far south as Corpus Christi. In many places there had never before been snow enough to cover the ground to any measurable depth.

FROST prevailed during the greater part of the past week in nearly all parts of the United Kingdom, and in the northern and midland districts the thermometer in the screen has on several nights fallen as much as 10° below the freezing point. Snow has fallen over the greater part of the country, and in Scotland the amount has been heavy. The type of weather has been chiefly anti-cyclonic, and an area of low barometer readings was for several days situated to the eastward of our islands, so that strong and cold northerly winds were experienced over the entire country. A correspondent at Dundee states that the temperature in that district during the last two months was unusually low. The average maximum temperature of January and February was 36°·6, and the average minimum, 24°·9, so that the average mean temperature for that vicinity was about 30°·7. The normal values published by the Meteorological Council for Leith, a little more to the south, give 39°·5 as the average mean temperature for the two months.

PROF. M. MÜLLER contributed an article to the January number of *Globus* (Brunswick) on meteorology and the figure of the earth, which contains much useful information upon the subject of atmospheric circulation, and the results of the author's own investigations. He points out very clearly the effects of the earth's rotation and of the polar compression on the motion of the air, and strongly opposes the theory of equatorial and polar currents as propounded by Dove and his adherents. He explains the enormous forces that would be required to transpose a kilogram of air from the pole to the equator, and shows that the motion of a particle closely resembles that of a ball which is kept in circular motion on a revolving plate by a juggler, the rapid rotation of the plate, and of the earth, acting similarly on both ball and air, and keeping both moving in comparatively small and nearly closed curves.

DR. A. CANCANI notes the existence of two systems of undulations in the Constantinople earthquake of July 10, 1894, one propagated with a velocity of 4·9 km. per second, the other with a velocity of 2·3 km. per second (*Rend. dell' Acc. dei*

Lincei, December 16, 1894). The latter estimate is obtained from the times furnished by magnetic or astronomical observatories, possessing instruments capable of recording long-period oscillations only. The instruments of the Italian seismic observatories, on the other hand, registered the rapid movements travelling with the greater velocity, as well as the longer oscillations, whose velocity is again found to be 2·3 km. per second. Dr. Cancani remarks that these results agree with the theory explained by him in a former paper (*Ann. dell' Uff. Centr. di Met. e Geod.* vol. xv. 1893).

NEWS has recently been received regarding the three attempts made last year to extend our knowledge of the higher mountains of Africa. The most important of these was Mr. Scott Elliot's expedition to Ruwenzori, some of the preliminary results of which he announced in a recent letter to NATURE. Mr. Scott Elliot seems to have found the higher slopes of the mountain extremely trying to the native porters. Botanical results of the highest interest may be expected from the work of such an experienced African botanist. As Mr. Scott Elliot did not succeed in reaching the highest zone in the mountain, his description of its geology may be incomplete. He has, however, announced one conclusion of the highest importance, viz. the discovery of traces of the existence of glaciers, seven miles below the existing snow-line. It will be remembered that in a recent paper published by the Geological Society, Dr. J. W. Gregory fully described similar glacial extension on Mount Kenya. The difficulty, however, has been felt that the same fact has not been recorded from Kilima Njaro, in spite of the numerous visits to that mountain. The glaciers there now seem to be at their greatest extension. It is probable that this is due to the fact that the peak with the existing glaciers is of very recent date. The absence of moraines from the older peak appeared perplexing. Mr. Scott Elliot's discovery, however, shows that the greater glaciation of Kenya was not due to a purely local cause, but to some change that affected the whole region.

WE have received a copy of the *British Central Africa Gazette* (vol. i. No. 15), describing Capt. Manning's recen ascent of Mount Mlanje, on October 22–25. The mountain ist now well known from the botanical collections made there by Mr. Whyte, under the direction of Mr. H. H. Johnston. Previous attempts to ascend it had, however, failed through lack of time. Capt. Manning's party do not appear to have found the climbing very difficult. The summit is estimated at 9680 feet; but we are not told by what method this was determined. Apparently it was only by aneroid. The party were helped up by a new method of roping, which ought to recommend itself to the Chamounix and Zermatt guides. They used a long loop of calico, which they called a "machila": the climber leant back at one end of it, six or eight strong men pulled at the other. Probably in time, to "machila the Matterhorn" will be the regular thing in a Swiss trip.

THE third expedition to which we have to refer, has unfortunately not been successful in its attempt to solve the mystery of the reported snow-clad mountain which occurs between Kenya and Abyssinia. The existence of this has been frequently reported since it was first recorded by Abbadie as Mount Wosho. It was hoped that Dr. Donaldson Smith's expedition would have finally settled this question of the height and position of this mountain. The expedition has, however, been stopped by the Abyssinians, and sent back to the Somali frontier at Barri. His companion, Mr. Gillatt, has been compelled to return home, but Dr. Smith has determined to continue the expedition. As the rainy season and unhealthy country are before him, and as such people as the Somali are easily dispirited by a first failure, it is hardly likely that Dr. Smith will reach Mount Wosho. He proposes to strike south for the Juba, and then westward across the Borana country to Basso Narok (Lake Rudolph). The expedition has already achieved some very interesting results, and if it succeed in its traverse of the Borana country, it will have amply atoned for its failure to reach its original goal of the Omo valley.

IN an address to the United States National Geographic Society, recently published in the *National Geographic Magazine*, Dr. C. Hart Merriam discusses the influence of temperature upon the geographical distribution of terrestrial animals and plants. It is well known that in the northern hemisphere animals and plants are distributed in circumpolar belts or zones, the boundaries of which follow lines of equal temperature; but difference of opinion prevails as to the period during which temperature exerts its restraining influence. Dr. Merriam opens new ground in the address to which we refer. Physiological botanists have long maintained that the various events in the life of plants, such as leafing, flowering, &c., take place when the plants have been exposed to definite quantities of heat, which are the sums total of the daily temperatures above a minimum (6° C.) assumed to be necessary for functional activity, and are termed the *physiological constants* of the particular stages. Dr. Merriam infers from this that there must also be a physiological constant for the species itself; and this *species constant* must be the total quantity of heat required by a given species to complete its cycle of development and reproduction. It follows that not only the mean temperature, but also the total quantity of heat in particular zones must be considered in estimating the influence of temperature upon the distribution of plants and animals. Dr. Merriam has constructed a pair of isothermal charts of the United States, of which one shows the distribution of the total quantity of heat during the season of growth and reproduction (*i.e.* the sum of daily mean temperatures above 6° C.), and the other the mean temperatures during the six hottest weeks of the year. By comparing these with a bio-geographical chart of the same region, Dr. Merriman concludes, from the striking coincidences which occur, that animals and plants are restricted in northward distribution by the total quantity of heat during the season of growth and reproduction, and in southward distribution by the mean temperature of a brief period during the hottest part of the year. The anomalous intermingling of boreal and austral types which occurs over an extensive area of the Pacific coast of the United States becomes explicable by the establishment of these principles, for here alone is a low summer temperature combined with a high sum-total of heat—the two conditions which permit extensive mixture in the same region of northern and southern types.

A CASE of dual brain action, presenting points of special interest, both in physiology and psychology, is described in *Brain* (Part lxix.) by Mr. L. C. Bruce. The patient who formed the subject of observation varied considerably in his mental condition, and the most obvious phenomena observed during these changes were that in one condition he spoke the English language, and in the other the Welsh language. When in the former state, he was the subject of chronic mania. He was right-handed, and exhibited a fair amount of intelligence. He remembered clearly things he had noticed in previous English periods, but his memory was a blank to any that occurred during the Welsh stages. He wrote by preference with his right hand, his letters were fairly legible, and he wrote from left to right. If asked to do so, he would write with the left hand, but then produced mirror writing, traversing the paper from right to left. When in the Welsh stage, however, he was left-handed and the subject of dementia. His speech was almost unintelligible, but what could be understood was in the Welsh language. In this stage he had no idea of English, and his mental and physical conditions altogether were the reverse of what they were in the English stage. From these observations, Mr. Bruce is led to believe that "the cerebral hemispheres are capable of individual mental action, and that the mentally active cerebrum has a preponderating influence over the control of the motor functions, the patient living two separate existences during the two stages through which he passes; the mental impressions received during each of these separate existences being recorded in one cerebral hemisphere only." If the cerebral hemispheres did not act independently, it is difficult to account for the patient's ignorance of events which happened to him in the Welsh stage when he passed into the English condition.

A note on the electrostatic capacity of resistance coils wound in the ordinary way to avoid self-induction, is published in the *Comptes rendus* (February 11). The author (M. J. Cauro) has experimentally determined the electrostatic capacity of coils wound in several different ways, using for this purpose a Wheatstone's bridge arrangement with a commutator similar to that used by Ayrton and Perry in their secohmmeter. By comparing coils of practically the same shape and resistance the author finds that the errors due to capacity may, in the case of coils containing a large number of turns, be considerable when the ordinary double method of winding is adopted, but these errors are considerably reduced if the method of winding proposed by M. Chaperon is employed. The best results of all are obtained by winding the two wires in alternate layers, always starting from the same end of the bobbin, the wire being brought back parallel to the axis of the coil. For instance, with coils having a resistance of about 14,000 ohms and about 9500 turns, the three methods of winding give apparent self-induction (due to capacity) of $-1·79$, $-0·27$ and $-0·16$ respectively. In order to make sure that the values obtained were really due to capacity, the author placed bundles of fine iron wire inside the different coils. The results obtained in this case were the same as those obtained without any iron core. By altering the connection of the two wires in the coil wound in the ordinary manner, so that the current traversed the two circuits in the same direction, the self-induction was found to be 0·13. Thus by winding the wire double, the error due to electrostatic capacity was about twelve times as great as the error to eliminate which this method of winding was adopted.

Two volumes recently added to the comprehensive Aide Mémoire series, published jointly by Gauthier-Villars and Masson, Paris, are:—"Appareils Accessoires des Chaudières a Vapeur," by MM. Dudebout and Croneau, and "Traité des Bicycles et Bicyclettes" by Dr. C. Bourlet.

The names of the members of the electrical and kindred industries throughout the world are contained in "The Universal Electrical Directory," published by Messrs. H. Alabaster, Gatehouse, and Co. For simplicity and facility of reference the names are divided into four groups—namely, British, Continental, American, and Colonial, which are again subdivided into alphabetical and classified sections. There are nearly twenty-one thousand names in all, or two thousand five hundred more names than were given in the Directory for 1894.

Among the forthcoming books to be published by Messrs. J. and A. Churchill, the following are announced to appear at an early date:—"A Manual of Botany" based on that of the late Prof. Bentley, vol. i., "Morphology and Anatomy," enriched with a large number of new illustrations, by Prof. J. Reynolds Green; "Elements of Health, an Introduction to the Study of Hygiene," by Dr. Louis C. Parkes; and "Mental Physiology, especially in its relation to Mental Disorders," with illustrations, by Dr. T. B. Hyslop.

A valuable work on the climatology of Africa, and on the distribution of disease in that continent, has just appeared. It is entitled "Tropical Diseases in Africa," by Dr. R. W. Felkin, and is published by Mr. W. F. Clay, Edinburgh. The volume is based upon a lecture delivered at the African Ethnological Congress held at Chicago in 1893, and contains, as an appendix, a paper, read before the Budapest Congress last September, on a new method for graphically illustrating the geographical distribution of disease. The book forms an important addition to the literature upon tropical disease in Africa.

Men of science are indebted to the beneficent provisions of the Smithsonian Institution for the generous distribution of scientific literature. A publication of special value to chemists is the "Bibliography of Aceto Acetic Ester and its Derivatives," by Mr. Paul H. Seymour, which, acting upon the recommendation of the American Association's Committee on Indexing Chemical Literature, the Institution has lately issued. The bibliography is arranged in chronological order from 1840, with author and subject indices appended. The outlines of memoirs are given, in order to show the scope of the originals. Mr. Seymour deserves the gratitude of chemists for this time-saving bibliography, upon which he has evidently bestowed much care.

Another paper prepared for the Committee on Indexing Chemical Literature, is "An Index to the Literature of Didymium," by Dr. A. C. Langmuir, just distributed as No. 972 of the Smithsonian Miscellaneous Collections. The index contains references to all the papers published on didymium, from the discovery of the element in 1842 to the year 1893. It furnishes a striking illustration of the wonderful results accomplished by the use of the spectroscope in modern chemistry. In addition to didymium, the following elements have now been indexed: Columbium, iridium, manganese, titanium, uranium, vanadium.

We note the publication of the *Bulletin Météorologique* of the Imperial Observatory of Constantinople, for the year 1894. Although telegraphic observations have been published in the Paris weather report, we believe that very few regular observations from Constantinople have been received in this country for some twenty years. The bulletin contains some means derived from twenty-seven years' observations, which show that the maximum shade temperature was 99°·5, in 1888, and the minimum, 17°·2, in 1869. The average yearly rainfall is 23·3 inches, and the average frequency, eighty-six days. Snow falls on about fifteen days, and fog occurs, on an average, on fifty-nine days. An appendix contains a list of the earthquakes in the Ottoman empire during the year 1894.

A sketch of the attainments and life-work of Dr. T. B. Rake, who died at Trinidad last August, is given in the *Journal* of the Trinidad Field-Naturalists Club for December 1894. Dr. Rake was the superintendent of the Leper Asylum at Trinidad, and presided over the Leprosy Commission. The reports issued during his eight years' administration of the Asylum are of the highest value, for he was well acquainted with bacteriological methods of research, and he put on record numerous observations referring to the leprosy bacillus. He was not, however, only a high authority on leprosy, but an enthusiastic and keen observer of nature. At the time of his death he was the President of the Trinidad Field-Naturalists Club, the members of which will remember him for many years to come. An excellently reproduced portrait of Dr. Rake forms the frontispiece of the *Journal* containing the very appreciative obituary notice.

A monument to the humanitarian spirit of the members of the Mulhouse Association pour prevenir les Accidents des

Fabriques is afforded by a ponderous volume, the second edition of which has been received from the Association. The volume is entitled "Collection of Appliances and Apparatus for the Prevention of Accidents in Factories." It is illustrated by thirty-seven finely-drawn plates, and the text is printed in French, German, and English. The London agents are Messrs. Dulau and Co. What strikingly indicates the high motives which actuate the Association is that the volume is published at the price it cost to reproduce. The one object of publication is to spread the knowledge, and encourage the adoption, of the numerous appliances devised for the prevention of accidents from machinery. The factory inspector and manager, the mechanical engineer, and all others who are concerned in the construction and use of machinery, should see this very useful volume.

WE have received the first two numbers (1892-1893) of the yearly *Bulletin of the Geological Institution of the University of Upsala.* This is a publication that should be of great interest to all British geologists whose work lies among the Lower Palæozoic rocks, since on those strata Swedish researches have thrown so much light. Among the contents are two papers by C. Wiman, on the structure of Graptolites; stratigraphical papers, by the same author, and J. G. Andersson; petrographical and mineralogical papers, by Prof. Nordenskiold and H. Sjögren; and others. Nine plates in all, illustrate the numbers. The papers are all in either English or German (French is the only other language permitted); this will be satisfactory to those British geologists who have found the Swedish language a serious barrier to the study of important geological papers in the past. We may add that the *Bulletin* will be sent, not only to all geological institutions, but also to all private workers who send their publications regularly in exchange.

AMONG the new editions received during the past week, is the second edition of the "Introduction to Physiological Psychology" (Swan Sonnenschein and Co.), translated from the revised and enlarged second German edition of Dr. Trichen's work, reviewed in these columns four years ago (vol. xliv. p. 145). The chief addition is a chapter upon the emotional tone of the ideas. Another new edition (the fourth), just received, is "A Treatise on Elementary Trigonometry" (Longmans, Green, and Co.), by Dr. John Casey, F.R.S., edited by Prof. P. A. E. Dowling. This little work has found favour among many teachers and students, and the new issue should be even more popular. Dr. W. H. Besant's "Conic Sections" (George Bell and Sons) has reached a ninth edition. The articles on reciprocal polars have been expanded into a separate chapter, and a chapter on conical projections has been inserted. Two other books, which may be included among new issues, belong to the handy series of Economic Classics published by Messrs. Macmillan and Co. One consists of select chapters and passages from Adam Smith's "Wealth of Nations"; the other contains the first six chapters of Ricardo's "Principles of Political Economy and Taxation."

MESSRS. SWAN SONNENSCHEIN AND CO. have in the press an important work on the Indian Calendar, written by Mr. Robert Sewell, in collaboration with Mr. Sankara Bâlkrishna Dikshit. The work contains complete tables for the verification of Hindu and Muhammadan dates for a period of 1600 years (A.D. 300 to 1900), and forms an attempt to carry out in practical form the exact fixation of the astronomical phenomena on which the Hindu Calendar depends, and without which no conversion of dates into European reckoning can be safely relied upon. It embraces the whole of India. The calculations have been based on the general tables published by Prof. Jacobi, of Bonn, checked and enlarged by Mr. S. Bâlkrishna Dikshit. The precise position of sun and moon at sunrise on the meridian of Ujjain on the first day of each year of the Luni-solar Calendar during the period referred to is given, and for the Solar Calendar the moment of the sun's passing the first point of Aries in each year is entered in time reckoning. Full details for the addition and suppression of months in the intercalary Luni-solar years are provided; and where necessary the calculations have been made for true as well as mean intercalations. The solar phenomena have, moreover, been computed by both the Ârya and Sûrya Siddhântas. It is hoped that the volume will form a standard work of reference for chronologists, as well as for all courts and offices in India.

THE additions to the Zoological Society's Gardens during the past week include a Giraffe (*Giraffa camelopardalis*, ♀) two Sable Antelopes (*Hippotragus niger*, ♂ ♀) two Brindled Gnus (*Connochætes taurina*, ♂ ♀), a Levaillant's Cynictis (*Cynictis penicillata*) from South Africa, two great Eagle Owls (*Bubo maximus*), European, purchased; two Rock-hopper Penguins (*Eudyptes chrysocome*) from New Zealand, four Black Francolins (*Francolinus vulgaris*) from India, a Robben Island Snake (*Coronella phocarum*) from South Africa, deposited; a Black-headed Gull (*Larus ridibundus*), British, presented by Mrs. Rees Davis; a —— Buzzard (*Buteo*, sp. inc.) from South Africa, presented by Mr. J. E. Matcham; a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by Dr. Arthur D. Bensusan.

OUR ASTRONOMICAL COLUMN.

SPECTROSCOPIC MEASURES OF PLANETARY VELOCITIES.—A new feature in the application of the Doppler-Fizeau principle has been recently brought forward by M. Deslandres (*Comptes rendus*, Feb. 25). It is to the effect that when we observe the spectrum of a body shining by reflected light the displacement of the lines due to movements in the line of sight depends upon the movement of the body with respect to the original source of light, as well as on its movement with regard to the observer.

The truth of this principle is demonstrated by an investigation of the rotation of Jupiter which M. Deslandres has carried out with his usual skill. The equatorial linear velocity of the planet is 12·4 kilometres, and the difference of the velocities of the two extreme edges 24·8 kilometres; actual measurements of the spectrum photographs taken near opposition, however, show a relative movement of twice this amount. The best results appear to have been obtained by allowing the equator of the planet to lie along the slit of the spectroscope, in which case the effect of the displacements at different distances from the centre is obviously to produce an inclination of the lines of the planet spectrum to the lines of the comparison spectrum, and this inclination affords the means of determining the velocities. This method has the advantage that the effects of small movements of the image on the slit during the long exposure necessary with the great dispersion employed are of little consequence; movements in declination will have no effect on the inclination of the lines, and movements in right ascension will only tend to make them somewhat more diffuse.

M. Deslandres points out that the new principle may possibly have many important applications in connection with planetary velocities, among which he specially mentions the determination of the rotation period of Venus, and even possibly of the solar parallax, the latter being derived from the radial velocity of Venus. M. Poincaré shows that M. Deslandres' results are quite in accordance with theoretical considerations.

THE SATELLITES OF MARS.—Prof. Campbell, of the Lick Observatory, took advantage of the recent opposition of Mars to secure a long series of micrometric measurements of the satellites with the 3-foot telescope (*Astr. Journal*, No. 337). The reduction of the observations of Phobos shows that the eastern elongation distance was nearly a second greater than the western, whereas Hall's observations in 1877 showed that the distance at western elongation was then about 2"·2 greater than the eastern. "If the orbit had remained unchanged from 1877, the western distance in 1894 should have been about 1"·8 greater than the eastern. The change of nearly 2"·8 was evidence of a marked transformation of the orbit during the years 1877–94. The line of apsides has probably revolved owing to a polar compression of the planet." The observations also appear to indicate a similar transformation of the orbit of Deimos, but the evidence is not quite so conclusive.

Both satellites are about 6 minutes behind Marth's ephemeris, so that the adopted values of their periodic times require slight correction.

ECLIPSE OF THE MOON, MARCH 11.—The following particulars with regard to the total eclipse of the moon on the morning of Monday, March 11, may be of interest:—

	G. M. T. h. m.
First contact with penumbra	0 58·4
,, ,, shadow	1 53·9
Beginning of total phase	2 51·8
Middle ,, ,, ...	3 39·2
End ,, ,, ...	4 26·6
Last contact with shadow	5 24·5
,, ,, penumbra	6 20·0

The first contact with the shadow will occur at 127° from the north point of the moon's limb towards the east, and the last contact at 69° towards the west, in both cases for the direct image as seen with the naked eye. The magnitude of the eclipse (moon's diameter = unity) will be 1·619.

The moon will be seen in the shadow at places between longitudes 5h. E. and 12h. W. Among the principal stars occulted during the eclipse will be 83 Leonis, mag. 7·5, which will disappear at 2h. 17m. at an angle of 95° and reappear at 3h. 12m. at an angle of 338°; and τ Leonis, mag. 5·0, which will disappear at 2h. 56m. at 86°, and reappear at 3h. 43m. at an angle of 345°; the angles being reckoned from north towards east.

THE NILE.[1]

I AM to speak to you to-night of the Nile, and I think I may fairly say it is the most famous river in all the world: famous through all the ages, for the civilisation that has existed on its banks; famous for its mystic fabulous rise, about which so many sages and philosophers have pondered; famous for its length, traversing one-fifth the distance from pole to pole; famous, and apparently destined to be famous, for the political combinations that ever centres around it. But I feel I must begin by an apology, for now that Egypt has come so completely within the tourist's range, probably many of my hearers have seen more of the Nile than I have.

If a foreigner were to lecture to his countrymen about the river Thames, and were to begin by informing them that he had never been above Greenwich, he might be looked upon as an impostor; and perhaps I am not much better, for I have never been higher up the river than Philæ, 610 miles above Cairo. For information regarding anything higher up, I must go, like you, to the works of Speke, Baker, Stanley, and our other great explorers. I shall not, then, detain you to-night with any elaborate account of this upper portion of the river, but will only remind you briefly of that great inland sea, the Victoria Nyanza, in extent only a little less than the American Lake Superior, traversed by the equator, and fed by many rivers, some of them taking their rise as far as 5° S. lat. These rivers form the true source of the Nile, the mystery only solved in the present generation.

The outlet of this great lake is on its north shore, where the river rushes over the Ripon Falls, estimated by Speke at only 400 or 500 feet wide, and with a drop of 12 feet. Thence the river's course is in a north-west direction for 270 miles, to where it thunders over the Murchison Falls, a cliff of 120 feet high. Soon after that it joins the northern end of Baker's Lake, the Albert Nyanza, but only to leave it again, and to pursue its course through a great marshy land for more than 600 miles, to where the Bahr Gazelle joins it from the west; a little further down the great Saubat tributary comes in on the east. This is the region in which the river is obstructed by islands of floating vegetation, which, if checked in their course, at last block up its whole width, and form solid obstructions known as *sadds*, substantial enough to be used as bridges, and obstacles, of course, to navigation, until they are cleared away. The waters of the Saubat are of very light colour, and tinge the whole river, which, above its junction, is green and unwholesome, from the long chain of marshes which it traverses. Hence it is called the White Nile. 600 miles further brings us to Khartoum, where the Blue Nile from the Abyssinian mountains joins it, and at 200 miles still further to the north it is joined by the Atbara river, also from Abyssinia, a torrent rather than a river.

Baker gives a graphic account of how he was encamped by the dry bed of the Atbara on June 22, 1861. The heat was intense, the country was parched with drought. During the night the cry went forth that the floods were coming, and in the morning he found himself on the banks of a river, he says, 500 yards wide and from 15 to 20 feet deep. All nature had sprung into life. A little north of the junction of the Atbara is Berber, whence you will remember is the short cut to Suakin in the Red Sea, which so many thought would have been the true route for our Army to take in relieving Gordon. From Khartoum to Assouan is a distance of 1100 miles of river, during which it makes two immense curves, for on a straight line the distance is not half so much, and it is in this part of its course that it passes over the six great cataracts or rapids which block all ordinary navigation. The first or furthest north cataract is just above Assouan, a distance of 750 miles from the Mediterranean, through the country known as Egypt. From the junction of the Atbara to its mouth in the Mediterranean, a distance of 1680 miles, the Nile receives no tributary. On the contrary, during every mile of its course its waters are diminished by evaporation, by absorption, and by irrigation. The river gets less and less as it flows through this rainless land, and its maximum volume is to be found during the floods at the junction of the Atbara, and at other seasons at Khartoum, 1875 miles from the Mediterranean.

The whole distance by river from the Victoria Nyanza to the sea is about 3500 miles. It may not be easy to derive any clear impression from this bare recital of mileage. Let me try to convey to you in some other ways the idea of the length of the Nile. Standing on the bridge at Cairo, I used to reflect that I was just about half-way between the source of the Nile and the White Sea. Or to put it another way: if we could suppose a river crossing our English Channel, and that the Thames should find its outlet in the Euphrates and the Persian Gulf, that river would be about as long as the Nile.

In this short sketch of the course of the Nile, I must not forget to mention one interesting feature. About 40 miles south of Cairo, the low Libyan chain of hills which bounds the Nile valley on the west is broken by a gap, through which the waters of the river can flow, and beyond this gap lies a saucer-shaped depression called the Fayúm, of about 400 square miles in area, sloping down to a lake of considerable size, the surface of whose waters stands about 130 feet below that of the sea. This lake is known as the Birket el Kurún.

From the time of the earliest Egyptian records, this province of the Fayúm was famed for its fertility, and to the Egyptian taste for its delightful climate. Many of the most precious monuments of antiquity have been found in the Fayúm. The famous Labyrinth is supposed to have stood just at its entrance; and what has excited most interest for the engineer in all times, it is here that Herodotus places that wonderful lake Mœris, which receiving for half the year the surplus supply of the Nile, rendered it back again in irrigation to Lower Egypt during the other half. Where this lake actually was, has excited discussion since any attention has been paid to ancient Egyptian history. It seems pretty clear that in earlier days the Birket el Kurún was of much greater proportions than it is now, but how it ever could have been large enough to allow of its waters flowing back into the Nile valley when the river was low, without at the same time drowning the whole Fayúm, is not very clear.

Now, what are the functions of a great river, what are the offices which it renders to man? And first of all, at least in this latitude, we would mention the carrying off to the ocean of the surplus water that descends from the skies. Nobly does the Nile fulfil this duty; but with this enormous qualification, that it transports the water from tracts where there is too much, and carries it all free of cost, not to waste it in the sea, but to

[1] A lecture delivered at the Royal Institution, on January 25, by Sir Colin Scott-Moncrieff.

bestow it on tracts where it is of priceless value, more than taking the place of rain in watering the fields.

The next function of a river is to form a highway through the land, and for most of its course the Nile fulfils this duty well too. Gordon considered it possible for steamers to ascend the Nile during the floods from its mouth to the Fola rapids, a distance of about 3040 miles; but at other seasons, the six cataracts cannot be passed. Leaving out the 1100 miles which they occupy, there is an unbroken 750 miles in the lower, and nearly 1200 miles in the upper river. I cannot look on it as probable that it will ever pay to make navigable canals and locks round these cataracts, as it would entail so much hard rock-cutting.

Another function of a river is to promote industry by the employment of its water-power. We know how valuable is this power even in England, and how much more in countries like Switzerland, where it abounds. and on the great rivers of America. Excepting a few very rude wooden wheels in the Fayúm, I do not know, through all the annals of the past, of a single water-wheel ever turned by the power of the Nile. But that power exists to an almost unlimited extent. And may we not prophesy that some day in the future, when that long stretch of Nubian cataracts has fallen into civilised hands, and when we know how to transmit electric energy with economy, that then our descendants will draw wealth to Egypt from its chain of barren cataracts?

As a drainage outlet to a continent, as a long highway, as a source of power, the Nile is great; but not so much so as many other rivers. Its unique position is due to the benefit it confers on Egypt in turning it from being a desert into being the richest of agricultural lands, supporting with ease a population of about six hundred to the square mile. Herodotus truly said Egypt is the gift of the Nile. It more than supplies the absence of rain, and this it does, first, by the extraordinary regularity with which it rises and falls; and secondly, by the fertilising matter which the waters carry in suspension, and bestow upon the land. Imagine what it would be to the English farmer if he knew exactly when it would rain and when it would be sunshine. When the Irrigation Department of Egypt is properly administered, the Egyptian farmer possesses this certainty, and he has this further advantage—that it is not merely water that is poured over his lands, but, during nearly half the year, water charged with the finest manure.

According to the early legend, the rise of the Nile is due to the tears shed by Isis over the tomb of Osiris, and the texts on the Pyramids allude to the night every year on which these tear-drops fall. The worship of Isis and Osiris has long passed away, but to this day every native of Egypt knows the *Lailet en Nuktah*, the night in which a miraculous drop falls into the river, and causes it to rise. It is the night of June 17. Herodotus makes no allusion to this legend of Osiris. In his time, he says, the Greeks gave three reasons for the river's rise. He believed in none of them, but considered, as the most ridiculous of all, that which ascribed the floods to the melting of snows, as if there could possibly be snows in such a hot region. It was many centuries after Herodotus' time when the snowy mountains of Central Africa were discovered.

The heavy rains commence in the basin of the White Nile during April, and first slowly drive down upon Egypt the green stagnant waters of that marshy region. These appear at Cairo about June 15. About a fortnight later the real flood begins, for the rains have set in in Abyssinia by May 15, and the Blue Nile brings down from the mountains its supply of the richest muddy water. It is something of the colour and nearly of the consistency of chocolate, and the rise is very rapid, as much sometimes as 3 feet per diem, for the Atbara torrent having saturated its great sandy bed, is now in full flood also. The maximum flood is reached at Assouan about September 1, and it would reach Cairo some four days later, were it not that during August and September the water is being diverted on to the land, and the whole Nile valley becomes a great lake. For this reason the maximum arrives at Cairo about the beginning of October. The rains cease in Abyssinia about the middle of September, and the floods of the Blue Nile and Atbara rapidly decrease; but in the meantime the great lakes and marshes are replenished in the upper regions, and slowly give off their supplies, on which the river subsists, until the following June. Yearly this phenomenon presents itself in Egypt, and with the most marvellous regularity. A late rise is not more than about three weeks later than an early rise. In average years the height of the flood at Assouan is about 25½ feet above the minimum supply. If it rises 29 feet above this minimum, it means peril to the whole of Egypt, and the irrigation engineer has a hard time of it for two months. If the river only rises 20 feet above the minimum, it means that whole tracts of the valley will never be submerged. Such a poor flood has happened only once in modern times, in 1877, and the result was more serious than the devastation caused by the most violent excess.

The mean flood discharge at Cairo is about 280,000 cubic feet per second, the maximum about 400,000. The mean lowest Nile is about 14,000 cubic feet per second at Cairo, but some years there is not more than 10,000 cubic feet per second passing Cairo in June, and within three months after this may have increased forty-fold.

Until this century, the irrigation of Egypt only employed the flood waters of the river, and it was this that made it the granary of the world. No doubt, rude machines for raising Nile water were used at all seasons and from all times. But by these it was not possible to irrigate on a large scale, and in reality they were only employed for irrigating vegetables or gardens, or other small patches of land. It must not be thought that the water of the flooded river is ever allowed to flow where it lists over the lands. The general slope of the valley on each side is away from the river, a feature which the Nile shares with all Deltaic streams. Along each edge of the river, and following its course, is an earthen embankment, high enough not to be topped by the highest flood. In Upper Egypt, the valley of which seldom exceeds six miles in width, a series of embankments have been thrown up, abutting on their inner ends against those along the river's edge, and on their outer ends on the ascending sides of the valley. The whole country is thus divided into a series of oblongs, surrounded by embankments on three sides, and by the slope of the desert hills on the fourth. In Lower Egypt, where in ancient days there were several branches of the river, this system was somewhat modified, but was in principle the same. These oblong areas vary in extent from 60,000 to 3000 or 4000 acres, and the slope being away from the river, it is easy to cut short, deep canals in the banks, which fill as the flood rises, and carry the precious mud-charged water into these great flats, or, as they are termed, basins of irrigation. There the water remains for a month or more, some three or four feet deep, depositing its mud, and then at the end of the flood it may either be run off direct into the receding river, or, more usually, passed off through sluices from one basin to another, and ultimately back into the river. In November the waters have passed off, and wherever a man and a pair of bullocks can walk over the mud, and scratch its surface with a wooden plough, or even the branch of a tree, wheat or barley is sown, and so saturated is the soil that the grain sprouts and ripens in April or May without a drop of rain or any fresh irrigation. And a fine crop is reaped. One of our great brewers told me the other day, that when barley grown in this country was spread in the malting-house, about three per cent. of it must be counted on as not sprouting and being dead. If grain two or three years old was used, as much as twenty per cent. would be found dead. With Egyptian barley, he said, even after several years, you could count on every grain germinating. The crop once reaped, the fields remain dry, and crack in the fierce summer heat until next flood comes on.

The tourist who only comes to Egypt to shun "winter and foul weather," knows nothing of the majestic glories of the Nile flood. The ancient Nilometer at the south end of the island of Roda, just above Cairo, is one of the most interesting sights of the place. The water enters from the river by a culvert into a well about 18 feet square, with a graduated stone pillar in the centre. On each side of the well is a recess about 6 feet wide and 3 feet deep, surmounted by a pointed arch, over which is carved in relief a Kufic inscription, and a similar inscription is carried all round the well, consisting of verses of the Koran. A staircase goes down the well, from the steps of which the initiated may read the height of the water on the pillar; but they are few in number, and the hereditary Sheikh of the Nilometer, whose duty it is to keep the record, is a person of some importance. The Nilometer dates from A.D. 861, and I believe in the archives of Cairo may be found the daily record for 1000 years.

I need hardly tell you that when our English engineers took the river in hand, we established a number of gauges at Wadi Halfa, Assouan, Cairo, and many other points, on more scientific principles than the venerable Nilometer of the Roda Island.

After the river has begun to rise, its height is daily chanted through the Cairo streets until it reaches 16 cubits on the gauge. At this point the Khalig el Masri, the old canal that flows through the heart of Cairo, is opened—up to this point it is dry, and full or empty it is little more than a sanitary abomination at present; but in former days it occupied an important place, and when the Nile water was high enough to flow down its bed, it was looked on that the flood had fairly set in, and that the kindly fruits of the earth might be duly expected.

The head of this canal is on the right bank of the river, just south of Cairo. The water enters a channel some 30 feet wide, with a high wall on its left, and a sloping bank on its right or southern flank. The water then flows under the pointed arch of an old stone bridge. The bed of the canal is cleared so that it would flow in at a gauge of about 14½ cubits, but an earthen bank is thrown across it about 4 feet higher.

There is no more interesting ceremony in Egypt than the annual cutting of the Khalig, as the opening ceremony is called. It takes place between August 5 and 15. Days before preparations are being made for the festival. Tents with innumerable lamps are placed along the wall on the one side. Frames for all manner of fireworks are erected on the sand-bank on the other side. All the notables are there in full uniform, or in canonicals. The Khedive himself, or his representative, the Sheikh ul Islam (the highest dignitary of the Muhammedan faith), the Sheikh el Bekri, the Sheikh es Sadát, all the learned scribes of the great university of the Azhár, the Cabinet Ministers and Under-Secretaries, the Sirder of the Army and his staff, the Judges, and the Financiers.

The Egyptian troops are turned out, salutes are fired, and about eight o'clock in the warm summer night the classes all assemble under the gaily-lighted tents, the masses crowd round the frames for the fireworks, the street is lined with harem carriages full of closely-veiled figures, though it is not much that they can see from their broughams. Out in the river, just opposite the canal's mouth, is moored an old hulk of a certain sea-going outline, which has been towed up from Boulak during the day, and is an emblem of the time when the great republic of Venice sent an envoy to witness the ceremony. This boat is full of lamps, and fireworks too. As the night deepens the excitement increases. The populace on the bridge and the opposite bank are shouting, yelling, and dancing wildly round the fireworks. On the other side are the gay uniforms and lighted tents, from whence we can look over the wall down on the dark water, where you see brown figures plunging in and waist-deep digging with their hoes at the embankment that blocks the canal's mouth.

Long before midnight the fireworks have gone out, and left the splendid stars to themselves; the grandees have all gone to bed, but the people keep up the revelry, and in the morning, by 7.30, every one has come back. Then but little of the bank is left uncut; a few more strokes of the big hoes will do it, and the brown skins and the brown water reflect the bright sunlight from above. Then the Sheikh ul Islam solemnly thanks the Almighty, Allah the All-powerful, the All-merciful. He implores His blessing on the flood, and at a signal the bank is cut, the waters rush in, and with them a crowd of swimmers. A bag of silver piastres is scattered among them, and the ceremony is at an end.

There is a pretty legend, worth telling, of the cutting of the Khalig. Amr, the Muhammedan General, took Cairo in A.D. 640. Long before then there had been a heathen ceremony, and a virgin was yearly sacrficed to the god of the river. When the season came round, Amr was called upon as usual to sacrifice the girl. He sternly refused. That year the Nile flood was a failure. You can fancy how the indignant heathen population must have raged at the invader, and said, "We warned you what would happen if you didn't propitiate the river god." Cannot we fancy, also, how Amr's wild Arab soldiers must have had their faith sorely tried, and how they must have felt puzzled as to whether in this strange new country, with all those demon-built temples and pyramids, obelisks and sphinxes, it might not be as well to make friends of the local gods. Could Allah really help them here? Again the Nile flood came round. This time surely Amr would sacrifice the girl, and save the land. No; he would not. The people rose in rebellion. Amr stood firm. But he wrote to the Kalif Omar for orders (Omar, whose name you will remember has come down in history as the destroyer of the Alexandrian library). Omar approved of his conduct, but sent him a paper to throw into the Nile. On the paper was written, "From Abd Allah Omar, Prince of the Faithful, to the Nile of Egypt. If thou flow of thine own accord, flow not; but if it be Allah, the one the mighty, who causeth thee to flow, then we implore him to make thee flow." Amr threw the paper into the water, and the Nile rose forthwith exactly as it was wanted. Since that day no girl has been sacrificed; but a pillar of earth is yearly left to be washed away in the middle of the canal, called the bride or the girl.

Such, as I have briefly described it, was the irrigation of Egypt until this century, when it fell under the rule of Muhammed Ali, a very sagacious and strong if a very unscrupulous ruler. He saw that the country could produce far more valuable crops than cereals. The European market could be supplied with these from the fields of Europe, but Europe could not produce cotton and sugar-cane. Egypt had the climate, had the soil, had the teeming population; but these crops required water at all seasons; nor would it do to flood the fields to any depth, for just at the flood season the cotton crop is ripening. There was plenty of water in the river; but how was it to be got on to the land? Perennial irrigation was a fresh departure. As I have said, the Nile rises about 25½ feet. A canal then running 12 feet deep in flood has its bed 13½ feet above the surface of the Low Nile. Either the Nile water had to be raised, or the beds of the canals had to be lowered, in order that one should flow into the other, and after that the water had to be raised from the canal on to the land. Muhammed Ali began by lowering the canal beds of Lower Egypt, an enormous work considering the great number of the canals; and as they had been laid out on no scientific principles, but merely to suit the fancies of Turkish pashas or village sheikhs, and as those who had to excavate them to this great depth had only the slightest knowledge of levelling, the inevitable result followed—the deep channel became full of mud during the flood, and all the excavation had to be done over again. Incredible as it may seem, this great work was done year after year. It was a great serf population; if they were not fighting Muhammed Ali's battles in Arabia and Syria, they might as well be digging out the canals. No one thought of paying or feeding the workmen. The bastinado was freely applied if they attempted to run away. If they died under the labour, there were plenty more to come. But of course the work was badly done. The water might enter the canal; but as the bed was not truly levelled, it did not follow that it would flow far. Then, as the river daily fell, the water in the canals fell too, and lessened in volume as the heat increased, and more was required. At last—in June, perhaps—the canal was dry, and the cotton crop that had been sown and watered, weeded and nurtured, since March, was lost altogether.

Then some one advised Muhammed Ali to throw a dam across the river, and so raise the water, and the result was the great Barrage.

About twelve miles north of Cairo the Nile bifurcates, and finds its way to the sea, by the Rosetta and Damietta branches. Across the heads of these two branches were built two stone bridges, one of 71, the other of 61 arches, each 5 metres or 16·4 feet span. These arches were intended to be fitted with gates; by lowering which, all the water would be dammed up, and diverted into three great trunk canals, taken out of the river just above these bridges. One to the right or east of the Damietta branch was to supply water to all the Provinces of the Eastern delta, one between the two bridges was to supply the splendidly fertile central delta, the third to the left or West of the Rosetta branch was to water all the Western delta down to Alexandria.

There was no intention of water storage at the Barrage, but it was merely with the object of controlling the supply. While there was water enough in the river, by closing the gates it could be kept to a uniform level, and sent down the three trunk canals, from which it was to branch, into many minor ones. As the river went down, gate after gate would be closed, and so a constant supply could be kept in the canals. The idea was thoroughly sound. The execution was feeble.

Mougel Bey, the French engineer in charge of the work had no doubt many difficulties to contend with. The work went fitfully on for many years, thousands of men being forced to it one year, and carried off to a campaign the next. But at last it was sufficiently finished to allow of an opening ceremonial in 1861. Gates had been fitted into the Rosetta branch arches, never into the Damietta.

The Central canal had been dug in tolerably satisfactory style. The Western canal, too, had been dug, but passing through a strip of desert it had become very much filled up with sand. The Eastern canal was dug some five miles, and then stopped. Of course the Barrage without these canals was useless. However, they began to experiment with it, closing the gates on the Rosetta side. It was intended to hold up 4½ metres, or 14 feet 9 inches of water. It never held up 5 feet, till in 1867, it cracked across from top to bottom, on the Western side. An immense coffer-dam was built round the cracked portion, and the water was never held up again more than about 3½ feet, while the work was looked on as a deplorable failure. In 1883, all hope of making anything out of the Barrage was abandoned, and the Government were on the point of concluding a contract with a company to supply Lower Egypt with irrigation by means of an immense system of steam pumps, to cost £700,000 to begin with, and £250,000 a year afterwards.

That year there was a wretched serf army of 85,000 men working at canal clearances for 160 days, unfed, unpaid. The burden was nearly intolerable. The irrigation was all by fits and starts. There was no drainage; every hollow became sour and water-logged. With waterways everywhere, there was no navigation. In Upper Egypt things were better, as the system was a simpler one. But when we came to look into them too, we found great abuse, and on an average about 40,000 acres never succeeded in obtaining water, though in the midst of abundance.

The Fayúm had long been a much-neglected province, though a most picturesque and attractive one. From carelessly allowing Nile water to flow into the lake during the floods, it had risen enough to swamp 10,000 acres of valuable land, and this mischief we found still increasing.

Throughout the whole country drainage had been absolutely neglected. And here I would point out that irrigation without drainage means the sure deterioration of the land sooner or later. Considerable pains had been taken in Egypt to get the water on to the land. No sort of effort had been made to get it off. In a properly irrigated tract, between every two canals of supply, there should flow a drainage channel; the former should follow as far as possible the highest lands, the latter should follow the lowest. The canal gets smaller, till at last it is exhausted, giving itself out in innumerable branches. The drain, like a river, gets larger as it proceeds, being constantly joined by branches. But if there be no drains, and if the canals are laid out to flow into one another, so as to divide the country into, as it were, a cluster of islands, you can understand how the drainage water has no means of flowing off into the sea, and settles in unwholesome swamps. These we found prevailing to an alarming extent in the rich provinces of the delta. Such was the wretched state of Egyptian agriculture—the one single source of the country's wealth—when Lord Dufferin laid down the lines of the English administration, which have been amplified and pursued ever since.

It was in May, 1883, that I took charge of the irrigation department in Egypt, having before then had some twenty years' experience of similar work in India; and I soon had the inestimable advantage of being joined by a band of the most indefatigable, energetic and able engineers, also from India, with whom it was my great privilege and happiness to be associated for the next nine years. I cannot talk too highly of these my colleagues—men who knew their work and did it, who kept constantly moving about in the provinces, badly lodged, badly fed, denied domestic comforts, constantly absent from their wives and families (they were all married men).

My friends, happy is the reformer who finds things so bad that he cannot make a movement without making an improvement. Happy the reformer who has as colleagues a staff of thoroughly loyal, duty-doing and capable men. Happy the reformer who is not pestered on all sides by the officious advice of the ignorant. Happy the reformer who has behind him a strong brave chief, as honest and truthful as he is strong. Such rare happiness fell to me in Egypt with my noble colleagues, and with Lord Cromer as our chief.

It is not my intention to enter into any details to-night of what our work was in Egypt. I have lately spoken about that elsewhere, and there would be no time to do so now. I must just describe it generally.

On first arrival, I was pressed, both by English and French men, to go into the question of the storage of the flood waters of the river on a large scale. I declined to do so, considering it would be time enough to think of increasing the quantity of water at our disposal when we had profitably used all that we already had, and while mighty volumes were daily flowing out to the sea, it could not be said that we were doing that. The first great work to be studied was the Barrage. We were warned on all sides to have nothing to say to it, as it was thoroughly unsound; but we felt sure we must either make it sound or build an entirely new one, and we resolved on the former. The work had failed because it was faulty in design, the floorings and foundations not being sufficiently massive, and faulty in execution from the dishonest use of bad materials and from bad workmanship. The bed of the river consists of nothing more stable than sand and alluvial mud for at least 200 feet deep. It was out of the question to think of getting down to solid rock. It was not, as we thought, very safe to excavate very deeply close to the existing works, so we decided not to try it, but merely to strengthen and consolidate the foundations, built as they were on sand. I have said that the work consisted of two great bridges over the two branches of the river. We could not shut up either branch entirely; but we decided to strengthen and complete one-half of each bridge each season, which meant four seasons' work. While the river was still in considerable flood each November, we began to throw out great embankments of earth about 200 feet from the bridge; one up-stream, the other down-stream of it, beginning at the shore end, and ultimately enclosing one half of the river as in a pond. This used to take three months' hard work. Then we pumped the water out of this enclosure, and laid bare the very bed of the river. Then we laid a massive stone flooring, 5½ feet thick, extending 100 feet up-stream, and as much down-stream, of the bridge. This was very difficult and hard work. It was kept going day and night, without intermission, from March till the end of June. Then we cut great holes in our embankments, cleared out our machinery, and prepared for the arrival of the flood at the beginning of July. Each year one-half of one bridge was finished, and the whole was completed at the end of June 1890.

In connection with the Barrage were completed the three great canals to carry off all the river supply from above it. So that practically now the Low Nile is emptied every season at the Barrage and diverted into these canals, and no water at all escapes to the sea. The natives wade everywhere across the river north of this point. Since it was completed the Barrage has given no trouble. It holds up every year 4 metres, or 13 feet of water. The three trunk canals were all supplied with locks 160 feet by 28 feet, and adapted for navigation. The whole of these works cost about £800,000. The annual increase of the cotton crop, compared to what it was before 1884, is never less than two and a half millions sterling, which has not been a bad investment for Egypt.

Turning to Upper Egypt, my colleague, Colonel Ross, directed his attention very closely to the adjustment of canals overlapping one another, passing under and passing over one another; so that in future I trust that with the feeblest Nile flood it will be possible to pour water over every acre of the land.

The question of drainage was very thoroughly taken up. Twelve years ago it may be said that there were no drainage channels in Egypt. Two years ago there were about 1000 miles of such channels, some with beds as wide as 60 feet and flowing deep enough to carry cargo boats, others with beds only 3 or 4 feet wide. I am glad to say by these means large tracts in Lower Egypt which had been abandoned as totally ruined have now been restored to cultivation. The level of the lake in the Fayúm was reduced by 13 feet between 1885 and 1893, and most of the inundated lands around it have been again dried.

I have already mentioned the cruel hardship of the corvée, the serf army of 85,000 men who were employed in the canal clearances from January to July, nearly half the year. I believe this institution was as old as the Pharaohs, and it was not easy to abolish it. But of course it went sorely against our British grain. Little by little we got money to enable us to pay our labour. By an annual outlay of £400,000 this spring corvée has entirely ceased since 1889, and now the Egyptian labourer carries out these clearances in as free a manner as his brother in Middlesex, and gets paid for his work.

Having thus, to the best of our powers, utilised the water in the river flowing past us, we turned our attention to the storage of the surplus waters. Without some such storage it is impossible to increase the cultivation during the Low Nile. All the water is used up. During High Nile there is always a grea volume escaping useless to the sea.

There are two ways in which the water may be stored; either by throwing a dam right across the river and forming a great lake above it, or, if such a place can be found, by diverting the flood water into some suitable hollow, and drawing it off from there at the season of low supply, as done by Herodotus' celebrated Lake Mœris. At one time there was a hope that such a storage basin might be found. An American gentleman, named Mr. Cope Whitehouse, in search of the real Mœris, found a very remarkable saucer-shaped depression just south of the Fayúm. We knew it could not have been Mœris, because in its bed we found no traces of a deposit of Nilotic mud, but it might be possible all the same to utilise it. The place was very carefully surveyed, and the project was estimated; but it was found that the cost of conveying the water into this basin would be so great that it was out of the question.

Attention was then turned to the possible sites where a stone dam might be built right across the river. The southern boundary of Egypt just now is near Wady Halfa, the second cataract. It is no use going to look for sites south of this, for the country is in the hands of the Mahdi and his fierce dervish soldiers. North of this point, unquestionably the best site, perhaps the only possible site is where the Nile valley is traversed by a broad dyke of hard Syenite granite, in passing over which the river forms its first cataract just south of Assouan. It is here divided into several channels between rocky islands, and no channel is deep, so that it would be easy to divert the water from one after another, to lay bare the bed of the river, and lay the foundations of the dam in the open air. It wants no engineer to understand what an advantage this is.

And the great dam, such as was designed by Mr. Willcocks, would have been a work worthy of the land of the Pyramids and Karnak—a great wall of squared granite blocks—82 feet thick at base, of a maximum height of 115 feet, 1¼ miles long, pierced by sluices large enough to allow of the whole Nile at highest flood rushing through. The lake formed would have been 120 miles long. Would this not have been a work of some majesty to commemorate for ever the English rule in Egypt—a work one would have been proud to have had a hand in? But it was not to be. The Egyptian saw no objection to it. The money could have been found. But there was an insuperable obstacle created when, on the Island of Philæ, about 250 B.C., Ptolemy II. built a temple to Isis, on the site of older buildings long disappeared. Round this temple other buildings clustered, built by Greeks and Romans. Those of you who have not seen them, are probably familiar from pictures with the group of venerable buildings standing amidst palm trees on the rocky island, and reflected in the waters below.

Had Ptolemy only built his temple on the island of Elephantine, a few miles north, it would have been unaffected by the great dam, but Philæ is just to the south, or up-stream side of where the great dam must necessarily have come, and in consequence the island, with its temples, would be drowned for about six months every year. You probably remember the outburst of rage and indignation which the announcement of this proposed desecration created in London last summer. It was not to be tolerated that England should commit such vandalism. In vain it was answered that the place belonged to Egypt, not to England—that the Egyptian, who was to gain so much by the dam, cared absolutely nothing about Ptolemy and his temples—that he was prepared to pay a large price for a great work to benefit his country. What business was it of England to forbid him?

And it was not only the English who were indignant. For once, and only for once, I fear, since we occupied Egypt in 1882, was educated opinion in England and France at one. Both alike insisted that Philæ should not be drowned. Nor must I admit had all the engineers that were interested in the question the full courage of their opinions. While they longed to build the dam, and lamented the perverse fate that had put Philæ there, still they wished to spare Philæ—and their voice has prevailed. The majestic structure has been cut down 27 feet, and now will only be 88 feet high, and Philæ will stand henceforth in a lake, but will never be drowned.

Personally I accept the situation, for I never believed that it would be sacrificed. But yet as an engineer, I must sigh over the lost opportunity for England of making such a splendid reservoir. And as a friend to Egypt, I sigh still more that the country will not have such a splendid supply of water as would enable Upper Egypt to have the full benefits now possessed by Lower Egypt, and Lower Egypt to expand and flourish.

The reduced scheme will, however, be a great boon to the country, and I trust will now be put in hand without delay.

In 1884, when the expedition up the Nile was first being considered, I was asked by the General Officer commanding in Egypt, whether I thought there was any possibility of the Mahdi diverting the river in the Soudan, and depriving Egypt of its water. The late Sir Samuel Baker was in Cairo at the time, and I consulted him as to whether he knew of any place in the Nile valley where during highest flood the water spills off to the right or left, towards the Red Sea or the Libyan Desert. He said he was sure there was no such place, and I then told the General it would be impossible for the Mahdi to divert the Nile. I was sure that with his savages he would never dam up the low supply until its surface attained the height of flood supply, and if even then during flood there was no spill channel, Egypt was safe enough.

But what the Mahdi could not do, a civilised people could do. A Government official has no business to talk politics, and the Royal Institution is no place for politics; but I may be allowed to point out an evident enough fact, that the civilised possessor of the Upper Nile valley holds Egypt in his grasp.

At this moment the Italians are on the eastern edge of that valley—a nation, I must say, who have been consistently most friendly to us in Egypt. Supposing that they occupied Khartoum, the first thing they would naturally and very properly do would be to spread the waters of the Low Nile over the Soudan; and no nation in Europe understands irrigation so well. And what then would become of Egypt's cotton crops? They could only be secured by a series of the most costly dams over the river, and the fate of Philæ would surely be sealed. But more than this: a civilised nation on the Upper Nile would surely build regulating sluices across the outlet of the Victoria Nyanza, and control that great sea as Manchester controls Thirlemere. This would probably be an easy operation. Once done, the Nile supply would be in their hands; and if poor little Egypt had the bad luck to be at war with this people on the upper waters, they might flood them, or cut off their water supply at their pleasure.

Is it not evident, then, that the Nile from the Victoria Nyanza to the Mediterranean should be under one rule? That time is perhaps far off. I conclude what I have to say to-night, by giving you the assurance, and I challenge contradiction, that at no time in the long history of Egypt under Pharaoh or Ptolemy, Roman or Arab, or Turk, have the people of the country been so prosperous, or so justly ruled as during the last nine years.

OBSERVATIONS OF SUN-SPOT SPECTRA.[1]

I. *The Widening of Iron Lines and of Unknown Lines in Relation to the Sun-spot Period.*

IT is now twenty-eight years since I discovered that the lines seen in sun-spots were subject to widening,[2] and that different lines were widened at different times.

It was not, however, till 1879 that I was enabled to commence daily routine work of such a nature that all observations were comparable *inter se*. This desideratum was secured by limiting attention to the twelve lines most widened between F and D.

In 1886[3] I gave an account of some of the early results obtained by this research. I have recently commenced the complete discussion of the whole series of observations to the present year.

This discussion, involving 21,000 lines widened during the period in question, has necessitated three special researches: the first, dealing with the lines with which, contemporaneously, coincidences have been found in the laboratory; the second, dealing with those the origin of which is so far unknown; and the third, with the distribution of both sets of lines in spots in relation to the sun-spot period.

To make the work as definite as possible, I am, in the first instance, confining the inquiry concerning the known lines to lines of iron based upon the examination of the pure electrolytic iron referred to in a previous communication.

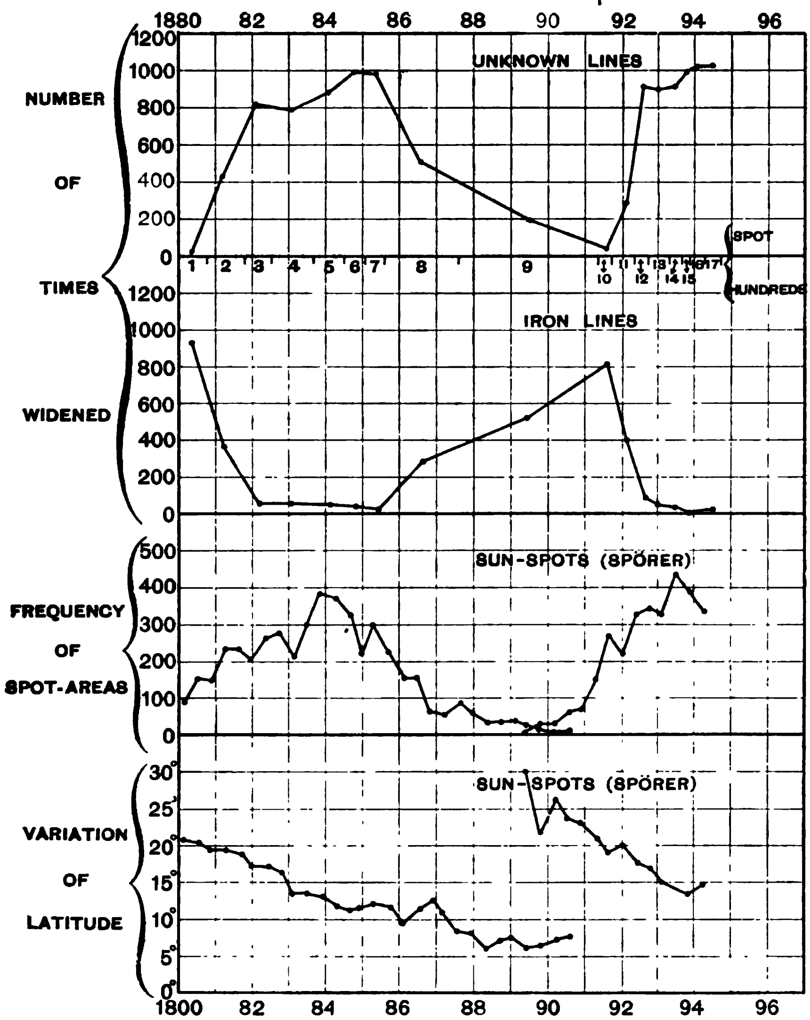
[1] A Paper read at the Royal Society, by J. Norman Lockyer, C.B., F.R.S.

[2] "Roy. Soc. Proc." vol. xv. p. 256, 1866.

[3] "Roy. Soc. Proc." vol. xl. p. 347.

[4] "Roy. Soc. Proc." vol. liv. p. 359.

The following statistics will show the relation of these iron lines to the Fraunhofer lines in the region F—D over which the spot work extends. In the table, "terrestrial lines" means lines which have been photographically recorded by myself or my assistants in the spectrum of some metal or another during the past twenty-four years; "unknown" means a line not so far traced by me in any metal with the exception of Cerium. This exception is necessitated by the fact that the spectrum of that metal contains practically as many lines as appear in the solar spectrum. The wave length map of Rowland's second series has been taken as a standard.



Region.	Fraunhofer lines.	Terrestrial lines.	Unknown lines.	Iron lines.
F				
4861—4900...	92	41	51	16
4900—5000...	175	96	79	45
5000—5100...	228	92	136	33
5100—5200...	176	92	84	39
5200—5300...	165	83	82	32
5300—5400...	211	76	135	29
5400—5500...	216	63	153	26
5500—5600...	186	57	129	31
5600—5700 ..	149	73	76	29
5700—5800..	198	48	150	22
5800—5895...	208	31	177	5
D				
	2004	752	1252	307

In the present communication I confine myself to submitting provisional curves based upon a preliminary inquiry into the number of times the lines of both categories have been observed to be widened in spots. Some slight corrections will, doubtless, be ultimately required when a few uncertainties connected with some of the earlier observations, made before Rowland's maps were available, have been cleared up. The highest points of the curves represent the maximum frequency of iron lines in one case and of unknown lines in the other.

The period embraced by the observations practically enables us to study what has taken place at two successive sun-spot minima and two maxima. It will be seen that the phenomena which followed the minimum of 1879 have been exactly reproduced after the minimum of 1890. At the minima the iron lines are prominent among the most widened lines; at the maxima we only find lines about which nothing is known. Since the discussion indicates that the iron lines involved, which ultimately disappear, are almost invariably those seen most prominent in the spark, the view put forward in my paper of 1886 that the change observed is due to the dissociation of iron in the spots as a sun-spot maximum is approached, is corroborated, and, so far, I have heard of no other simple and sufficient explanation.

It will be noted that the maxima and minima of solar temperature thus revealed to us, if my hypothesis be confirmed, lag behind the spot maxima and minima. This may explain the lag observed in those meteorological conditions, the secular changes in which have been held by Balfour Stewart, Broun, Meldrum, Blanford, Chambers, and others, to prove that the disturbances and changes in our own atmosphere are affected by those taking place in the atmosphere of the sun.

VARIATION IN ANIMALS AND PLANTS.[1]

THE importance of variation as a factor in organic evolution is not seriously disputed; but, if one may judge from the expressions contained in recent essays, naturalists are not agreed as to the manner in which variation among individuals is associated with specific modification.

The view originally put forward by Darwin and Wallace is that specific modification is at least generally a gradual process, resulting from "the accumulation of innumerable slight variations, each good for the original possessor" ("Origin of Species," chap. xv.). This view rests on the assumption that each of those small differences which are to be observed among a group of individuals belonging to the same species has generally some effect upon the chance of life. "Can we doubt (remembering that many more individuals are born than can possibly survive) that individuals having any advantage, however slight, over others, would have the best chance of surviving and of procreating their kind?" ("Origin of Species," chap. iv.).

Of late years, another view has received support from various writers. An examination of any series of animals of the same species preserved in a museum shows in most cases a large majority of specimens which are superficially alike: those individual differences, upon which stress is laid by Darwin and by Wallace, are often so slight as to escape attention unless minute comparison is made between individual and individual.

[1] A paper read at the Royal Society on February 28, by Prof. W. F. R. Weldon, F.R.S.

But there will commonly be found a few individuals which differ so remarkably from their fellows as to catch the eye at once. Such large deviations differ from the smaller ones, at least in most cases, by their extreme rarity; but they have been extensively collected, and most museums contain numerous examples of their occurrence. Some naturalists have been led, from the striking character of such variations, to assume for them a preponderant share in the modification of specific character. These persons assume, if I understand them rightly, that the advantages or disadvantages which accompany the more frequent slight abnormalities are in themselves of necessity slight; and that the effect of such slight abnormalities may be neglected, in comparison with the effect produced by the occasional appearance of considerable deviations from the normal type. They regard change in specific character as an event which occurs, not slowly and continuously, but occasionally and by steps of considerable magnitude, as a consequence of the capricious appearance of "sports."

Without presuming to deny the possible effect of occasional "sports" in exceptional cases, it is the object of the present remarks to discuss the effects of small variations, as it may be deduced from the study of two organs in a single species.

The case chosen is the variation, during growth and in adult life, of two dimensions of female *Carcinus mœnas*, recently investigated by a Committee of the Royal Society; and what is here said may be considered an appendix to the report of that Committee.

The questions raised by the Darwinian hypothesis are purely statistical, and the statistical method is the only one at present obvious by which that hypothesis can be experimentally checked.

In order to estimate the effect of small variations upon the chance of survival, in a given species, it is necessary to measure *first*, the percentage of young animals exhibiting this variation; *secondly*, the percentage of adults in which it is present. If the percentage of adults exhibiting the variation is less than the percentage of young, then a certain percentage of young animals has either lost the character during growth or has been destroyed. The law of growth having been ascertained, the rate of destruction may be measured; and in this way an estimate of the advantage or disadvantage of a variation may be obtained. In order to estimate the effect of deviations of one organ upon the rest of the body, it is necessary to measure the average character of the rest of the body in individuals with varying magnitude of the given organ; and by the application of Mr. Galton's method of measuring correlation, a simple estimate of this effect may be obtained. In the same way a measure of the effect of parental abnormality upon abnormality of offspring may be numerically measured by the use of Galton's correlation function, and such measurements have been made, in the case of human stature, by Mr. Galton himself.

It is to be observed that numerical data, of the kind here indicated, contain all the information necessary for a knowledge of the direction and rate of evolution. Knowing that a given deviation from the mean character is associated with a greater or less percentage death-rate in the animals possessing it, the importance of such a deviation can be estimated without the necessity of inquiring how that increase or decrease in the death-rate is brought about, so that all ideas of "functional adaptation" become unnecessary. In the same way, a theory of the mechanism of heredity is not necessary in order to measure the abnormality of offspring associated with a given parental abnormality. The importance of such numerical statements, by which the current theories of adaptation, &c., may be tested, is strongly urged.

The report itself describes an attempt to furnish some of the numerical data referred to for two dimensions of the shore crab. The data collected give an approximation to the law of frequency with which deviations from the average character occur at various ages. The conclusions drawn are (*a*) that there is a period of growth during which the frequency of deviations increases, illustrating Darwin's statement that variations frequently appear late in life; (*b*) that in one case the preliminary increase is followed by a decrease in the frequency of deviations of given magnitude, in the other case it is not; and that (*c*), assuming a particular law of growth (which remains, as is admitted, to be experimentally tested), the observed phenomena imply a selective destruction in the one case, and not in the other.

It is not contended that the law of frequency at various ages, adopted in the report, is exact. It is, however, hoped that the approximation is sufficiently exact to give numerical estimates of the quantities measured, which are at least of the same order as the quantities themselves, and for this reason it is hoped that the method adopted may prove useful in other cases.

SCIENCE IN THE MAGAZINES.

IN the February number of the *Fortnightly*, Dr. A. R. Wallace discussed in some detail Mr. Bateson's views on variation in relation to the method of organic evolution. He concludes his attack in the current number, and considers Mr. Francis Galton's views, stated in "Natural Inheritance" and in "Thumb and Finger Marks." It is held that the methods of organic evolution favoured by Mr. Bateson and Mr. Galton have failed to establish themselves as having any relation to the actual facts of nature. The reason for their failure is stated by Dr. Wallace as follows:—"they have devoted themselves too exclusively to one set of factors, while overlooking others which are both more general and more fundamental. These are—the enormously rapid multiplication of all organisms during more favourable periods, and the consequent weeding out of all but the fittest in what must be on the whole stationary populations. And, acting in combination with this *annual* destruction of the less fit, is the *periodical* elimination under recurrent unfavourable conditions, of such a large proportion of each species as to leave only a small fraction—the very elect of the elect—to continue the race. It is only by keeping the tremendous severity of this inevitable and never-ceasing process of selection always present to our minds, and applying it in detail to each suggested new factor in the process of evolution, that we shall be able to determine what part such factors can take in the production of new species. It is because they have not done this, that the two authors, whose works have been here examined, have so completely failed to make any real advance towards a more complete solution of the problem of the Origin of Species than has been reached by Darwin and his successors."

A story worth repeating here is told by Mr. John Murray, the publisher, in *Good Words*. One day Charles Darwin came to see the late Mr. Murray, and brought with him a MS. As he laid it on the table, he said, "Mr. Murray, here is a book which has cost me many years of hard labour; the preparation of it has afforded me the greatest interest, but I can hardly hope that it will prove of any interest to the general public. Will you bring it out for me, as you have done my other books?" The book was Darwin's famous work on "Earthworms," which in the course of three months reached a fifth edition. Mr. Murray gives the incident as an illustration of the extreme modesty of a very distinguished man. The same magazine contains some stories of snake cannibalism, by Mr. H. Stewart. A very readable story, in which observations of the planet Mars, and projects of signalling to our ruddy brother, are described, is contributed by Mr. J. Munro to *Cassell's Family Magazine*. Mr. Munro makes the Martians signal to us by means of lights from various incandescent elements, the natures of which are detected spectroscopically. He has a lively imagination, and is fairly accurate in his astronomical references. In the *English Illustrated*, we notice another of Mr. Grant Allen's "Moorland Idylls"—this time on butterflies; and also something about lions, by Mr. Phil Robinson. In the *Strand Magazine*, Mr. J. Holt Schooling gives a number of ingenious diagrams for graphically representing statistics relating to the population of different countries. There is also the concluding part of an article by Mr. W. G. FitzGerald, on "Some Curiosities of Modern Photography," in which, among other illustrations, occur Prof. Boys' pictures of moving bullets, and a good reproduction of Dr. Roberts' photograph of the nebula in Andromeda. Another article of interest to photographers appears in *Le Monde Moderne* for February, under the title "Les Mouvements de l'Ouvrier." A number of excellent reproductions of some of M. Marey's photographs accompany this article. The same magazine contains a description of compressed air systems of tramway traction.

In addition to the magazines mentioned in the foregoing, the following have been received, but they do not contain any articles of scientific interest:—*Contemporary*, *Century*, *Scribner*, *Chambers's*, *Longman's*, *National*, *Sunday Magazine*, and *Humanitarian*.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—An examination will be held at Merton College on Tuesday, July 2, 1895, and following days, beginning at 10 a.m., for the purpose of electing to three open Natural Science Scholarships, of which one will be at Merton College, one at New College, and one at Corpus Christi College.

The scholarships are of the value of £80 per annum, and are open to all candidates whose age on July 8, 1895, will not exceed nineteen years. The subjects of examination will be (1) Chemistry, Mechanics and Physics, or (2) Biology. An English essay, and a paper in Algebra and Elementary Geometry, will also be set to all candidates. Candidates will have an opportunity of showing a knowledge of higher mathematics. Candidates who offer Biology are requested to send to the Tutor in Natural Science, Merton College, at least one fortnight before the examination, a general statement as to the portions of the subject which they have studied, and the practical work which they have done. All such candidates will be required to show some acquaintance with Chemistry, Mechanics and Physics.

CAMBRIDGE.—The following is the speech delivered on February 28th by the Public Orator, Dr. Sandys, Fellow and Tutor of St. John's, in presenting for the honorary degree of Doctor in Science Sir William MacGregor, M.D. (Aberdeen), K.C.M.G., Administrator of British New Guinea:—

Orbis terrarum inter insulas, praeter Australiam latissime patet insula Australiae parti septentrionali ex adverso posita. Tota quidem insula insulis Britannicis duplo maior: insulae autem pars a Britannis occupata Angliâ ipsâ maior dimidio. Nostrae vero coloniae ibi administrandae praepositus est vir insignis, olim in Academiâ Aberdoniensi medicinae doctor, nuper scientiarum complurium non modo fautor et adiutor, sed etiam ipse auctor atque investigator indefessus. Praesidis nostri auxilio, Anthropologiae, Geographiae, Geologiae, aliis denique scientiis nova lux affulsit, adeo ut coloniam illam remotissimam non tam imperii nostri propugnaculum quam scientiarum arcem et castellum longinquum appellaverim. De Caledoniae filiis, quibus ubique terrarum plurimum debet Britannia, nonnumquam dicitur, cum peregre absint, tum demum sese sentire esse domi. Huic Caledoniae filio paullisper reduci gratias hodie idcirco agimus, quod, a patriâ vocatus, non modo imperii nostri in utilitatem, sed etiam scientiae ad fructum, patriam relinquere est dignatus. Gens autem illa antiqua, ex quâ ortus esse confitetur, olim sedibus paternis expulsa et ipso nomine prorsus privata, hodie, talium virorum auxilio, non sine nomine, non sine gloriâ est. Etenim gens illa Alpina, gentem fortissimam a poetâ Romano quondam laudatam aemulata,

> duris ut ilex tonsa bipennibus,
> nigrae feraci frondis in Algido,
> per damna, per caedes, ab ipso
> ducit opes animumque ferro.

Duco ad vos equitem insignem, WILLELMUM MACGREGOR.

The Report of the Syndicate for the encouragement of advanced study and research has just been issued. It proposes that approved graduates of other universities, of not less than twenty-one years of age, should be admitted as Advanced Students, with certain special privileges. Such students are to pursue, under the supervision of committees of the special Boards of Studies, (*a*) courses of advanced study, or (*b*) courses of research. The former class may be admitted, after three terms, to a part of a Tripos examination, and if they attain therein a sufficiently high standard, their names will appear in a special list distinct from the Tripos list. After residing two years, they may be admitted to the B.A. degree, and thereafter proceed in the usual course to the M.A. and other higher degrees. Research students are, after three or more terms' residence, to present a dissertation adjudged by a Degree Committee to be "of distinction as an original contribution to learning, or as a record of original research." For this a special "Certificate of Research" is to be granted by the University. Holders of the certificate who have resided at least two years, are to be entitled to the B.A. degree, and to proceed to higher degrees in the ordinary course. Cambridge graduates may, on like terms, obtain the "Certificate of Research." The original proposal to establish new degrees (B.Litt. and B.Sc.) for the class of advanced students, has been dropped; but the possibility of proceeding to the higher degrees of the University is a new feature of importance. The Report is signed by all the twelve members of the Syndicate, including the Vice-Chancellor and eight professors, representing both the literary and the scientific departments of University study. It will come before the Senate for public discussion during the present term. The main lines of the scheme resemble those of the plan provisionally adopted at Oxford, with the important difference that Oxford has taken up the idea, discarded at Cambridge, of founding special literary and scientific degrees for post-graduate students, and does not propose that they shall be eligible for the degree of Master of Arts.

A University Lectureship in Pure Mathematics will be vacant at the end of the present term, by the resignation of Dr. Forsyth, elected Sadlerian Professor. The lecturer will hold office for five years from Midsummer, 1895. Applications are to be sent to the Vice-Chancellor before Wednesday, April 24, 1895.

An examination for diplomas in Agricultural Science will be held in Cambridge in the week beginning July 1, 1895. The names of candidates are to be sent to the Registrary by June 12.

ONE or two of the new provisions in the Revised Code for Elementary Day Schools, presented to the House of Commons last week, are worth noting here. Kindergarten methods of instruction have been recognised in infants' schools for some time, but they have usually ended in the infant school. "Object-lessons and suitable occupations" are now, however, to be counted as class subjects in the lower standards of elementary schools, so that the lessons which are so valuable in training the intelligence of the infant children will be extended. Properly carried out, these natural methods of instruction are of extreme importance in developing such powers of observation and reasoning as young children possess. Another commendable addition which Mr. Acland has introduced into the Code permits visits to be made, during school hours, to museums and art galleries; not more than twenty hours in the school year to be thus employed. Visits to the museums at South Kensington cannot but have a beneficial influence upon the minds of children, and if the guide is competent, they may be made of great value. Perhaps the new feature will lead to the establishment of science museums in towns where none at present exist. It may also assist in the reduction of the bric-a-brac element (which makes many small museums little more than variety shows), and improve the arrangement and character of the collections.

SCIENTIFIC SERIALS.

American Meteorological Journal, February.—The cause of the cyclones of the temperate latitudes, by W. H. Dines. Two theories have found considerable support: (1) the convectional theory, commonly known as Ferrel's, because he so fully explained it, and showed that cyclones were caused by the convectional ascent of a current of warm air in the central parts, the heat necessary to sustain the current being supplied, at least in part, by the latent heat set free by the condensation of aqueous vapour; (2) the theory proposed by Dr. Hann, who considers that the storms are merely eddies formed in the general easterly drift of the atmosphere in temperate latitudes, just as small whirls are formed in a river. Dr. Hann found that the temperature at high mountain stations in the Alps is higher during anticyclonic conditions than during the passage of storms. Mr. Dines thinks that the evidence is in favour of Ferrel's theory, as mathematical laws show that it is a possible one, and that the latent heat set free by the condensation of moisture will, if it take the form of kinetic energy, be sufficient to produce a most violent storm.—Recent foreign studies of thunderstorms: Russia, by R. De C. Ward. The Imperial Geographical Society of Russia instituted a special study of thunderstorms in 1871, which has been continued until the present time. This service, and others subsequently established, such as that in south-west Russia by Prof. Klossovsky, have led to some valuable results. The district of greatest thunderstorm activity is the Caucasus, then the southern central region. The predominant direction of movement is north-east, and the storms occur most frequently in June and July, the maximum frequency being in the afternoon.—The *Journal* also contains other articles of minor importance, including one on the moon and rainfall, by Prof. H. A. Hazen. The figures for Boston show a remarkable maximum at the day of new moon, and an equally remarkable minimum two days after full moon.

Journal of the Russian Chemical and Physical Society, vol. xxvi. parts 2 to 8.—Among many valuable papers inserted in these issues, the following are especially worthy of notice:—On the speed of formation of the amines, by N. Menschutkin.—On the nitration of saturated hydrocarbons by means of nitric acid, by M. Konovaloff.—On the solubility of anhydrous calcium sulphate, by A. Potilitsine.—On the isomerisation of aromatic hydrocarbons obtained by Fridel's method, by M. Konovaloff.—On the structure of terpenes and similar compounds, by G. Wagner.—On the nitration of unsaturated hydrocarbons, by means of nitric acid, by M. Konovaloff.—On the halogen compounds of nitrogen, by Th. Selivanoff.—In the physical part: On the electric resistance of bismuth to alternating currents, by A Sadovsky.—On the variation of electrostatic energy, by M. Schiller.—On the variation in length of iron wire during magnetisation, by M. Rosing.—Experiments with alternating currents of high frequency, by N. Slouginoff.

Part 2 of the *Journal* contains also, as a supplement, the first number of the Memoirs (*Vremennik*) of the Central Board of Measures and Weights, which was instituted in 1893, and is placed under Prof. Mendeléeff, who is also the editor of this publication. In this first part we find besides a preface by the editor, several papers of more than local interest, namely:—The measurements made to compare the iron *sajène* of the "Committee of the year 1833" with various units of length, accomplished in 1884, by MM. Glukhoff and Zawadski. The comparison was also made with the bronze and iron yards of Airy.—On the weight of a litre of air, a very elaborate paper by Prof. Mendeléeff, in which some remarks concerning the measurements of Leduc and Lord Rayleigh, and the corrections which should be introduced into their measurements, are specially valuable. The average value arrived at by Prof. Mendeléeff is, in grams,

$$e_0 = 0{\cdot}131844\,g \pm 0{\cdot}00010.$$

—First list of the standard measures of weight and length at the Central Board, by Th. Zawadski.—Data for the elaboration of an instruction for verifying the weights and measures in the trade establishments.—Preliminary researches into new scales for grain, as a means of determining the quality of the latter, by Th. Selivanoff.

SOCIETIES AND ACADEMIES.

LONDON

Royal Society, February 7.—"On the Application of the Kinetic Theory to Dense Gases." By S. H. Burbury, F.R.S.

February 14.—"An Instrument for Cutting, Grinding, and Polishing Section-plates and Prisms of Mineral or other Crystals accurately in the desired direction." By A. E. Tutton, Demonstrator of Chemistry at the Royal College of Science, South Kensington.

In a recent communication (*Phil. Trans.* 1894, Series A. p. 887) the author described an instrument for grinding accurately orientated section-plates and prisms of crystals of artificial preparations. The success of that instrument is so complete that another instrument has deen devised and constructed, which enables equally accurately orientated plates or prisms to be prepared from the relatively harder crystals of natural minerals. The instrument is not intended to replace the one previously described, which is fully adapted for all the purposes of chemical crystallographers, and the cost of which is only two-thirds that of the one now described. It is intended especially for the use of mineralogists, but, naturally, will serve all the purposes of the smaller instrument. It is constructed upon a scale one-fifth larger than the former one as regards such parts as are fundamentally similar, to confer greater strength. The mode of supporting the outer fixed cone within which the movable axes rotate, the construction of the circle and its axis and fine adjustment, and of the gun-metal axis and its counterpoising levers designed for controlling the pressure between crystal and lap, as also of the inner steel axis from which are suspended the crystal and its centering and adjusting movements, are similar in principle to the corresponding arrangements in the smaller instrument, although many details are altered for the sake of greater rigidity. The same likewise applies to the goniometrical telescope and collimator and their mode of support. The main innovations are those of a cutting apparatus, and a larger grinding table capable of being readily furnished with any one of nine interchangeable grinding and polishing laps, suitable for use with crystals of every degree of hardness. Four metallic laps are provided, of iron, gun-metal, hard white metal, and pewter respectively, the first for rough grinding with coarse emery and brick oil or water, the second and third for fine grinding with flour emery, and the fourth for polishing with rottenstone and water. A polishing lap of hard felt, for use with putty powder and water, and a lap of boxwood, are supplied. Three glass laps, one coarsely ground, another finely ground, and the third of ordinary polished plate glass, are likewise provided for use with artificial crystals. The cutting apparatus is carried upon a horizontal arm pivoted about the back pillar of the instrument, in order to permit of its removal out of the way during grinding and polishing operations, and further supported when in use upon an adjunct of the right front pillar. It consists of a 4-inch disc of soft iron, supplied with diamond edge, and intended to be lubricated with brick oil, driven by an independent driving gear carried upon the arm. The supporting attachment to the front pillar is removable when not required, and includes a traversing apparatus for directing and controlling the cutting, and a safety back-spring to prevent the possibility of undue pressure being induced between the cutting disc and the crystal by injudiciously rapid rotation of the traversing screw. Instead of actuating the driving gear of the cutting or grinding apparatus by hand, a small electric, gas, or water motor may be employed.

"On the Ratio of the Specific Heats of some Compound Gases." By Dr. J. W. Capstick, Fellow of Trinity College, Cambridge.

The experiments described are a continuation of those of which an account is given in the *Phil. Trans.* vol. clxxxv. p. 1, Kundt's dust-figure method being used, and the ratio of the specific heats corrected for deviation of the gas from Boyle's law. The results are as follows:—

Name.	Formula.	γ
Methylene chloride......	CH_2Cl_2	1·219
Chloroform	$CHCl_3$	1·154
Carbon tetrachloride ...	CCl_4	1·130
Ethylene chloride	$C_2H_4Cl_2$	1·137
Ethylidene chloride......	$C_2H_4Cl_2$	1·134
Ethylene	C_2H_4	1·264
Vinyl bromide...........	C_2H_3Br	1·198
Allyl chloride	C_3H_5Cl	1·137
Allyl bromide	C_3H_5Br	1·145
Ethyl formate	$HCOOC_2H_5$	1·124
Methyl acetate...........	CH_3COOCH_3	1·137
Sulphuretted hydrogen	SH_2	1·340
Carbon dioxide	CO_2	1·308
Carbon disulphide	CS_2	1·239
Silicon tetrachloride ...	CCl_4	1·129

From these, and the results given in the former paper, it follows that

(1) Replacement of one halogen by another in a compound has no effect on γ.

(2) One H in a paraffin molecule may in some cases (*e.g.* ethane and propane) be replaced by Cl without altering γ, but a second replacement always causes a fall.

(3) Carbon and silicon can be interchanged without effect on γ.

(4) Isomeric compounds have the same γ.

(5) Using γ to calculate β, the ratio of the rates of increase of intramolecular and translational energy of the molecule on a rise of temperature, we find $\frac{\beta+1}{n}$ is constant for the paraffins and their monohalogen derivatives, whence it follows that for these the ratio of the increase of mean total energy to the increase of kinetic energy of translation of the molecule is proportional to the number of atoms in the molecule.

"On some Considerations showing that Maxwell's Theorem of the Equal Partition of Energy among the Degrees of

Freedom of Atoms is not inconsistent with the various Internal Movements exhibited by the Spectra of Gases." By Prof. G. F. Fitzgerald, F.R.S.

It has been generally held that a sufficient freedom of internal motion in an atom to explain the spectra of gases proved that the theorem as to equal partition of energy among all degrees of freedom could not hold, and various suggestions have been made as to why the *proof*, as given by Maxwell, Boltzmann, and others, fails in this case. Prof Schuster has suggested that the numerous lines need not involve the same number of degrees of freedom, as it is possible that there may be connections between them such that one or two coordinates would define a motion which when analysed into its Fourier components, as is done by a grating or prism, would produce a very complex system of lines. However, even one degree of internal freedom would interfere very seriously with the observed value of the ratio of specific heats, and the object of this note is to explain how this difficulty may be surmounted without supposing that the theorem as to equal partition of energy is untrue, for it is not by any means disproved because a certain form of proof fails in certain cases.

It has been long held that the motion of the electrons on neighbouring atoms is very much controlled by the ether between them. The wave-length of light is generally many times as great as the molecular distances, so that the ether is a practically rigid connector between neighbouring electrons. Suppose now, as a particular example, that 10^6 atoms are in this sense, and so far as the motion of electrons is concerned, within one another's control. In this case the motion of these 10^6 electrons might be defined by means of, say, three coordinates. Hence, if the atoms were spheres, there would be 3×10^6 degrees of freedom plus these three degrees defining the motions of all the electrons. Now, if the total energy be equally distributed among all these degrees of freedom, each atom will only have its share of the electromotions, and its energy of external motion will only be diminished by 3×10^{-6}th part owing to the existence of the internal motion of its electrons. I need hardly say that our methods of calorimetry are by no means sufficiently delicate to detect anything of this kind. There might be a thousand such internal degrees of freedom, and yet the ratio of specific heats would agree with observation.

There is some analogy between this suggestion and the case of a sphere moving in a liquid. The presence of the liquid, although apparently endowed with an infinite number of degrees of freedom, does not really increase the degrees of freedom at all, because its motion is entirely defined by the motion of the sphere. In a somewhat similar manner, I would suggest that the presence of the million electrons does not sensibly increase the degrees of freedom of motion of the million atoms, as all their motions may be defined in terms of the motion of a few of them. That the ether would so control the motions of electrons seems almost certain from what we know of the rapidity with which electromagnetic actions are transmitted by it, showing how completely it behaves in respect of them as a system of rigid connections.

"Note on the Disease of Cabbages and allied Plants known as 'Finger and Toe,' &c." By George Massee, Royal Gardens, Kew.

The disease known in different parts of Britain as "finger and toe," "clubbing," or "anbury," attacks turnips, rape, cabbages of all varieties, radishes, and, in fact, most cultivated plants belonging to the order *Cruciferæ*. Several common weeds are also attacked, namely, charlock (*Brassica sinapistrum*, Boiss.); garlic-mustard (*Sisymbrium alliaria*, Scop.); treacle-mustard (*Erysimum cheiranthoides*, Linn.), and shepherd's purse (*Capsella bursa pastoris*, D.C.). The last-named is reported from the United States by Halsted (New Jersey Agric. Coll. Expt. Station; *Bulletin* 98, 1893), and has not been observed to be diseased in Britain, although one of our commonest weeds. The disease is characterised by the formation of numerous nodules on the root, which becomes much distorted and soon decays, forming a slimy, fœtid mass.

Berkeley (*Gard. Chron.*, p. 500, 1856) appears to have been the first to investigate the disease from a scientific standpoint, and although he did not succeed in determining the true cause, distinctly states that microscopic examination revealed the presence of a factor previously unknown in connection with plant diseases. Furthermore, Berkeley pointed out that wood ashes were a cure for the disease, and supposed this to be due to the presence of potash salts in the ash.

Owing to the serious amount of damage caused by "finger and toe" to the cabbage crop in Russia, the Government of that country offered a reward for the discovery of the cause of the disease. Woronin ("Pringsheim's Jahrb," vol. xi. p. 548, tabs. xxix.-xxxiv., 1878) undertook the investigation, and after years of patient study published an elaborate account, proving clearly that the disease was caused by a minute organism related to the fungi, to which he gave the name *Plasmodiophora brassicæ*.

In 1859, Voelcker (*Roy. Agric. Soc. Journ.*, vol. xx. p. 101, 1859) pointed out that the disease was influenced by the amount of lime present in the soil. Where little or no lime existed, as in light and sandy soils, the disease abounded, whereas in soil containing lime the disease was absent. This opinion is corroborated by the same author at a later date (*Op. cit.*, series iii. vol. v. p. 321, 1894).

A series of experiments have been carried out during four successive years at Kew, and they demonstrate the following points:—

(1) That in addition to cultivated plants, several common weeds belonging to the order *Cruciferæ* are attacked by the *Plasmodiophora*. Hence the necessity for preventing the growth of such weeds in fields and hedge-banks.

(2) That the germs of disease are present in soil that has produced a diseased crop, and retain their vitality for at least two years.

(3) That the development of *Plasmodiophora* is favoured by the presence of acids, and checked by the presence of alkalies, agreeing in this respect with the fungi rather than with bacteria.

(4) For the purpose of sterilising infected soil, experiments prove that either a dressing of lime or a manure containing potash salts is effective, the last being most valuable, as it not only destroys the germs in the soil but also arrests the disease in seedling plants, and at the same time supplies one of the ingredients necessary for the healthy growth of turnips.

February 21.—"Iron and Steel at Welding Temperatures." By T. Wrightson.

The object of this paper was to demonstrate that the phenomenon of welding in iron is identical with that of regelation in ice.

The author recapitulated experiments made by him in 1879–80, described in the *Proceedings* of the Iron and Steel Institute for those years. These experiments were upon cast iron, and proved that this form of iron possessed the property of expanding while passing from the liquid to the plastic state during a small range of temperature, and then contracted to the solid state, and that the expansion amounted to about 6 per cent. in volume. This property of iron resembles the similar property of water in freezing, which, within a range of about 4° C., expands about 9 per cent. of its liquid volume, and then contracts as the cooling proceeds.

This property of water was investigated by Prof. James Thomson and by Lord Kelvin. The former showed that from theoretical considerations there was reason to expect that in the case of a body exhibiting the anomalous property of expanding when cooled and contracting when heated, it should be cooled instead of heated by pressure or impact. Lord Kelvin investigated the problem experimentally as affecting freezing water, and completely demonstrated the truth of his brother's reasoning.

The experiments made by the author in 1879 and 1880 suggested the view that this property of ice was connected with the property of welding in iron, but this was only hypothetical, as the experiments had been made on cast iron, which probably, on account of the presence of carbon, does not possess the property of welding. Further, it was not practicable to experiment with wrought iron in the same way as with cast iron on account of the difficulty of dealing with that substance in its liquid form. Prof. Roberts-Austen has, however, given metallurgical research a recording pyrometer, and this has enabled the author to resume the investigation at the Mint. The method adopted was the heating of bars in an electric welder, and as soon as the junction of the bars was at a welding temperature, end pressure was applied by mechanical power, and the weld effected.

Observations show that a molecular lowering of temperature took place immediately the pressure was applied to the bar when in the welding condition.

The fall in temperature varied from 57° C. to 19° C., according to the circumstances of temperature and pressure.

The experiments appears to prove that wrought iron at a welding temperature possesses the same property of cooling under pressure which was proved by Lord Kelvin to exist in freezing water, and on which demonstration the generally received theory of regelation depends.

The author distinguishes the process of melting together of metals from that of welding. Either process forms a junction, but the latter takes place at a temperature considerably below the melting point.

The well-known and useful property of welding in iron appears, therefore, to depend, as in the case of regelation in ice, upon this critical condition, which exists over a limited range of temperature between the molten and the plastic state.

"Note on the Spectrum of Argon." By H. F. Newall.

In the course of a spectroscopic investigation in which the author has been for some time past engaged, a line spectrum, which so far as he was able to make out was unknown, had frequently presented itself upon his photographs. It appeared in May and June, 1894, under conditions which led him to call it, for the sake of convenience, "the low-pressure spectrum." It now appears that the lines are argon lines.

The argon of which the spectrum was observed was obtained from air, from which nitrogen was eliminated by passing electric discharge through it in presence of hydrogen or moisture and acid. Seventy-two lines in the author's "low-pressure spectrum" had their wave-lengths given in the paper, and side by side were given the measurements of the wave-lengths determined by Mr. Crookes for the argon lines.

The agreement of the measurements s hows conclusively that the same spectrum was observed. The agreement of grouping and intensity, also, leaves no doubt as to the identity of the two spectra.

The experiments were repeated, with slight variations, several times with results which, so far as the spectrum of argon is concerned, were constant. But it was noted that continued passage of the discharge appears to result in the attaining of a certain minimum pressure, after which there is slight and slow rise to a tolerably-fixed pressure.

It is interesting to find argon asserting itself, unsolicited, in quite new circumstances, and under conditions which practically constitute one more mode of separating argon from nitrogen—namely, the getting rid of nitrogen by passing electric discharge through it in the presence of hydrogen or moisture and acid.

February 28.—"The Effect of Environment on the Development of Echinoderm Larvæ: an Experimental Inquiry into the Causes of Variation." By H. M. Vernon (from the Zoological Station, Naples).

The conditions of environment under which an organism develops are known to be of considerable influence in the production of variations. It was thought to be of interest to determine by exact measurement the effects which such slight changes in the environmental conditions as might occur naturally would produce in the growth of some organisms. The animal chosen was the larva or pluteus of the sea-urchin *Strongylocentrotus lividus*. These larvæ develop readily from artificial fertilisations, and they can, moreover, be obtained at all times of the year, irrespective of season. In all 10,000 larvæ were measured.

The effects of temperature on development were first studied. It was found that if the ova were placed in water at about 8° or 25° C. for an hour, or even for a minute, at the time of impregnation, the resulting larvæ after eight days development were, on an average, 4·6 per cent. smaller than those impregnated at from 17° to 22°, though all the subsequent conditions of development were identical. If kept at the abnormal temperature for only ten seconds during impregnation, the resulting larvæ were only 1·7 per cent. smaller.

The time of the year when the artificial fertilisations are prepared has a very marked influence on the size of the larvæ. Thus, those obtained in the middle of August are about 20 per cent. smaller than those obtained in April, May, and October, whilst those obtained in June and July are intermediate in size.

The salinity of the water has also a great influence on the development.

The effects which the various colours of the spectrum have upon the development were also determined, though these are not conditions of environment which occur in nature. The development of the larvæ seems to be but little affected if it is carried out in absolute darkness, the size only being diminished by 1·3 per cent. Larvæ grown in semi-darkness are apparently 2·5 per cent. larger than the normal.

The body-length of the larvæ appears to be uninfluenced by the number of larvæ developing together in a given volume of water, if it be kept below 30,000 per litre. The arm-lengths are, on the other hand, considerably affected.

Certain products of metabolism exert a favourable influence on the developments of the larvæ, and not, as would be naturally expected, a harmful one.

As the number of measurements made was so large, it was thought to be of interest to subject them to statistical examination. It was found that with the body-length and oral arm-length measurements the deviations from the average occurred with a frequency indicated by the theoretical law of error. The measurements of the aboral arm-length did not agree so well, possibly owing to dimorphism.

Physical Society, February 22.—Captain Abney, F.R.S., President, in the chair.—An abstract of Mr. G. H. Bryan's paper, on the mechanical analogue of thermal equilibrium between bodies in contact, was read by Mr. Elder. After commenting on the difficulty in applying the kinetic theory of gases to the case of two substances in contact which do not mix, the author goes on to describe a system by which the phenomena of thermal equilibrium unaccompanied by diffusion can be explained. The two substances are represented by two sets of molecules designated by P and Q. Two parallel planes A and B, at a small distance apart, are imagined to divide space in three parts. Plane A (to the left of B) is supposed to be permeable to the P molecules, but to repel the Q molecules, whilst B is permeable to the Q set of molecules, and repels the P set. The spaces to the left of A and to the right of B are thus entirely occupied by the P and Q molecules respectively. Between the planes both P and Q molecules exist, and therefore have opportunities of colliding with one another and transferring energy from one gas to the other. Using generalised coordinates, it is shown by Boltzmann's method that when equilibrium is attained the mean kinetic energies of translation of the two kinds of molecules are equal, just as in the case of molecules which mix. Instead of assuming the planes A and B to repel the Q and P molecules respectively, the P molecules may be assumed to be positively electrified, and the Q ones negatively electrified, whilst the planes A and B are maintained at a constant difference of potential. The difference of potential thus assumed is analogous to "contact E.M.F." whose existence is proved by experiment. The communication concludes with a development of Prof. Boltzmann's paper on the application of the determinantal relation to the kinetic theory of polyatomic gases, read before the British Association at Oxford. Dr. Stoney thought the arguments were based on actions depending on the distances of the molecules, and the supposition that they were rigid. In his opinion events occur in nature which are not represented by this simple theory, and great reservation should be shown in accepting dynamical problems which leave out of account actions occurring between matter and the ether. In nature nothing was large and nothing was small except relatively. Even molecules might possess infinite detail of structure. Their interaction with the ether must be considered in any complete theory.—Mr. G. U. Yule's paper on a new harmonic analyser, and one by Mr. H. N. Allen, on the electromagnetic field, were postponed.

Chemical Society, February 21.—Dr. Armstrong, President, in the chair.—The following papers were read:—The electromotive force of an iodine cell, by A. P. Laurie. The E.M.F. of a cell consisting of a zinc and platinum plate immersed in iodine dissolved in potassium iodide solution is constant, but is the smaller as the iodine solution is the more dilute; the effect of varying the constituents of the cell on the E.M.F. has been investigated.—Contributions to the chemistry of cellulose, by C. F. Cross, E. J. Bevan, and C. Beadle. The melting-points of mixtures, by H. Crompton and Miss M. A. Whiteley. When a solution deposits the pure solvent on cooling, the relation $\log s = \frac{\rho}{1 \cdot 98} \cdot \frac{T - T^1}{TT^1}$ holds; s is the number of molecules of solvent per molecule of solution, ρ is the molecular latent heat of fusion of the solvent, and T and T^1 the melting-points of the solvent and the solution respectively.—The volumetric determination of manganese, by J. Reddrop and H.

Ramage. Schneider's process for the determination of manganese may be rendered much more accurate by substituting sodium bismuthate for bismuth peroxide.—Bromocamphoric acid, an oxidation product of π-dibromocamphor, by F. S. Kipping. A bromocamphoric acid is obtained by oxidising π-dibromocamphor; its anhydride has been prepared together with a new hydroxy-acid and a nitrobromocamphor.—Note on the action of diastase on cold starch-paste, by H. T. Brown and G. H. Morris.—On the magnetic rotation of some unsaturated hydrocarbons, by W. H. Perkin. The magnetic rotations of a number of unsaturated open-chain hydrocarbons have been determined; a comparison of hexane, hexylene, diallyl, and dipropargyl shows that the differences between the latter pair are of a different order to those of the former pair.

Linnean Society, February 7.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. Thomas Christy exhibited a dried specimen of *Aplopappus Llaretæ* and samples of the so-called Gum Kino, *Pterocarpus erinaceus*, of which some account was given by Mr. E. M. Holmes. Mr. George Murray exhibited a number of lantern slides of floating *Algæ*, of which he gave brief descriptions referring to the localities in which they had been found and the literature relating to them.—By permission of the Director of the Royal Gardens, Kew, Mr. W. B. Hemsley exhibited dried specimens of a number of new plants from Eastern Asia. Conspicuous amongst these was a new genus of *Scitamineæ* from the mountains of Northern Siam, characterised by having minute unisexual flowers destitute of staminodia, a one-celled ovary with parietal placentation, and two filiform stylodia; a remarkably broad-leaved *Lysimachia* from the same region; new species of *Hypericum*, *Ventilago*, *Mesona*, and *Helicia* from Formosa; and a new genus of *Cyrtandreæ*. From a collection made in Yunan, Western China, by Mr. W. Hancock, of Hong Kong, came a new *Jasminum*, allied to *J. nudiflorum*, with primrose yellow flowers an inch and a half in diameter; an elegant species of *Petrocosmea* (Cyrtandreæ), and a showy *Brandisia* (Scrophularineæ) with long racemes of crimson flowers, which were much admired.—Mr. Thomas Hanbury exhibited a beautiful collection of fresh fruits of the *Aurantieæ* grown in his own garden at La Mortola, Mentone, and gave an account of some of the more remarkable varieties, their mode of growth, and the conditions under which they had been grown.—A paper was then read by Mr. H. M. Bernard, on the comparative morphology of the *Galeodidæ*. Having described a possible origin for the Crustacea from a chætopod annelid by an adaptation of the anterior segments to a method of feeding, whereby the parapodia would function as jaws, the author attempted the same for the Arachnida with a view to solve the question of their relationship with the Merostomata. The *Galeodidæ* were chosen for special study because, unlike other arachnids, they have retained some segments of the cephalothorax as free movable segments, and hence might be expected to throw light on the subject. The author believed that he had solved the question of the primitive specialisation of the arachnid phylum from their annelidan ancestors, and expressed the opinion that as arthropods they are not related either to the Crustacea (including *Limulus*) nor to the Hexapoda; but that all these are distinct derivations of the Annelida. In an interesting discussion which followed, the paper was criticised at some length by Mr. A. D. Michael, Prof. Howes, and Mr. R. I. Pocock.

PARIS.

Academy of Sciences, February 25.—M. Lœwy in the chair.—On the penetration of a projectile in semi-fluids and solids, by M. H. Resal.—On a class of equations of which the general integral is uniform, by M. Émile Picard.—On the measurement of time in astronomy by a method independent of personal equation, by M. G. Lippmann. The author employs a photographic method. A platinum wire is rendered incandescent for a very short time at the commencement of each second by mechanical means. The light from the wire is, by the aid of arrangements described, thrown on to a photographic plate in such a way that the image formed corresponds precisely with the meridian of the place of observation. By suitable exposure a photograph is obtained of a portion of the heavens on the same plate. The time of transit of a given star can then be easily deduced from the horary circle photographed as above. M. d'Abbadie remarked with reference to an alternative micrometric method proposed by M. Lippmann, that Breguet had used a moving wire grating for measurement of the same quantities fifty years previously.—On the mutual relations of potential determinants, by M. de Jonquières.—Ebullioscopic study of certain colouring matters from triphenylmethane, by MM. A. Haller and P. Th. Muller. The conclusion is drawn that, under the given experimental conditions, the hydrochlorides of the colouring substances of the triphenylmethane amido group are not dissociated, whereas the chlorides of ammonium bases and nitrosodimethylaniline hydrochloride are most clearly dissociated. Hence an argument may be drawn in favour of formulæ of the type of ClC : $(C_6H_4.NH_2)_3$ due to M. Rosenstiehl.—M. Sappey gave a short description of the "Atlas of Descriptive Anatomy," presented by M. Laskowski.—The Academy elected M. Weierstrass as foreign associate, the votes given being: M. Weierstrass 43, Prof. Frankland 1, Prof. Huxley 1.—A closed communication from M. E. Carvallo, accepted May 2, 1892, was opened. It gave the theory of the laws of crystalline absorption. For uniaxial crystals these are: (1) For the ordinary ray, the index of refraction and the coefficient of absorption are constant, whatever may be the angle between the luminous ray and the crystallographic axis. (2) The law of the index of the extraordinary ray is not altered sensibly by absorption. (3) The absorption of the extraordinary ray is represented by the formula

$$\frac{k}{n^3} = \frac{k_o}{n_o^3}\cos^2\theta + \frac{k_e}{n_e^3}\sin^2\theta,$$

where k, n, θ represent the coefficient of absorption, the index of refraction, and the angle between the normal to the plane of the wave and the crystallographic axis. A memoir will shortly be brought out dealing with these results and their developments.—M. L. L. de Koninck claims priority for the properties of nickel and cobalt sulphides.—Spectrum researches on the rotation and movements of the planets, by M. H. Deslandres. (See "Our Astronomical Column.")—Observations on the subject of the preceding communication by M. Deslandres, by M. H. Poincaré. The theoretical views which have been confirmed by the foregoing results.—Determination of the position of the pole by photography, by M. C. Flammarion. By exposure of a fixed plate, circular traces of the circumpolar stars are obtained as shown in the figure given with the paper. Hence the position of the pole can be obtained with great accuracy.—On a surface of the sixth order which is connected with Kummer's surface, by M. G. Humbert.—On functional equations, by M. Lean.—On the exact invariants of an ordinary differential equation of the second order, by M. Tresse.—On some theorems of Arithmology, by M. N. Bougaief.—Lowering of the freezing point and relative diminution of vapour pressure in dilute solutions, by M. A. Ponsot. The author deduces formulæ differing somewhat from those given by Wüllner and Raoult, and agreeing with those of van t'Hoff and Duhem, with the exception that a different meaning is given to one of the terms.—On the lowering of the freezing point of very dilute solutions, by M. A. Leduc. The author proposes the substitution of the measurement of a considerable pressure for a small temperature difference. A theoretical demonstration.—On a sensitive pressometer, for the measurement of fluid pressures, by M. Paul Charpentier.—The measurement of the intensity of light by the chemical action produced; experiments with mixtures of ferric chloride and oxalic acid, by M. Georges Lemoine.—On some combinations of lead iodide with other metallic or organic iodides, by M. A. Mosnier. A number of new double salts have been obtained and their composition determined.—On some combinations of nitric oxide with the chlorides of iron, by M. V. Thomas. The substances: (1) $Fe_2Cl_6.NO$, (2) $2Fe_2Cl_6.NO$, (3) $FeCl_2.NO.2H_2O$, and (4) $FeCl_2.NO$, have been obtained and their composition determined by analysis.—Action of formaldehyde on hydroxylamine hydrochloride and on methylamine hydrochloride, by MM. A. Brochet and R. Cambier.—Active amyl ethereal salts, by MM. Ph. A. Guye and L. Chavanne. A paper on the product of asymmetry.—New researches on the correlative variations of the intensity of thermogenesis and respiratory changes, by M. Laulanié.—"*Autonarcose carbonico-acétonémique*," or winter sleep of the marmot, by M. Raphael Dubois.—On the *Rhinatrema bivittatum*, Cuvier, by M. Léon Vaillant.—Evolution of the nervous system and of the vibratile organ in the larvæ of compound ascidians, by M. Antoine Pizon.—On the rôle of Amæbocytes in the Annelids, by Émile G. Racovitza. Amæbocytes serve not only to deposit the excretory pigment in the epidermis, but when necessary, take up and digest for the benefit of the organism all the accumulated reserve substances.—Natural and artificial protophylline, by M. C. Timiriazeff.—On some applications of Oceanography to Geology, by M. J. Thoulet.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, MARCH 7.

ROYAL SOCIETY, at 4.30.—The Rubies of Burma and Associated Minerals: their Mode of Occurrence, Origin, and Metamorphoses. A Contribution to the History of Corundum: C. Barrington Brown and Prof. Judd, F.R.S.—The Action of Heat upon Ethylene, Part II. Prof. V. B. Lewes. —On the Measurement of Pressures by the Crusher-Gauge: W. Kellner and W. H. Deering.
SOCIETY OF ANTIQUARIES, at 8.30.
LINNEAN SOCIETY, at 8.—On the Genus Cupressus: Dr. Maxwell T. Masters, F.R.S.—On the Insects, Arachnida, and Crustacea collected during Mr. T. Bent's Expedition to Hadramant, Arabia: W. F. Kirby, Chas. Gahan, and R. I. Pocock.
CHEMICAL SOCIETY, at 8.—Dimethylketohexamethylene: Dr. Kipping.—The Use of Barium Thiosulphate in Standardising Iodine: Dr. Plimpton and T. C. Chorley.—The Magnetic Rotation of the Plane of Polarisation of Light by Liquids: J. W. Rodger and W. Watson.—Trimethylsuccinic Acid: Prof. W. H. Perkin, F.R.S., and Dr. W. Bone.

FRIDAY, MARCH 8.

ROYAL INSTITUTION, at 9.—The Physical Work of Von Helmholtz: Prof. A. W. Rücker, F.R.S.
PHYSICAL SOCIETY, at 5.—Exhibition, by Mr. Naber, of a Voltameter.—(1) The Focal Heliostat; (2) An Improvement in Siderostats Dr. G. Johnstone Stoney, F.R.S. -On a New Harmonic Analyser: G. U. Yule. —On the Electromagnetic Field: H. N. Allen.
ROYAL ASTRONOMICAL SOCIETY, at 8.—Micrometrical Measures of the Diameter of the Satellites of Jupiter: Micrometrical Measures of the Ball and Ring System of Saturn, and of the Diameter of Titan: E. E. Barnard.—Transit of Mercury, 1894 November 10: W. F. Gale; J. P. Thomson.—A List of Probably New Double Stars: R.T. A. Innes.—Double Star Measures: W. H. Maw and J. Tebbutt.—Notes on the Variable Stars X and W Sagittæ: Lieut.-Colonel Markwick.—Note on a Suggested Form of Equatorial Mounting for a Modified Newtonian Reflector: Rev. C. D. P. Davies.—On the Proper Motions of B.A.C. 793 and Cephei 24 (Hev.): W. T. Lynn.—The Wilsonian Theory and the Stonyhurst Drawings of Sun-spots: Rev. W. Sidgreaves.—Observations of Encke's Comet: Royal Observatory, Greenwich.—An Apparatus for Mechanically Calculating Star Corrections: W. E. Cooke.—Note on the above Paper: Prof. H. H. Turner.
INSTITUTION OF CIVIL ENGINEERS, at 8.—The Coordinate System of Surveying as employed in South Africa: A. Struben.
MALACOLOGICAL SOCIETY, at 8.
CLINICAL SOCIETY, at 8.30.

SATURDAY, MARCH 9.

ROYAL INSTITUTION, at 3.—Waves and Vibrations: Lord Rayleigh, F.R.S.
ROYAL BOTANIC SOCIETY, at 3.45.
ESSEX FIELD CLUB (at Stratford), at 6.30.—Notes on the Remains of Pleistocene Mammals found in the Neighbourhood of Chelmsford: E. T. Newton, F.R.S.—Note on the Section at Chelmsford in which the Mammoth and other Remains were discovered, November 1894: T. V. Holmes.

Band, 2 Heft (Leipzig, Engelmann) —Scribner's Magazine, March (Low).—Zeitschrift für Naturwissenschaften, 66 Band, 5 and 6 Heft, 67 Band, 1 to 5 Heft (Leipzig, Pfeffer).—National Review, March (Arnold).

CONTENTS.

THURSDAY, MARCH 14, 1895.

THE LIFE OF DEAN BUCKLAND.

The Life and Correspondence of William Buckland, D.D., F.R.S. By his Daughter, Mrs. Gordon. (London: John Murray, 1894.)

IN the early decades of this century Geology had not established for itself an acknowledged place in the circle of the natural sciences. With as yet no settled philosophical basis, it offered a boundless field for indulgence in the wildest conjectures and the boldest speculation. Its votaries were, therefore, hardly regarded as serious students by the scientific men of the day. On the other hand, they incurred much popular odium. They had drawn such strange and almost incredible pictures of what they averred to have been the past history of the earth, so utterly at variance with all accepted beliefs, that they were looked upon with suspicion by some, sneered at by others, while by a large body of blatant opponents they were openly denounced as freethinkers, who, under the guise of natural science, aimed at the subversion of all religion. It needed some courage to be a geologist in those days, and still more to be a champion of the new inquiry.

Among the most prominent and effective of those who stood in the front of the battle and fought the hard fight was William Buckland. No man did more than he to raise geology from its depressed beginnings to the dignity of a definite branch of natural knowledge. And his name will ever be remembered with gratitude and affection as that of one of the clear-eyed, large-hearted fathers of English geology. This proud position he gained by a two-fold claim. The amount, the wide range and the intrinsic value of his original contributions to the science would have been enough to place him in the front rank of the leaders in that heroic age of geological discovery. But it was not merely, perhaps not even chiefly, by these qualifications, admirable as they were, that he attained to his unquestioned pre-eminence among his contemporaries. It was rather the unique personality of the man which gave him his remarkable influence, irresistibly engaging the sympathies and admiration of all who came in contact with him, bearing down gently but firmly all opposition, and gaining for him the affectionate esteem even of those from whom he differed.

His solid work remains and can be examined and weighed, and its influence on the progress of his favourite science can be accurately determined. But that personal sway passed away with him who wielded it, and is now only a memory. It has not yet been adequately pictured for the comprehension of those who never felt it, or who coming after have only heard feeble narratives of it, together, perhaps, with some of the many quaint stories still in circulation that illustrate it. At the time of his death numerous appreciative obituary notices of him appeared, some of them by personal friends who knew him well, and mourned the loss of so much that was bright, inspiriting and lovable. Some pleasant recollections of him by his son Frank were published in the last edition of Buckland's famous Bridgewater Treatise. But some more detailed biography might have been expected. He was a ready and copious correspondent, and it might have been supposed that abundant material must remain to furnish a picture of the man himself in his daily life, in his family, in his lecture-room, in his warm discussions with his friends, in his rambles with his students, in his intercourse with farmers and masons and labourers, and in his correspondence with many of the most interesting men of his time.

It was therefore with no little expectation that we received the volume of which the title is placed at the head of this notice. We have read it with interest and pleasure, and yet, it must be frankly confessed, with some measure of disappointment. Mrs. Gordon deserves the thanks of all lovers of science for the filial devotion and affectionate enthusiasm with which she has prepared this memoir of her father. We rise, indeed, from the perusal of the book with a somewhat fuller knowledge of Buckland's career, and with a little more insight into that personality which gave him his charm and his influence. But the information is neither of the kind nor of the amount which might have been looked for from the title of the volume.

Nearly half a century has passed since Buckland was stricken down by the malady which removed him from active life, and after some eight years of sad seclusion carried him to his grave. There can be few alive now who remember him in his prime, and from whom reminiscences of the man could be obtained. Mrs. Gordon appears to have done her best to procure such records from surviving friends, and she has received several of much interest. But it was from his own letters and jottings that most of real importance was to be looked for. The "correspondence," however, which appears on the title-page, forms but an insignificant part of the book. Long extracts are given from his lectures, his addresses and his sermons. Those who want to know more of the man himself would gladly exchange these citations for the brief notes and the longer epistles, in which he continually unbosomed himself and told so graphically what he was doing and thinking about from day to day. That Mrs. Gordon has made such comparatively slight use of such material must mean, we fear, that she has not been able to recover it. In that case we must sympathise with her disappointment. The task, perhaps, has been too long delayed.

In looking over the nature and amount of the work done by Buckland during his busy life, one is astonished at the great extent of subjects which claimed his attention, and in which he laboured and wrote. At one time he is absorbed in the study of changes of topography, whether it be the valleys of the south of England, or the solution of the chalk, or the destruction of the coast by landslips, or the sculpturing of the Highlands and of Wales by glaciers. At other times, or even when he had some of these topographical questions in hand, we find him hard at work upon problems in tectonic geology—British or foreign—the structure of the Alps, the geology of Nice, our south-western coal-fields, or the coast of Dorset. But undoubtedly it was the palæontological side of geology that most fascinated him. And what a mass of observations he accumulated in that department of the science! Every grade of the animal kingdom had an interest for him. He was passionately devoted to living animals, and he made use of his knowledge of them and their ways in interpreting the remains of their remote ancestors imbedded in the geological formations. He would take endless trouble to satisfy himself as to the habits of some living animal, in the hope of thereby throwing light on the history of extinct forms. Witness, for example, his rapid journey to the Pentland Hills in Midlothian, for the purpose of examining the drained bed of a large reservoir, where he expected to find materials for elucidating the history of old lacustrine limestones.

In those days geology had not become a science of detail. There were new fields to be cultivated on every side, and Buckland was the first to enter some of these. His researches in caves opened up a fresh chapter in geological history. And his chivalrous support of Agassiz, in the face of much ridicule, when he announced the former existence of glaciers in Britain, must be recognised by all glacialists as one of the first steps which led to the recognition and cultivation of glacial geology in this country.

There was ever in Buckland's science a strong vein of practical common sense. He was imaginative beyond most of his compeers, and sometimes, perhaps, allowed his imagination too free a rein, but he never lost sight of the fact that geology has a very definite practical side, and may be turned to useful account in many of the affairs of daily life. He was an active farmer, in order that he might try various methods for the improvement of crops. To him we owe the introduction of coprolites, so valuable a source of artificial manures. He never lost an opportunity of preaching the true principles of drainage, and he insisted on the value of geological knowledge in all questions of water-supply. These are familiar enough applications of the science now, but it was largely through Buckland's influence that they were recognised.

Of the man himself as he lived and moved, Mrs. Gordon's volume gives a pleasing though hardly adequate picture. His boundless energy and enthusiasm were infectious, and led many a man and woman captive into the geological fold. His industry enabled him to carry on a busy scientific life, while at the same time he had on hand enough of other work to fill up fully the time of most men. His wide sympathies and large range of knowledge broadened his grasp of his own special science, and led him to see where he could find the most useful collateral information. His eloquence as a speaker and writer commanded the attention of his audiences, and did much to make his subject popular. His unwearied hospitality and his generous large-handedness opened a way for him into the hearts of men, while his overflowing vivacity, his brilliant wit, and his racy talk made him the central figure in any company where he might happen to be. Truly there were giants in the land in those days, and no one of them deserves to be more warmly remembered for all that he did, and all that he was, than William Buckland.

OUR BOOK SHELF.

The Birds of Eastern Pennsylvania and New Jersey. Edited by Witmer Stone. Pp. 185. (Philadelphia: Delaware Valley Ornithological Club, 1894.)

THE Delaware Valley Ornithological Club has only been established about five years, but steps were taken shortly after its organisation to compile a list of the birds observed by the members in the vicinity of Philadelphia. In this volume the important results of the club's ornithological investigations are brought together in a compact form by the committee of three—Messrs. Morris, Rhoads, and Stone—appointed to prepare the work. A list of the birds to be found in the Delaware Valley and along the New Jersey sea-coast has naturally a limited sphere of usefulness, even though it may furnish a work of reference for ornithologists in general. But this volume contains not only an annotated list of the birds of the district to which it refers, and a bibliography of ornithological literature relating to Pennsylvania and New Jersey; it comprises, in addition, outlines of the knowledge of the geographical distribution and migration of birds, thus giving it increased value. These chapters

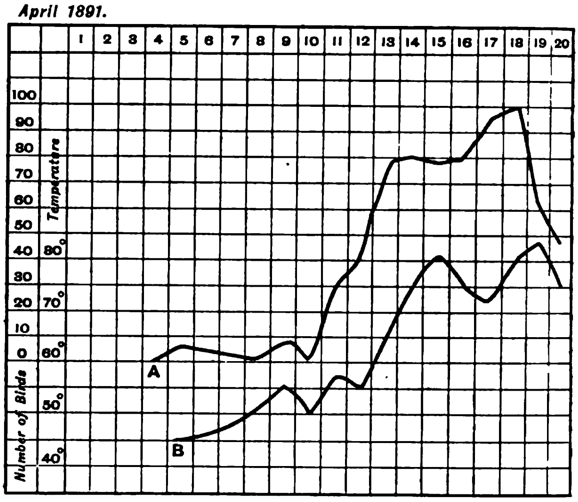

FIG. 1.—A, Migration Curve; B, Temperature Curve.

will lead beginners in the study of birds to understand the importance of simple observations.

The influence of meteorological conditions upon the migration of birds is an important point, and one which requires careful investigation. The records of the club's observers furnish some valuable facts for the study of migratory waves or rushes, and their relation to meteorology. It is pointed out that, during migrations, the flight of birds is not uniform, but is made up of a series of waves or rushes and rests or lulls. The relation of these rushes to temperature is well shown in the accompanying diagram, reproduced from the volume. The curve A represents graphically the fluctuation of the April migration of 1891, based upon observations of the Flicker, Chipping Sparrow, and Brown Thrasher; the curve B shows the temperature variation during the month of observation, based upon the daily maximum temperature. The connection between the two curves is very distinct, and it is especially interesting to observe that the "bird waves" occurred a day or two after a decided increase of temperature.

In conclusion, we think the Delaware Valley Ornithological Club is to be congratulated upon its activity, and Mr. Stone for this admirable addition to the literature on the birds of Eastern Pennsylvania.

Conspectus Floræ Africæ, ou Enumération des Plantes d'Afrique. Par Th. Durand et Hans Schinz. Vol. v. Monocotyledoneæ et Gymnospermeæ. 8vo. Pp. 977. (Bruxelles, 1895.)

IT may, perhaps, be asked why the fifth volume of a work should appear before the fourth and all the preceding ones. Doubtless the authors were influenced thereto by the fact that neither Oliver's "Flora of Tropical Africa," nor Harvey's "Flora Capensis," has reached the groups enumerated in the bulky volume under notice. Certainly this course has the advantage of utility, and will be of great service in the elaboration of the continuation of the works named. As an index to the scattered literature of the subject, the present volume is indeed invaluable. It covers all that may be called African, including the Atlantic islands from Madeira to Tristan d'Acunha, and the islands of the Indian Ocean, from St. Paul and Amsterdam to Mauritius, Madagascar, and Socotra. It is true, the geography of the plants is not worked out all through so fully as Mr. C. B. Clarke has done the Cyperaceæ. For instance, the characteristic grass of Tristan d'Acunha and St. Paul and Amsterdam islands, *Spartina arundinacea*, is only recorded from the former group. In other respects, Mr. Clarke's elaboration of the 800 Cyperaceæ is by far the most complete and thorough part of the volume, though it is blemished by the introduction of a very large number of names of new species without descriptions.

But, leaving all criticism out, this volume will be welcomed alike by horticulturists and botanists; by the former, more especially, because it contains the petaloid monocots, so numerous in South Africa. Synonyms and references to figures in the various illustrated serials add to the usefulness of the enumeration. To give an idea of the extent of this compilation, it may be mentioned that the Liliaceæ include nearly 1100 species, belonging to 67 genera. *Aloe* alone numbers nearly 100 species. The Irideæ are about 700 strong; *Gladiolus* being the largest genus, with 143 species. Orchids also exceed 1000 species, belonging to 74 genera; and 160 species of *Habenaria* are enumerated. Palms are less numerous than might have been expected, considering the comparatively large number in a small group of islands like the Seychelles. Only 63 species are given, which is about a quarter the number inhabiting British India. This is largely due to the genus *Calamus* being represented by only one species in Africa, whereas there are 72 in India.

W. B. H.

Leçons de Chimie. Par H. Gautier et G. Charpy. (Paris: Gauthier-Villars, 1894.)

THE general plan of the second edition of this work does not differ essentially from that of its predecessor. The introductory portion on generalities—dealing with states of aggregation, laws of combination, equivalents and atomic weights, physical and chemical transformation, chemical equilibrium, the velocity of reaction, thermochemistry, &c.—has been recast, and now occupies one-fifth of the volume. In the descriptive portion, which is concerned with inorganic chemistry only, Moissan's work on fluorine, the diamond, and boron has been introduced. It is characteristic of a French text-book that even now it is deemed necessary to print alongside each important atomic equation the corresponding equation based on equivalents. In the same connection it will be somewhat disconcerting to English students to find that "Le poids atomique est égal au poids équivalent pour les éléments suivants: . . . Pour tous les autres éléments, la valeur du poids atomique est double de celle de l'equivalent." In other respects the book is well up to date, and contains much useful information expressed with the clearness and precision for which French text-books are deservedly famed.

J. W. R.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Variation and Specific Stability.

I AM afraid that in my anxiety to compress too long a statement, I did not make the points which I wished to bring forward in the recent discussion at the Royal Society sufficiently clear. I have therefore written out the following summary:—

(1) All organisms vary. That in doing so they obey Quetelet's law was suggested by Mr. Darwin himself more than twenty years ago. He observes (NATURE, September 25, 1873, p 432):—"It is known from the researches of Quetelet . . . that men may be grouped symmetrically about the average with reference to their height. . . . We may presume that this is the usual law of variation in all the parts of every species under ordinary conditions of life."

(2) Prof. George Darwin supplemented this in a following number (October 16, p. 505) with a very lucid account of the principle. In this he says:—"We may assume with some confidence that under normal conditions, the variation of any organ in the same species may be symmetrically grouped about a centre of greatest density."

(3) A well-known illustration is that of a marksman shooting at a target. The distribution of his shots will follow the same law; they will be grouped round a centre of greatest density, which is easily ascertained, as it is the centre of gravity of the circumscribed figure. And on successive trials, if all conditions remain unaltered, the position of the centre will remain the same, though the positions of the shots will be different.

(4) No two individual representatives of a species in nature are exactly alike. All differ in some respect. We may picture the aggregate, however, as grouped with respect to any discriminating character like the shots on the target. Our conception of the species to which they belong is an abstraction which we endeavour to represent in our museums by a specimen which would be placed as near as possible to the centre of greatest density. Such an abstraction we may call the *mean specific form.*

(5) Returning to the case of the target, it is obvious that if some new condition be introduced, such as a wind blowing transversely, every shot will be affected, and the centre of density of the system will be shifted. What is the analogous result when we are dealing with the aggregate of individual organisms representing "a species"?

Natural selection will come into play, to begin with. It may be that some hitherto indifferent variation may be favoured by the new condition. Others will be relatively handicapped, and such a favoured variation will get the upper hand. It is obvious that the result will be to shift the centre of density: the mean specific form will have undergone a corresponding change.

(6) It is probable that so simple a result is not the usual one, and what actually takes place is much more complex.

Mr. Darwin concludes "that organic beings when subjected during several generations to any change whatever in their conditions, tend to vary." ("Variation of Animals and Plants," ii. p. 250.) I infer therefore, and all the facts which have come under my observation confirm it, that a change in the external conditions, otherwise the *environment*, will provoke *some* variation in the organism, which I may call the *stimulated variation.*

(7) It appears to me that from the Lamarckian point of view, the stimulated variation ought to be immediately adaptive. From the Darwinian this is not necessarily the case. It may be either advantageous or, at any rate, indifferent. ("Changed conditions generally induce mere fluctuating variability." Darwin, "Origin," 6th ed. p. 131.) Prof. George Darwin, in the note above cited, traces out the result in the two cases. In the former case, "with continual intercrossing," the new variation will get the upper hand, and the centre of density will be shifted; in the latter it will, by continuous "weeding out," be, after a temporary displacement, eventually restored.

(8) This leads to the consideration of the *stability* of the mean specific form. Some species seem to yield pretty rapidly, though with an appreciable *inertia*, to the influence of changed condi-

tions; others seem almost indefinitely to resist it. Probably, however, even the most intractable cases may eventually be broken down. This stability has been largely used as an adverse argument to organic evolution generally. Prof. Decaisne was much influenced by it, and stoutly maintained not merely the permanent stability of species but even of varieties. His experiments on the seminal reproduction of cultivated pears, which extended necessarily over a long series of years, was, as might be expected, adverse to varietal stability, and left him in a position from which he never extricated himself.

The existence of specific stability is, however, undoubted. Mr. Carruthers devoted his address to Section D of the British Association in 1886 to a useful summary of the ascertained facts on the subject. He laid particular stress on the well-known data, which are illustrated in the Kew Museums, as to the flora of Egypt. This, 4000 years ago, was composed of species which differed apparently in no particular from their present living representatives.

An even more striking illustration is afforded by the history of standards of weight. From Prof. Ridgway's researches it appears that these were originally based on seeds ("Origin of Currency and Weight Standard"). He finds (p. 182) that "the Troy grain is nothing more than the barley-corn." Further, "in 1280 (8 Edward I.) the penny was to weigh 24 grains, which . . . were as much as . . . 32 grains of wheat" (p. 180). The ratio still obtains. "In September, 1887, I placed in the opposite scales of a balance 32 grains of wheat 'dry and taken from the midst of the ear,' and 24 grains of barley taken from ricks of ears grown in the same field at Fen Ditton, near Cambridge, and I thrice repeated the experiment; each time they balanced so evenly that a half-grain weight turned the scale." Further, he found that "practically 4 wheat grains = 3 Troy grains" (p. 182). The same fact of stability can be illustrated from other seeds used as standards of weight. No working naturalist will then be disposed to very much quarrel with the conclusion arrived at by Mr. Carruthers, that "species must be dealt with as fixed quantities."

(9) Notwithstanding this, the counterfact remains that it is doubtful if there is any species the stability of which cannot be broken down by appropriate methods. I, however, prefer to say not that a species is "fixed," but that its mean specific form is appreciably stable under permanently uniform conditions. And this is probably what Mr. Carruthers really meant.

The interesting question then arises, how is this stability brought about?

(10) The principle of stability seems to me scarcely to have received the attention it deserves. Mr. Darwin has, I think, never expressly stated it, though he was evidently well acquainted with it, and has supplied some explanation of its causes.

In dealing with the facts referred to above as to the Egyptian flora, he simply says: "In Egypt, during the last several thousand years, the conditions of life, as far as we know, have remained absolutely uniform." ("Origin," 6th ed. p. 169.) The implication, though he does not actually say so, is that under such circumstances evolution is in abeyance. If it were not, it seems to me that we must admit Nägeli's "innate tendency towards progressive and more perfect development." Mr. Darwin states, however, the correlative principle with greater definiteness. "The influence of changed conditions accumulates, so that no effect is produced on a species until it has been exposed during several generations to continued cultivation or domestication." ("Animals and Plants under Domestication," ii. 261.) I have no doubt that this is true, and I entirely agree with De Vilmorin, cited by Mr. Darwin (*l.c.* p 262) that "the first step is to get the plant to vary in any manner whatever, . . . for *the fixed character of the species* being once broken, the desired variation will sooner or later appear."

More or less close interbreeding will, it is well known, tend to stability. Mr. Darwin tells us: "After a dozen generations of self-fertilisation, it is probable that the new variety would remain constant, even if grown under somewhat different conditions." ("Cross and Self-fertilisation," p. 460.) The same fact is illustrated "by the survival during at least half a century of the same varieties of the common pea and the sweet-pea." (Darwin, *l.c.* p. 39.) Self-fertilisation has the positive advantage that it "assures the production of a large supply of seeds." (Darwin, *l.c.* p. 41.) The price ultimately paid is, however, probably a very heavy one—that of extinction. (*Cf.* Darwin, "Life," iii. 276.)

(11) The case of wheat is peculiarly interesting. It is not worth while pressing the evidence too far. But it may be remarked that wheat has by no means lost its power of variability. Mr. Carruthers remarks:—"The improved varieties of our cereals now under general cultivation have been obtained almost entirely from the selection of individual plants." (*Journ. R. Agric. Soc.* 4th ser., iv. p. 684.) Mr. Darwin ("Animals and Plants," i. 318) quotes the authorities for the statement that the wheat cultivated by the lake-dwellers in Switzerland had very small grains. Still we may admit that for a very long period the average wheat grain has not appreciably varied. This appears to me to prove nothing more than that wheat has got into a stable state, which I should attribute to the average uniformity of the conditions under which it has been cultivated. I shall not press the question of its self-fertilisation, which is generally accepted, but which Darwin (*l.c.* i. 316) thinks not invariable. Somewhere he has stated, though I cannot put my hand on the reference, that the size of the grain is disadvantageous.

If so, this would be unfavourable to its increase. De Candolle ("L'origine des plantes cultivées," p. 370) regards the original source of the wheat-plant as extinct, and suggests that the attractiveness of its grains for birds may have been the cause. At any rate it appears certain that but for cultivation it would now entirely disappear. The conclusion seems to be that mankind has brought it up to a certain standard which was sufficient for its purpose, and has not been compelled to carry it further by unconscious selection.

The case of maize, which has also been quoted, is much less to the point. It is now pretty certain that its origin is to be found in a form still existing in which the grains are only two-rowed. But maize, under existing cultivation, proves to be extremely variable.

(12) It appears to me that an important light is thrown upon what I may be allowed to term the *stability problem* by the remarkable investigation recently presented to the Royal Society by Prof. Weldon. It is one which I am persuaded would have given Mr. Darwin peculiar pleasure.

Prof. Weldon measures very carefully some organ in each individual of a given population. The measurements are plotted out along a base line; the number of individuals in which each measurement occurs are represented proportionately by lines drawn perpendicular to the base line. The summits when connected form a curve, which is termed a *frequency curve*. For a discussion of the general principle and of the interpretation of such curves reference must be made to the able investigation for which biologists are indebted to Prof. Karl Pearson (*Phil. Trans.* 1894, A., pp. 71–110).

Prof. Karl Pearson (p. 72) terms "a frequency curve which for practical purposes can be represented by the error curve," a normal curve. Such a normal curve, I apprehend, is only another way of representing the result of Quetelet's law, which, as I stated above, there was reason to suppose was the ordinary law of variation. For he adds: "When a series of measurements gives rise to a normal curve, we may probably assume something like a stable condition; there is production and destruction impartially round the mean.

By applying the method to a crab from Plymouth Sound, Prof. Weldon has been able to throw light, it seems to me for the first time, on a most important factor in the stability problem.

"About 7000 females . . . were chosen (at random, except as regards their size), and two dimensions were measured in each. The results were then compared with those of the corresponding measurements, made upon a sample of 1000 adult females from the same locality."

The result was to show that "selective destruction" takes place in early life amongst individuals, which deviate from the "mean specific form." Prof. Weldon arrives at the conclusion "that the position of minimum destruction should be sensibly coincident with the mean of the whole system," is a condition which "may be expected to hold for a large number of species, which are sensibly in equilibrium with their present surroundings, so that their mean character is sensibly the best." The actual statistical demonstration of this fact, in my opinion, deserves to rank amongst the most remarkable achievements in connection with the theory of evolution.

(13) When the frequency-curve is abnormal, Prof. Karl Pearson infers "the pressure at a given time of some particular form of natural selection." The mathematician may in this case be able

to render assistance to the biologist of supreme importance. "The amount and direction of the abnormality will be indicated if this [abnormal] frequency-curve can be split up into normal curves." Analysis would in this way give us information which we could perhaps not even guess at.

I agree with Prof. Karl Pearson that "resolution into two" will be sufficient. The stress of natural selection at any moment must always be between the best and the next best.

In tolerably simple cases I have no doubt that the result of Prof. Karl Pearson's labours will be to throw great light on the matter. In more complicated ones we must look for some disappointment in view of "the great variety of solutions which may be suggested" (p. 106). And the tentative discovery of "component normal curves" seems likely to be fallacious (p. 90).

(14) I think it is important to insist that the importance of Prof. Weldon's present results has reference to the stability problem. He is fully aware of this fact when he says that "they cannot be expected to hold in cases of rapid change such as those induced artificially by selection under domestication, or naturally by rapid migration or other phenomena resulting in a rapid change of environment." These will lead to abnormal frequency curves.

(15) A few remaining points in Prof. Weldon's paper deserve some remarks.

I entirely agree with him in minimising the value of "sports" in evolution. As against Nägeli and his followers, I see no ground for believing in any innate progressive tendency in organisms. When the organism is in stable relation with its environment it will continue so indefinitely. That is the conclusion I deduce from the flora of Egypt, and other facts which have been cited of the same kind. Prof. Weldon seems to me to have supplied this position with a most important proof by establishing the "selective destruction" of variations aberrant from the mean specific form. When the environment varies, stability is destroyed; but it will be ultimately re-established, though with a different centre, by the operation of natural selection. The result is that the organism has undergone some permanent degree of change. As I conceive the process, it is one of continuous adjustment of "slight" variations on one side and the other. But it is important to keep in view that variation in the environment stimulates the variation in the organism which supplies the ultimate material for adjustment. That the amount of the adjustment at any moment is slight is not incompatible with its amounting to almost anything we like in the aggregate, if sufficient time be allowed. We might as well deny that a curve can be built up from its infinitesimal elements.

The value in this respect of sports may be easily overrated. It appears to me that generally, so to speak, they attempt too much and overshoot the mark. The improbability of a casual sport being exactly what is wanted to bring the organism into an advantageous relation to the environment at any particular juncture seems to me very great. That such a thing may occur is not denied, but it can hardly be more than a "fluke."

(16) This is confirmed by the fact that in the vegetable kingdom sports are rare, and they seem to have little power of holding their own in competition. I instanced the cases of the occurrence of copper-coloured and laciniate foliage in many trees, as well as the occurrence of varieties with weeping and fastigiate habit. It is well known that to some extent these are perpetuated by seed. But the existence of such forms would undoubtedly be transient if it were not for their perpetuation as curiosities under cultivation.

(17) In museums it is usual to attempt the representation of the mean specific form. The association of strikingly aberrant specimens is interesting and often suggestive. But I do not see that they illustrate more than the possibilities of variation and the fact that it may be discontinuous.

(18) I placed upon the table plants of the feral type and of a recent cultivated form of *Cineraria cruenta* from the Canaries. The difference in habit and in the form and colour of the flowers was enormous. This has undoubtedly been brought about by human selection. As far as is known it has been accomplished by the gradual accumulation of small variations. The horticulturist has not troubled himself about the foliage, which, though more luxuriant, has remained practically unchanged. But it must not be assumed that it is unchangeable. In the case of the Chinese primrose, the feral form from north-west China, for which we are indebted to Dr. Henry, has palmatifid leaves rounded in outline; but the distal lobes are occasionally lengthened out. The horticulturist, as a matter of fancy, working on this, has now split the type into two races, one of which has palmatifid and the other pinnatifid leaves. Many botanists would, undoubtedly, if they did not know their history, assign to such a different specific rank.

(19) I am not sure that I quite understand Prof. Weldon when he says that "the statistical method is the only one at present obvious by which [the Darwinian] hypothesis can be experimentally checked." In the first place, I should myself hardly call it experimental at all. In the next place, though I think it will throw important light on the stability problem, in the important cases where evolution is actually taking place, the mathematical analysis appears to me to be beset with very great difficulties. We must not, therefore, expect too much from it.

(20) On the other hand, museums, as at present organised, do not help very much the study of evolution. In the case of plants, I doubt if herbaria will ever be able to present material in a sufficiently compendious or complete form to be of much use. The study, however, of extensive series of a few species of insects ranging over the whole of a large geographical area, such as Mr. Elwes has brought together in the case of butterflies, must, it seems to me, afford most important material for future discussion. W. T. THISELTON-DYER.

Royal Gardens, Kew, March 10.

Do Plants Assimilate Argon?

IT is a well-known fact that some plants are able to assimilate nitrogen from the atmosphere and form compounds. Now, as argon cannot be induced—at least up to now—by any known process of inorganic chemistry or physical science to enter into a combination with one or more of the known elements, it occurred to me whether that peculiar power which produced the cell is not able to form combinations with argon. The experiment to grow suitable plants in an atmosphere of pure argon, or argon mixed with pure oxygen, on a bed of pure sand, &c., would easily settle the question.

If this experiment has not yet been made, perhaps you will find space in your paper for the above few lines.

Essen-Ruhr, March 6. E. BLASS.

THE first thing is obviously to find whether there is any argon in a nitrogenous vegetable; and experiments are now nearly completed in my laboratory to see if nitrogen obtained from peas contains any argon. Similar experiments are being made with nitrogen from mice. In a few days I shall know the results. But this is, of course, on the assumption that the process which liberates nitrogen also liberates argon; and it is by no means certain. It should be remembered that argon and nitrogen have absolutely no similarity, and that their occurrence together in air is a pure accident, due to the inertness of both.

The Measurement of Pressures in Guns.

IN a paper "On Methods that have been adopted for Measuring Pressures in the Bores of Guns" (Report of the British Association, 1894), Captain Sir A. Noble has remarked that it seems to him "that there is no method so satisfactory, despite its attendant labour, as that of *making the projectile write its own story*" (p. 540). That might be sufficient for *smooth* bore guns, where there was little or no friction in the bore, but it is quite unsatisfactory when applied to *rifled* guns, and especially B.L. guns.

The two methods of experimenting now in use employ the *pressure gauge* and the *chronograph*, both of which we will, for this occasion, suppose perfectly accurate. The pressure gauge measures directly the pressure of the powder gas P, the quantity wanted. The chronograph will measure P, the same pressure of the powder gas, *minus* F, the resistance offered to the motion of the shot by the rifling, the friction of the driving-band, &c., $= P - F$, where F is often very great. The difficulty is to see how these two different processes can confirm one another, as F is unknown and of great importance.

The only satisfactory method of determining the maximum pressure of powder gas at any point in the bore of a *rifled* gun is to measure it *directly*, by the pressure gauge, which requires many precautions to be taken, or by some other more simple method. F. BASHFORTH.

Horncastle, March 9.

The Velocity of the Argentine Earthquake Pulsations of October 27, 1894.

IN several recent notes in NATURE (pp. 232, 371, 393), attention has been drawn to the great Argentine earthquake of last October 27, and to the record of its pulsations in Europe. In one of these (p. 371) a rough estimate is given of the velocity, but a more detailed one seems desirable on account of the great distance traversed by the pulsations.

According to M. Noguès (*Comptes rendus*, vol. cxx. pp. 167–170), the epicentral tract includes Rioja, San Juan and Mendoza. There is thus some uncertainty as to the exact position of the spot from which the pulsations started. In the following estimate I have supposed it to coincide with San Juan.

San Juan is about 312 km. from Santiago, and 11,600 km. from Rome, the difference being 11,288 km. The earthquake was registered by a seismograph at Santiago at 8h. 50m. 26s. p.m., Greenwich mean time. The slight preliminary pulsations were recorded by the great seismometrograph at Rome at 9h. 7m. 35s., the first maximum at 9h. 49m. 50s., and the principal maximum at 9h. 55m. 40s. Assuming that the first maximum (or beginning of the larger pulsations) corresponds to the movement which started the seismograph at Santiago, it follows that the distance of 11,288 km. was traversed by the pulsations with an average velocity of 3·17 km. per second.

It should be remarked that this estimate agrees very closely with those obtained for the same phase of the movement in the cases of the Greek earthquake of April 27, and the Constantinople earthquake of July 10, 1894 (namely, 3·21 and 3·20 km. per sec. respectively).

For the first slight movements recorded at Rome, Charkow and Nicolaiew, we must admit either that the pulsations producing them started some time before the great earthquake, or else that they travelled with a far higher velocity. If they left San Juan simultaneously with the larger pulsations (*i.e.* at 8h. 48m. 48s.), their average velocity must have been 10·38 km. per second. The horizontal pendulums at Charkow and Nicolaiew also recorded these early movements, beginning at 9h. 8m. 36s. and 9h. 12m. 6s. respectively; soon after which the curves more or less completely disappeared. San Juan is about 13,625 km. from Charkow and 13,240 km. from Nicolaiew, the average velocities to these places being therefore 11·47 and 9·47 km. per second. The latter obviously corresponds to a later phase of the movement.

Whether the slight preliminary pulsations start before, or at the moment of, the earthquake, is a question of the greatest practical importance from the point of view of earthquake-warnings. To answer it, one of the Italian seismometrographs or a horizontal or bifilar pendulum should be placed beside a seismograph in the immediate neighbourhood of the centre of disturbance. C. DAVISON.

Birmingham, March 6.

The Society of Spelæology.

THE attention of your readers has already been called to the formation of this Society in Paris (NATURE, January 3), the promotion of which is due to the action and enthusiasm of M. E. A. Martel, the author of the beautifully-illustrated work "Les Abîmes," reviewed by Prof. Bonney in your pages of the 28th ult. This book describes and illustrates a number of extraordinary and often hazardous subterranean explorations in the underground caves and watercourses of the limestone districts of France, Belgium, Austria, and Greece. The Society is intended to carry on the work thus initiated by M. Martel and his devoted co-workers in a more effective manner, and over a wider area than has been possible by private enterprise. The formation of the Society, M. Martel writes me, is now an accomplished fact. About 130 gentlemen of all nationalities, some of whom bear well-known names in the ranks of science, have signified their adhesion. A provisional code of rules has been printed and adopted, and a meeting has already taken place, under the presidency of the president-elect, M. F. Deloncle, Deputy for the Basses-Alpes.

The first article of the rules states the object of the Society as follows:—"The Society of Spelæology is instituted in order to ensure the exploration—to facilitate the general study—to cooperate in the regulation or ultilisation—of subterranean cavities of all sorts, known or unknown, whether natural or artificial; to encourage and aid with funds investigations relating thereto; in a word to popularise and develop in a way, at once practical and theoretical, utilitarian and scientific, researches of all kinds in the interior of the earth." The subscription for ordinary members is fifteen francs per annum. It is intended to publish a quarterly bulletin; to a copy of which each member will be entitled.

In order to fully carry out the objects of the Society, the programme of which is a comprehensive one, more members are required, and I shall be glad to furnish any of your readers who may wish to join the society with the proposal form or *Bulletin d'Adhésion*, or they may be obtained from M. Martel, General Secretary, 8 Rue Ménars, Paris.

M. Martel, I may say, is desirous of extending his investigations to the British Isles, if sufficient inducement be offered in the exploration of some large cave, as yet unworked or imperfectly known, and where his apparatus of rope ladders, collapsible boats, &c., would be useful aids. Information on this head will be thankfully received by me. MARK STIRRUP.

Bowdon, near Manchester, March 6.

Contraction of Trees caused by Cold.

THE splitting of forest trees by frost is often ascribed to the same cause which bursts a pipe charged with water when the temperature falls below 32° F., namely, the expansion of the water on turning into ice. Botanists know that this is not so, but the splitting is owing to a contraction of the wood by frost, similar, but in a less degree, to what happens when the wood is dried. With the thaw the trees expand to their original dimensions. Evidence of such contractions and expansions is furnished by the measurements herewith.

For some years past, I have regularly taken the girths of a number of forest trees during summer, in order to note the amount of growth. To do this accurately I have to use a steel tape, and of course to girth the trees at exactly the same place. My experience, thus acquired in measuring to a nicety, is a sufficient reason for confidence that the following figures are substantially correct.

Girth of trees in October 1894, when done growing and before the frost.		Girths, February 8, 1895, 9 a.m. Temp. 3° F.	Girths, March 2, 1895, 3 p.m. Temp. 39° F.	Amount of contraction with frost.

Bradford, March 4. J. CLAYTON.

The Barrenness of Precambrian Rocks.

REFERRING to the paragraph in NATURE (February 28, p. 423), on the sudden appearance of a rich fauna in the Lower Cambrian rocks, I should like to make a suggestion for the consideration of geologists. May not the extreme poverty of organic remains in Precambrian (Archæan) strata be largely due to a scarcity of carbonate of lime in the water of the Precambrian seas? The Uriconian and Longmyndian rocks of Shropshire, which, at the very least, must include five miles of sediment, comprise hardly a scrap of limestone. The same remark will apply to the Precambrian strata of Charnwood, South Wales, the mainland of North Wales, and the great Torridonian group of Scotland. The Pebidian rocks of Anglesey contain bands of limestone, it is true, but it is highly probable that they are of chemical origin, and not derived from oceanic waters. There are, of course, plenty of limestones in the older Archæan rocks of North America, and a few of them in the Lower Archæans of

Britain; but the proof of their marine origin remains to be written. They contain no undisputed organic remains. The rocks in which they are intercalated are not proved to be altered sedimentaries. There were numerous animals living in the Salopian area in the Longmyndian epoch, for their trails are quite abundant in some of the slaty seams; but, if there were no carbonate of lime in the sea, there could, of course, be little material to provide shells for its inhabitants. Numerous creatures of many types might have been evolved, whose soft tissue would leave no traces in the rocks. In succeeding ages, as the forces of denudation cleared off the newer Archæan, and cut down into partially decomposed crystallines, abundance of calcic carbonate would be carried down into the sea.

C. CALLAWAY.

Wellington, Shropshire, March 1.

The Artificial Spectrum Top.

IN your issue of March 7, we notice a letter from Dr. Dawson Turner, in which he says he has had a "Benham's Spectrum Top" made on glass, by an optician, for the lantern, and recommending others to do the same.

Will you allow us to state that we have sold all rights in this copyright top to Messrs. Pears, reserving to ourselves only the sole right of making them as lantern slides, in which form we have been supplying them for some time.

The tops can be obtained from Messrs. Pears, and the lantern slides from us; any one else supplying either will, of course, be infringing the copyright.

NEWTON AND CO.

RESEARCH IN EDUCATION.[1]

NO branch of *research work* at the present day offers greater opportunities, whilst none is more urgently in need of *original* workers, than that which lies open to the teacher in school or college; and it is surprising how small an amount of sound work is accomplished in it—how little it is realised that there is a science of education to be developed by persistent study, application and research. An analytical habit of mind seems to be the very last qualification sought for in a teacher—such is the influence acquired by clerical instructors in the course of centuries by the universal extension of methods of teaching originated in the monkish cell and cloisters, and wielded with but slightly diminished force, even to-day, by their lineal descendants, whose voices still preponderate in educational affairs. Conservative and sheep-like—as we cannot fail to be if all our early life be spent in an atmosphere of dogmatism—the slowness with which we evolve and apply new ideas is phenomenal. It cannot be that sterility is the outcome of excessive labour in days gone by, and consequent exhaustion of the soil; still less, that it is owing to absence of demand; for it is only too clear that the entire change in the conditions of life witnessed within the century renders it necessary that our children should be so educated that they may successfully grapple with the new conditions, and it stands to reason that the preparation which sufficed in the case of their forefathers must be insufficient in theirs. This is now being universally recognised, but all too slowly and imperfectly. Thus the academic oration first on my list, delivered only in September last, at Freiburg, by the Professor of Anatomy, is a vigorous protest against the practice prevailing in the German "Humanistic" Gymnasia of devoting an enormous proportion of the school-time to classical studies, and the consequent neglect of drawing, natural science, geography and modern languages, as well as of gymnastic exercises, which is very strange, as he points out, when it is remembered that the meaning of *gymnasium* is a place for athletic pursuits. He especially complains of the way in which exercises in classical style are insisted on and monopolise attention, and strenuously advocates their banishment from the three lowest classes at least. He refers with feeling to the pressure which is brought to bear in school and at home on the child to whom such work does not appeal, and the unhappy state of house and family on "style-days," remarking that every one who, like himself, has had this experience in his own person and that of his children, will sympathise with this view. He tells us that his own bitter experience of thirty-five years ago still follows him in his dreams, and that he can never forget the encouraging words hurled at him by the master of the "Prima" of the Stuttgart Gymnasium when he had done a bad Latin exercise—"You never in your life will come to any good, as sure as my name is Schmid." Is not this too often the attitude of our schoolmasters, and is it not too often forgotten that the human mind, fortunately, will not in all cases respond to one uniform system of treatment? Surely the time must soon come when it will be the main duty of headmaster and headmistress to study their scholars, and assort them in accordance with their aptitudes; when no headmaster will set down a boy as of inferior intellect merely because he does not get on well on the classical side, and cannot therefore be made use of with effect as the winner of a scholarship at the university—a course which some of our most noted headmasters appear too often to countenance if report belie them not. Fortunately we are not here so much the victims of educational overpressure as is Germany under the terrible influence of its military system, although there is enough to complain of, especially in the case of girls' schools, owing to the improperly large number of subjects included in the time-table; moreover, examinations, such as the London University Matriculation, are exercising a most insidious effect: and now that County Councils all over the country are granting scholarships on the results of examinations, it behoves us to be much on our guard, and to take steps to secure that all such examinations are so conducted that reasonably well-taught and reasonably intelligent scholars can be submitted to them without any interference with the normal school course. Prof. Wiedersheim, referring to the very one-sided training given in the Gymnasia to the future jurist, theologian and philologist, calls attention to the importance to such students of some knowledge of natural science in the following passage, which undoubtedly deserves our attention, as we suffer in like manner: "Kein Gebildeter vermag sich heutzutage dem Einflusse, welchen die Naturwissenschaften auf das Geistesleben aller Culturnationen gewonnen haben, mehr zu entziehen. Die ganze moderne Weltansschauung, unser Leben und Denken, die Forschung auf allen Gebieten—ich erinnere nur an das auch in der vergleichenden Linguistik zur Geltung kommende genetische und causale Element—stehen unter der Signatur der inductiven Forschung. Mit diesem Umschwung hat auch das humanistische Gymnasium zu rechnen, sollen nicht Juristen, Philologen und Theologen in ihrem ganzen Bildungsgang einen Fehler aufweisen, der oft nicht mehr gut zu machen ist." But this is nowhere properly recognised. And yet Charles Kingsley long ago dreamt of a day when every candidate for ordination should be required to have passed creditably in at least one branch of physical science—*if only to teach him the method of sound scientific thought.* Dr. Percival

Matthews, and the Editor. (New York and London: Macmillan and Co.)

has urged in Convocation at Oxford that the elements of natural science should take their place in Responsions—side by side with the elements of mathematics, and equally obligatory. The late Master of Balliol, I believe, also recognised the importance of such a change; but the reformer who will carry it into effect is not yet in evidence, and perhaps his services will not be required, as the schools must soon do that which the universities ought long ere this to have had the foresight to enforce. We are, in fact, only beginning to escape from the bonds of tradition, and it cannot be denied that our release is being gradually effected—not through any action taken by our ancient universities, but rather in spite of them—mainly through the persistent efforts of a small but untiring and resolute body of outsiders whose position has yet to be made clear to the public, most of whom undoubtedly regard the teaching of experimental science much in the way that the introduction of pianos into Board Schools was regarded a few years ago by a majority of Londoners—as something very nice for those who can afford it, but as in no sense a necessary element in the education of the masses. We, on the contrary, contend that the human mind cannot, as a rule, be completely educated by exclusive attention to literary and mathematical studies, and that lessons in experimental science must form an integral portion of the entire school course, because such lessons alone afford the means of fully developing a side of the intelligence which perhaps more than any other is of importance in life—the faculty of observing and of reasoning correctly from observation: with Kingsley, we desire that the method of sound scientific thought should be taught universally in schools, to the exclusion of dogmatism and eyelessness; and we desire to inculcate habits of self-helpfulness and handiness. The motto from Montaigne adopted by Prof. Wiedersheim fully expresses the modern view of education: "Es ist nicht ein Geist und nicht ein Körper den wir erziehen sollen, sondern ein Mensch, und wir dürfen ihn nicht theilen." Hitherto more often than not, we have cut him up into pieces, and thrown the most important aside. It is only in Germany that a public address on such a theme can be delivered in celebration of the birthday of a Royal Highness—here we must fall back on the British Association; but this body has strangely wasted the unrivalled opportunities which its organisation affords of appealing to the public on such matters.

Fortunately, help seems to be at hand from a quarter from which it was least expected, as the schoolmasters are at last awakening to the necessity of reform, and have themselves taken action which, if persevered in, must be attended with most important consequences. At the recent meeting of the "Incorporated Association of Head Masters," which now numbers nearly 300 members, on the motion of Mr. C. Stuart, of St. Dunstan's College, Catford, London, S.E., it was resolved—

(*a*) "That the Association is of opinion that Examining Bodies should encourage a more rational method of teaching science, by framing the syllabuses in such a manner that the practical work required may be strictly illustrative of the theoretical instruction given."

(*b*) "That it be referred to the General Committee to appoint a small Sub-Committee, so that a report may be presented to the next summer general meeting containing detailed suggestions, which it is proposed to make to Examining Bodies concerning examinations in science."

As I ventured to point out, when speaking on these resolutions, the consequences of their adoption will probably be far greater than those who have accepted them are likely to have contemplated. Thoughtful examiners have long been waiting for a sign: no one has been more dissatisfied with their examinations than they themselves have been, but it has been impossible for them to examine much in advance of the teaching, as it would obviously have been most unfair to candidates to make them victims of a system for which they are in no way answerable; and at most it has been possible to gradually give a practical turn to questions in subjects which can only be taught properly by means of practical lessons. The gage thrown down by the headmasters will, therefore, certainly be uplifted forthwith by all examining bodies whose work is not done in a purely perfunctory spirit, and the schools will find that of their own accord and most properly they have brought about a complete revolution in their own methods of teaching; for if they ask for proper examinations, they necessarily must be anxious to see corresponding proper methods of teaching adopted in their schools, and will provide for their introduction. Nothing could be more gratifying to those among us, who, during years past, have been pointing out the necessity of introducing radical changes and improvements.

A serious responsibility will now be cast on teachers, and it is clear that if workers are forthcoming with minds imbued with the proper spirit of inquiry, there will be ample opportunity of gaining distinction in the field of educational research. There is clearly much leeway to be made up, for although we are all agreed that every branch of natural science must be taught practically, we are, unfortunately, far from always practising what we preach—the system of mere lesson learning not only prevails far too widely and extensively, but is far too frequently regarded with approval as all-sufficient. The practical and theoretical work are seldom, if ever, made sufficiently interdependent—in fact, this is the blot on which the headmasters have laid their finger. Even in my own subject, chemistry, which is generally supposed to be in a stronger position than most others, as it has been taught practically from a considerably earlier date, much misconception prevails, and we are credited with having advanced far more than we deserve. Liebig, the founder of the laboratory method of teaching, appears to have taught *chemistry*—we are told that when Hofmann became a student under him, although a beginner, he was set to work at research; and we know that Liebig gave all his students problems to solve. But the march of progress and, especially, the press of numbers have long since led to the introduction of the anti-research method which some of us irreverently term test-tubing. Such and such *is* the case—do so and so, and *if* you do so and so, this and that *will* happen, are instructions so often dinned into beginners' ears, that they become part of their very being, and they in consequence are ever afterwards unable to give a straightforward account of what *they* have done, and insist, instead, on telling you, the teacher, what to do and what will, not what does, happen. Nothing is more rare in a chemistry examination paper than a straightforward answer, not in terms of if and will, showing that the writer is describing from personal knowledge something that *has been* done. The true object of experimenting is thus lost sight of as the habit grows of requiring to know in advance what will be the outcome of any particular experiment: the spirit of curiosity is rarely awakened. At the same time the worst possible literary style is encouraged, a real opportunity of developing a good one being most perversely sacrificed. Analytical tables were originally introduced with the laudable object of presenting knowledge to the student in a systematic form, but gradually we have allowed them to pass from the position of good servants to that of bad master—mainly because they offer so very convenient a method of keeping students occupied with a minimum of attention and labour on the part of the teacher and at a minimum cost, as a few test-tubes and weak solutions form almost the only stock in trade. Quantitative work is also done in an almost equally perfunctory way, as a rule, with the object of qualifying the student to do technical analyses, and the importance of measurements in establishing first principles is never taught practically, but is merely talked about: the result is that only the few who study the subject professionally, really grasp the meaning of the fundamental quantitative conceptions of our science. It is not surprising that under such a system, being helped over every stile, and having no training in research methods, our students are so very rarely properly educated. And altogether false ideas have arisen also as regards the value of true research work, this having been allowed in far too many cases to degenerate into mere preparation-making, or mere measurement work. There are many among us who have recognised these shortcomings in our method, but tradition exerts its all-powerful influence, and little short of a revolution is required to reintroduce a truly scientific procedure into our schools and examinations—to lead teachers to recognise that the only proper method is to make students researchers from the very outset. These remarks are but prompted by the desire to acknowledge that if I throw stones, I am fully aware that I dwell in a glass house; and especially to make it clear what is the point of view from which I regard the problem before the teacher of any branch of natural science.

The teaching of physics practically is of quite recent introduction. When I was a student at the Royal School of Mines, there were only lectures on physics; and when, about fourteen years ago, my colleague Prof. Ayrton and I visited all the chief continental schools, we found the practical courses in a very embryonic state. Now, although we have nowhere a laboratory which will compare in size or completeness of fittings with the palace erected at Zürich, practical physics is taught in all science schools and colleges, and the London University requires even candidates at the Intermediate Science and Preliminary Scientific (M.B.) examinations to pass a practical test. Many of the courses are very complete. I shall not easily forget the pleasure which I experienced on the occasion of a recent visit to Prof. Quincke's laboratory at Heidelberg from seeing there the marvellously simple, but yet exact, apparatus used in the practical course; the insight into the inner meanings of things afforded by his arrangements struck me as most perfect, and led me to wish that it were possible to teach my own subject so as to give the course an equally high educational value. There are also nowadays many admirable books from which the student may gather instructions how to make experiments in the various branches of physics—there can be no doubt, in fact, that the practical text-books in this subject are generally of a very high quality. But I venture to think that they need modification in some not unimportant particulars. Whilst in advance of the practical books at the disposal of the chemist, inasmuch as they stand in direct relation to the instruction in theory, being intended, as a rule, as Prof. Nichols happily states in the introduction to his first volume—to illustrate and therefore impress more thoroughly on the mind the principles and laws which have previously been taught by text-books or lectures, yet for this very reason the attitude in which they place the student is a wrong one. A "law" is dogmatically stated, and the student is told how to verify it experimentally, so that the young worker, instead of being led to *inquire*, is perpetually told in advance what are the facts, and is instructed to repeat the experiments merely in order to *prove* certain things. Consequently, in physics as in chemistry, students are far too little encouraged to find out things and to help themselves—instead of becoming imbued from the outset with the spirit of inquiry, they are led to expect and require assistance at every step. While galvanometer needles wag, they calmly put their hands into their pockets, and it becomes very difficult to induce them ever to adopt any other mental attitude. Whilst therefore our teaching is enormously improved by bringing students into personal contact with the facts to an extent altogether undreamt of even in my student days, by the very wealth of appliances now at their disposal, they are fast becoming spoilt—perfect sybarites, and the self-helpfulness engendered by the rude and scanty apparatus of days gone by is strangely infrequent. The system apparently fails to engender or develop originality and powers of observation, however much it may tend to train even well-informed and exact workers; but I imagine that little more than a change in the form of the instruction is required, in order to make it impossible to say of any one, "that he knows *about* all sorts of things, but he can't *do* them," the only text, it seems to me, worth preaching from at present. The principle it embodies is the one of all others upon which the whole practice of education must be built up, whatever the subjects taught; but it is undoubtedly one which has not been kept persistently under notice, as it should have been by teachers generally.

The habit of mind complained of, so characteristic of all but a few gifted individuals among our students, is probably largely engendered by the training they have received during the early years at school; and it is incumbent on all teachers working in the field of educational research to do their utmost to develop methods which will counteract the evil effects of mere lesson learning and desk work, as these cannot be altogether dispensed with.

As illustrating—how not to teach elementary science, the "Manual" first on my list must be assigned to a high place; no doubt the intention is good, the information may be interesting and useful in its way, although often very bald if not inaccurate, but such a book has no right to figure as a "Manual of elementary science." It comprises instructions for object lessons, on every possible topic, to children in the six standards of elementary schools, in the form of very short chapters either of "special information for the teacher" or "introductory specimen lessons," and of "notes of lessons" in which, in parallel columns, the kind of question to be asked is set out under "method," and the information to be imparted under "matter." As in all books of this class, far too much is attempted. In the hands of a really capable teacher—who would not need such a book, however,—object lessons may be made of the highest value, but even in such hands the tendency always is mainly to impart information; the kind of lessons that would be given by the uninstructed teacher gaining inspiration from Mr. Major's manual, is easier imagined than described, and their educational effect could not fail to be harmful. We are better without such "science," and had better stick to the plain bread and butter fare of "prescientific" days, if we cannot teach in such a way as to inculcate the practice of scientific method; in fact, we do not want "science" teaching of any kind introduced into elementary or, indeed, any schools unless it take the form of work done by the children themselves: in no other way can the end we have in view—that of training them to do, not merely to know—be achieved, and any other kind of teaching must be a pretence and but an encouragement of priggishness.

As regards the course of the future, there is no doubt that much may be done in very early days to lead children to take note of everything about them, to describe what they see, and to collect and describe common materials of every kind. Some slight preparation for the study of botany may also be laid at this stage. But the science lessons proper begin when the children know enough arithmetic to measure and weigh. All who have studied the problem practically are probably agreed that simple measurement lessons must form the foundation, and there cannot be a doubt that it is both desirable and possible to largely incorporate these with the arithmetic lessons—to teach parts of arithmetic and some geometry practically, in fact. Gordon's "Elementary Course of Physical Science" is probably the type of book which will be used with advantage at this stage, judging from the success the course has met with in Board Schools commencing with the fourth standard.

But the pioneer worker in this field is Prof. Worthington. His admirable little book, "An Elementary Course of Practical Physics," published in 1881, well known to all teachers of physics in schools, was expanded in 1886 into a larger work, "A First Course of Physical Laboratory Practice." These books have been of the very greatest service, and have probably rescued physics from being made a cram subject in schools; but they are scarcely simple or comprehensive enough for such young workers as I am contemplating. As they are intended to be used in connection with lectures, the motive for each experiment is rarely explained at sufficient length, and unfortunately they have the fault common to all such books, to which I have referred above, that the student rarely approaches the experiment in the attitude of the would-be discoverer.

Mr. Earl's book, although it deals only with measurements of length, mass, and time, is of greater length than Prof. Worthington's, but it does not need lectures to supplement it. It has a short but admirable preface, showing that the author has grasped the nature of the problem to be solved, but it is one thing to do this and another to succeed in solving it; and here I think he has been less successful. The style is far too didactic—the descriptions are far too elaborate—the aim is too high, and far too much is told, not enough left to be found out: to use a homely phrase, which I trust will not be misunderstood, far too much fuss is made about the work. Such work should be done by young children; it must not be postponed until the evil effects of desk work have warped the scholar's mind, and natural curiosity begins to die out. But the book is far above such students. What, for instance, is the value of an introduction telling us what science is, and why we learn it? If taught to work, children will very soon insensibly learn to appreciate what they are doing, and nothing is gained by pointing out to them, for example, that "each individual stands a centre for himself of all things, knowing that around him are centres of endless variety, &c." Platitudes such as these are out of place in an elementary text-book, and they are beyond children of nine to twelve years of age, by whom simple measurement work will ere long be done in schools generally. In the next chapter, in like manner, we find at the outset a somewhat elaborate disquisition on the meaning of the words standard and quantity, and a description of how measurements of length are made, and then follow directions for a series of exercises: children cannot grasp such disquisitions, and are wearied by them, but most of them will use a foot or centimetre rule with great pleasure. This criticism may be applied to the book generally—the introductory instructions are too frequently high-flown, and too many refinements are introduced into them and into the exercises. The book, in fact, contains material enough both for a junior and a senior course, and would be more generally available if the matter were thus rearranged. But whilst objecting to it on the score of over-elaboration and absence of that simplicity of statement which is indispensable in a book to be used by young beginners, taken as a whole, and regarded from what I conceive to be the author's point of view, it is a contribution to educational literature of great value. The short preface alone is a manifesto of singular importance, coming as it does from a teacher in a public school of high standing. We find in it the remarkable and, I believe, novel expression—the "scientific sides" of Public Schools, one, it may be hoped, that will soon take the place of "modern side," to which so great a stigma is attached through the ill-advised action of masters having sympathy only with classical training—action which has led to the modern side being often characterised as the refuge for the intellectually destitute; if the modern side once become the seat of training in scientific method, a fair share of the intellect of the school being allowed to it, there cannot be a doubt that it will soon reap payment "by results" sufficient to secure to it an honourable revenge. To return to the preface, we read that care has been taken to make the course logically progressive, the end in view being to train boys to observe accurately, to reason rightly, and to front nature with an open and inquiring mind. That it must be admitted more generally than is customary that the retention of facts should be subordinate in scientific education to a sound comprehension of them, a mind which has been trained to observe and compare accurately being more likely to acquit itself well in the world. That the right way of learning is chiefly to be cultivated, the matter being obviously less important than the method in learning science, and a logical and inquiring habit of mind being more valuable than the memory of facts and laws, as it is better equipment for future research and knowledge. It is urged that the course should afford some training in correctness of expression and accuracy of language, no insignificant part of scientific education, although this is seldom recognised. Lastly reference is made to the lack of continuity in work often prominent as a defect, especially in the modern sides of schools, and to the fact that much of the average "capacity of learning" is never utilised, owing to frequent change both of subject and matter. The book may serve in some degree, the author suggests, to bridge over with safety the distance between the laboratory and other class-rooms, by acting as a Practical Arithmetic and, to some extent, as a Practical Grammar. Trite as some of these remarks may appear to be, those who are aware of the state of affairs in schools will know that, tested by the standards which generally prevail, they are the rankest heresy, but none the less heresy that must ere long revolutionise existing beliefs and practices. In fine, I am inclined to regard Mr. Earl's book as the account of an important research some results of which he has described in a previous publication, this being his second appearance as the author of an educational work. There is the clearest evidence that he has set himself to work out a problem of which he was able to realise, perhaps, only the general nature at the outset; and that, as so often happens in experimental inquiries as experience is gained, the nature of the underlying problem has been more clearly grasped as the work progressed, and important modifications of procedure have consequently been introduced. I look forward with expectancy to his next memoir, in which the results of his further studies will be presented to us, I trust, in far less elaborate guise, so as to render them available to the simplest understandings.

"The Laboratory Manual of Physics and Applied Electricity," arranged and edited by Prof. Nichols, of Cornell University, U.S.A., is intended as a college course, and is stated to be the outgrowth of a system of junior instruction which has been gradually developed during a quarter of a century, and I shall therefore venture to criticise it broadly from an outsider's point of view, as though it were a report on the results of an inquiry, with reference to its general character and the arrangement of the subject-matter. The first volume by Messrs. Merritt and Rogers is intended for beginners, and, we are told, affords explicit directions together with demonstrations and occasional elementary statements of principles. It is assumed that the student possesses some knowledge of analytical geometry and of the calculus; also that he has *completed* a text-book and lecture course in the principles of physics. Here we may at once join issue with the authors. If, as is so frequently and indeed almost always the case at present, the student come to college knowing a good deal of mathematics and no physics, the first assumption is a legitimate one, but it is time that we began to insist that such educational abortions should not be reared, and that girls and boys be no longer allowed to grow up so ignorant that, although they have learnt a good deal of mathematics, they require to be told, when they come to college, how to use squared paper, how to make simple experiments illustrating the principle of the parallelogram of forces, how to roughly determine density by weighing in water and by means of a bottle—all of which, as well as a number of other practical arithmetic exercises for children, are included by Prof. Nichols in his first volume. The incongruity is made still greater by the appearance in the introduction, ten pages after the description of the graphical method of representing results, of a somewhat elaborate discussion of "probable error" and the application of the method of least squares. Surely, also, no student nowadays should be allowed to complete a text-book and lecture course before entering on practical work—are we not seeking rather to invert this order? Were it not that the editor tells us that it is not expected that the experiments will be taken consecutively, the book might be regarded as helping teachers in the choice of a properly graduated course of experiments; and with this confession before one, it is impossible also to take exception to the somewhat extraordinary classification of the experiments—an instance of which is afforded by placing an exercise on the measurement of the curvature of a lens by means of the spherometer first in the course, at p. 26, whilst the determination of relative density "roughly" by weighing in water is relegated to chapter ii. p. 80. Some indication of the editor's experience as to the order in which the experiments are advantageously arranged in a junior course would have been valuable, as even to meet the exigencies created by the simultaneous presence of a large body of students, it is scarcely desirable to take physical exercises in any order. Again, we are told that no attempt has been made to provide a complete and sufficient source of information for laboratory students—on the contrary, it has been thought wise to encourage continual reference to other works and to original sources, so that it is impossible to complain of the book on the score of the incompleteness of many of its descriptions.

The second volume is more interesting, logical and original, and less fragmentary. It is intended for students who have completed the "course" in vol. i. and who are prepared to take up special work; in it the needs of those who are in training to become electrical engineers have been specially considered—a sign of the times—and it is for them especially that the parts treating of applied electricity, heat, and photometry have been written. Parts i. and ii. occupy about half the book, and comprise 53 direct and 64 alternate current experiments, the intention clearly being to frame a systematic course suited to those who have gone through a simple qualifying course in general physics. The instructions are very tersely worded, and but serve to give general guidance—which is very desirable in the case of students in whom it is desired to develop habits of independence. Immediately after the electrical engineering course, there is a very short section on electric-light photometry. Following this comes the least satisfactory section in the book, that on heat—dealing with the experimental determination of specific heats, heat of combustion, vapour pressure, vapour density, heat of vapourisation, mechanical equivalent of heat, cubic expansion, and measurement of temperature by means of thermoelectric couples. Much of this might with advantage be placed in the qualifying introductory course, and the engineering student would gain little from the exercises which do not properly find a place there. Moreover, this section is grievously behind the times in many respects—under vapour density, not only is the sole method described "the classic one used by Dumas," but the picture is that which has figured in every text-book since Dumas' description was published in 1826, showing a stove which it would be impossible to find. Experiment 9 is headed, "Use of the Favre and Silbermann water calorimeter," an instrument which it is difficult to imagine *in use* by students. But Mr. Matthews, who is responsible for this section, is clearly not a Rip van Winkle, as he also describes the Bunsen ice calorimeter and Berthelot's heat of vapourisation apparatus.

Part. iv. of the second volume comprises outlines of advanced work in general physics, based chiefly on researches done in the physical laboratories of Cornell University, written for the use of students who have completed the routine work, and desire to enter upon original investigation. This section will scarcely be of value to outsiders, as every competent head of a laboratory has problems enough awaiting solution, and a textbook of research is scarcely a much-felt want. Excellent advice is given at the outset of this section, and yet it is, in part, of such a kind as to bring out only too clearly how much we are behind in our conception of what is right and proper in education. At this stage—the commencement of original investigation—says Prof. Nichols, there is a critical point. Further success depends upon several matters which have been necessarily somewhat neglected during the earlier periods. In the first place, the student must acquire independence and self-reliance; he himself must face the experimental difficulties of the problem upon which he may be engaged, and must overcome them by devices of his own. Surely, we ought not to wait so long—the first essential in teaching scientific method should be to develop habits of independence; and if from the outset we lead students, as far as possible, always to take up the attitude of the discoverer, there should be no critical point in their career, but they should insensibly escape from leading-strings and walk alone.

Being prepared specially for students at Cornell University, the book will scarcely be used very widely, and, indeed, is not suited for general use, I imagine; yet it appears to me to be of considerable interest to teachers, as marking a distinct step forward in the evolution of the text-book of the future. There can be little doubt that those students, at all events, who have a technical career in prospect, will be taught on lines such as are indicated by the arrangement of the subject-matter adopted by Prof. Nichols—that after going through a qualifying introductory course, in which they gain a general understanding of the main principles and of method, they will devote their attention to the technical study of whatever branch they may select. But it is to be hoped that they will be so taught at school that the introductory college course will not only be much shorter than is at present necessary, but of a much higher character; and that, as I have said above, they will be inquirers from the outset.

To carry such a scheme as I contemplate in this article into execution, however, teachers of all subjects must be trained in the school of research: surely this is the keynote of future progress in education, indeed of our national progress.

HENRY E. ARMSTRONG.

NOTES.

THE Council of the Royal Society have fixed Wednesday, May 1, for the first Soirée of the Session. The Ladies' Conversazione will be held on some convenient day in June, probably the 12th.

WE understand that Sir Joseph Lister, Bart., the Foreign Secretary of the Royal Society, will be nominated for the presidency of the Liverpool meeting of the British Association, to be held in 1896.

PROF. W. C. UNWIN, F.R.S., will deliver the "John Forrest" lecture this year, at the Institution of Civil Engineers, on "The Development of the Experimental Study of Heat Motors."

A SERIES of Cantor Lectures, on Commercial Fibres, will be commenced at the Society of Arts, John Street, Adelphi, on Monday next, by Dr. D. Morris, C.M.G. The subsequent lectures will be on March 25 and April 1.

THE 1895 conference of the Camera Club will be held on April 2 and 3, under the presidency of Captain W. de W. Abney.

THE death is announced of Sir Edward Bunbury, the author of "History of Ancient Geography." Mr. Alfred Giles, whose name is well known among engineers, has also recently died.

AT the meeting of the Royal Meteorological Society, to be held on Wednesday, the 20th instant, a lecture will be given by Mr. W. N. Shaw, F.R.S., on "The Motion of Clouds considered with reference to their Mode of Formation."

THE Council of the Society of Arts invite members to forward to the Secretary, on or before April 13, the names of such persons as they may think worthy of the Albert Medal for 1895. The medal, which is given annually in recognition of "distinguished merit for promoting Arts, Manufactures, or Commerce," will be awarded in May.

IT is interesting to note, in connection with the subject of Mr. Stromeyer's letter published last week, that Reuter's correspondent at San Francisco reports that vessels arriving there announce the occurrence, on the 2nd inst. of an earthquake in the bed of the Pacific Ocean. The disturbance was accompanied by a loud roar, coming, apparently, from the sea, which became covered with a mass of white foam, and subsequently rose in numerous geyser-like columns.

MR. HYDE CLARKE, the author of numerous works and memoirs on philology and mythology, and a member of the Council of the Anthropological Institute, died at the beginning of this month, in his eightieth year. So long ago as 1836 he planned, as engineer, and also surveyed, the Glasgow and South-Western Railway, with the Morecambe Bay Embankment. He was engaged a few years later in acoustic telegraphy, and was employed to report on the telegraph system for India. His writings cover a wide range of subjects, but he was best known for his contributions to philology.

OUR attention has been drawn to a scheme, which owes its initiation to Canon Tristram, and for which further sympathy and support is needed. With the object of creating a more general interest in the study of Natural History, and to stimulate observation and research, it has been proposed to establish a fund for a medal or other prize to be given annually by the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne, for the encouragement of field work and original observations in any branch of the subject, whether Botany, Geology, or Zoology. The prize will be offered for the best essay evincing intelligent study of any of the common objects noticed in the fields or woods, on the moors, or by the sea-shore, &c.; competitors to be residents in the counties of Northumberland or Durham, or in Newcastle-upon-Tyne. It has been determined to associate the medal with the name of the late Mr. John Hancock. The capital fund required to provide the medal will not be less than £200, towards which amount over £100 has already been given and promised. Subscriptions towards the fund may be sent to Mr. A. H. Dickinson or Mr. M. C. Potter, Hon. Secretaries of the Natural History Society, Newcastle-upon-Tyne.

THE intention of the Ottoman Government to establish a geodynamic observatory at Constantinople has already been noticed in these columns (p. 180). The new institution forms a section of the Imperial Observatory, and is under the direction of Dr. G. Agamennone, who has just issued a valuable list of earthquakes felt throughout the empire in 1894. The chief interest of this catalogue centres in the accounts of the great earthquake of July 10, and the detailed record of its after-shocks. In the Observatory registers there are also preserved many seismic notices relating to previous years, which are to be edited and published at the earliest opportunity.

THE seismic history of several districts in Italy has been worked out with great care and thoroughness by Dr. Mario Baratta. In his last paper (*Rivista Geogr. Ital.*, Gennaio, 1895), he treats of the earthquakes of Calabria Ultra. In this province there are five well-marked seismic centres, or radiants. From their position, and from the direction in which the epicentre is displaced, it is clear that they are closely connected with the prominent faults which have helped to shape the present surface features of the district. Dr. Baratta concludes that the earthquakes of 1783 were produced by vibrations of these faults, and that the shock of last November 16 was a repetition of the terrible disturbance of February 5, 1783, the areas most strongly affected by them both being almost or quite identical.

THE Council of the Marine Biological Association has authorised the expenditure during the present year of a considerably larger sum for boat hire than has been spent in previous years. Naturalists who visit the laboratory during the coming season may thus expect increased facilities in their work, and ample supply of material for their researches. The Council, moreover, has authorised the director to offer free tables in the Plymouth Laboratory to naturalists who will be willing to render assistance in the arrangement of the collections in the museum, and in the collecting operations at sea. It is to be hoped that many will take advantage of the efforts which are being made to extend the usefulness of the magnificent laboratory at Plymouth.

THE Prince of Monaco has recently reported upon the first scientific cruises of his yacht the *Princesse Alice*. The area investigated included the western basin of the Mediterranean, the Straits of Gibraltar, and the Gulf of Gascony, along the western coasts of Morocco, Portugal, and Spain, down to a depth of 4898 metres. Fifty-eight soundings and forty-six temperatures and samples of sea-water were taken in these localities. The trawlings made by the *Princesse Alice* in the western basin of the Mediterranean merely confirm the known poverty of the fauna of the great depths of this part of the Mediterranean; the Atlantic operations of the ship in 1894 were unfortunately impeded by prolonged and violent northerly winds.

MR. J. Y. BUCHANAN, who has investigated the samples of water taken by the *Princesse Alice*, finds that the density of the Atlantic water is the same along the whole south coast of Spain as far as Cape Gata, owing to the existence here of a strong surface current setting eastwards. From Cape Gata eastwards only the denser water of the Mediterranean proper is met with. The difference between the ratios of salinity to alkalinity in the case of the Atlantic and Mediterranean waters is not very great, but is clearly marked. The mean coefficient of the Atlantic samples examined by Mr. Buchanan was 0·5000, and of the Mediterranean 0·4875; while the minimum coefficient of the Atlantic samples was greater than the maximum coefficient of the Mediterranean. A possible cause of the difference between the Mediterranean and Atlantic waters is sought in the abundance of calcareous rocks on the coasts of the former sea.

THE first number of the new Chilian *Journal of Hygiene* has recently been issued. It is published under the direction of the Institute of Hygiene recently established in Santiago, and is printed in Spanish. The present volume confines itself to the history and development of the organisation of public hygiene in general throughout Chili, and an account is also given of the provision for official hygienic administration in Germany, France, England, and Belgium. One of the functions exercised by the Santiago Hygienic Institute is the analysis of substances for purposes of trade and commerce, and the granting of official certificates as to their quality. Considering the enormously high death-rate of Santiago, which is stated to reach 57 per 1000, some reform in hygienic matters is urgently needed, and it is to be hoped that the establishment of this new Bureau of Public Health may beneficially stimulate public and private enterprise in this direction.

WE could not have a better example of the insufficient morphological descriptions which have become attached to some micro-organisms, than that afforded by Mr. A. Coppen Jones in his memoir on the tubercle bacillus, lately published. This investigator has studied this micro-organism for several years past at Davos, where he has had ample opportunity for the collection of tuberculous material, and, after most elaborate and painstaking researches, he considers that we are not yet in a position to assign its correct morphological place to the organism associated with consumption. Mr. Jones is of opinion that it probably stands in close relation to the moulds, and that it has far more right to be regarded as belonging to this category than to the schizomycetes in the strictest sense of the word. The conclusions are based upon very careful observations, and the memoir is abundantly furnished with beautiful illustrations. The tetanus bacillus has also been seen associated with mycelium threads, and Almquist is stated to have isolated two bacterial forms which produced a branched mycelium. The subject is a most interesting one, and well worthy the attention of morphologists.

AT the meeting of the French Meteorological Society on February 5, an important discussion took place on the subject of anemometry and the vertical currents of the atmosphere, which have sometimes been recorded by the so-called clino-anemometer. M. Ritter thought that the ascending currents registered by those instruments were simply due to deviations of the atmospheric currents by obstacles, such as the tower on which the recording instrument was placed, which divides the current laterally, and also inflects it in an upward direction. M. Angot stated that such vertical currents do not rise to any great height, in proof of which he said that on making the ascent of the Pic du Midi, with an ascending wind caused by striking the incline of the mountain, a number of small papers thrown into the current only rose a few metres, and then fell down behind the observer. These observations tend to modify to a great extent the results of experiments on vertical atmospheric currents, which have from time to time been published, and make it advisable for further experiments to be carried out.

THE Report of the Meteorological Council for the year ended March 31, 1894, has been recently presented to Parliament. In the department of ocean meteorology, the preparation of current charts for all oceans have been regularly proceeded with; the Council have procured from foreign meteorological offices nearly all the observations for the Pacific Ocean, with the view of rendering the generalised results as trustworthy as possible. The preparation and extraction of data for the south Atlantic and west coast of South America, have also been actively prosecuted. In the branch of weather telegraphy and forecasts, an important addition has been made by the receipt of daily reports from two stations in the Azores. Forecasts are prepared three times a day, either for publication in newspapers, or for the preparation of storm warnings, while during the hay-harvest season, forecasts were supplied to farmers and others, and were also widely distributed by the Board of Agriculiure. The total percentage of success of these agricultural forecasts reached 91, being the highest yet recorded. Among the various publications the *Weekly Weather Report* supplies a very complete view of the chief meteorological changes over the greater part of Europe; considerable progress has also been made with the rainfall tables of the British Isles, the total number of stations for which the values for 1881–90 will be furnished is approximately 430, so that the general distribution of rainfall over our islands will be well represented. Among the miscellaneous researches carried on by the Council, we may mention the comparison of Dines's pressure tube anemometer, which shows the wind pressure at each instant; the vane is erected 93 feet above the ground, and the recording portion is in a room in the Meteorological Office. Upon the whole, the comparison speaks strongly in favour both of the reliability of this instrument, and of the mean record yielded by the Robinson cup anemometer, which has hitherto been generally in use, both in this country and abroad.

IT has often been observed that a bright scarlet uniform will in a good photographic dark-room with ruby-glass windows, appear perfectly white. On this subject Herr H. W. Vogel made some interesting communications to the Physical Society of Berlin at a recent meeting. Experimenting with oil lamps provided with pure red, green, and blue colour screens, he found that when white light was rigidly excluded, all sense of colour disappeared to the observers, and nothing but shades of black and white could be distinguished on objects in the room. He further found that a scale of colours illuminated by red light showed the red pigments as white or grey, which abruptly turned into yellow, and not red, on adding blue light. Hence a colour was perceived which was not contained in either of the sources. Red and yellow patches appeared of the same colour, so that they could hardly be distinguished. But the difference was at once brought out by adding green instead of blue light. How very much the kind of sensation experienced depends upon the intensity of illumination is easily seen in the case of the region of the spectrum near the G line of Fraunhofer. This region appears violet when its luminosity is feeble, blue when it is stronger, and may even appear bluish-white with strong sunlight, so that the assertion often made that with normal eyes a definite colour-sensation corresponds to a definite wave-length, cannot be upheld. Herr Vogel comes to the conclusion that our opinion as to the colour of a pigment is guided by our perception of the absence of certain constituents. Thus a red substance is only recognised as such when light of other colours is admitted, and we perceive its inability to reflect these.

AT the meeting of the Institution of Civil Engineers, on Tuesday, March 5, two papers, dealing with the transmission of power by electricity, were read. The first, on "Electrical Haulage at Earnock Colliery," by Mr. Robert Robertson, contained an account of the general features of the colliery and of those of its seams into which electrical hauling-engines had been introduced to drive endless ropes, and to replace horse-traction between the main haulage-roads and the working-faces. The electrical generating plant comprised a dynamo for supplying power to the electrical hauling-engines, capable, at a speed of 620 revolutions per minute, of an output of 100 amperes at 490 volts. Two electrical hauling-engines, of which the main features were similar, were used. The two cables of stranded steel wire ¾ inch in diameter, operated circuits of 2160 yards and 1020 yards in length respectively. The cables were driven continuously at a uniform speed, and the coal-hutches were attached to or detached from them by a Smallman clip. The efficiency of the plant as compared with the horse-traction, which it had replaced, was also considered. The electrical haulage-system in the Ell coal seam was capable of a daily output of 400 tons. The daily output by horse-traction had been 180 tons, and to increase this to 400 tons, thirty or forty horses would have been required, a number which could not have been employed in the available space without confusion. The daily output of the electrical haulage-system in the main coal-seam, which was not yet working at its full capacity, was between 150 and 200 tons. The yearly working expenses of the two systems were compared, upon the results of one and a half years' working, and were found to be £4130 and £1990 by horse-traction and by electrical haulage respectively, showing that an annual saving of £2140 had been effected by the latter. The total cost of the electrical installation had been £3500.

IN the second Paper—"Water-Power applied by Electricity to Gold-dredging," by Mr. Robert Hay—an account was given of plant which had been erected in New Zealand to utilise water-power for generating electricity to be transmitted to motors operating a dredge in different portions of a distant river. The plant described had been constructed for gold-dredging in the River Shotover, the course of which was for the most part in rocky gorges through rugged country, accessible only by tracks cut down the leading spurs and gullies. The water was obtained at a creek 1½ miles distant from the dredging ground, and was brought by a race cut in the side of the hill, or, in places where the ground was not suitable, in a timber-flume, to a pressure tank at a level of 524 feet above the pipes at the generator-house. From this tank to the wheel employed the water was carried in rolled-steel pipes. The prime-mover of the generating plant was a Pelton reaction water-wheel, upon the buckets of which the water, from a nozzle 1½ inches in diameter, impinged at a pressure of 228 lbs. per square inch. This wheel drove two series-wound dynamos working at a normal speed of 700 revolutions per minute, each developing a current of 40 amperes at an electromotive force of 650 volts, or together nearly 70 h.p. The conductors, of a length of two miles, were of No. 4 S.W.G. bare copper wire, and were supported upon insulators carried by cross-arms upon old 40-lb. rails. The current was conducted to two motors in the dredge, one for driving a centrifugal pump, and the other for operating the buckets, winches, and revolving cylinder. Two 10-ampere arc-lamps lighted the dredge at night, and were joined in multiple-series with the motors, with suitable arrangements for their control. The cost of the installation and the weekly working expenses were £7000 and £35 respectively.

AT a recent meeting of the Academy of Science of Amsterdam, M. Kamerlingh Onnes presented a paper by M. L. H. Siertsema, on magnetic rotary dispersion in oxygen. Since making a preliminary communication on this subject, the author has improved his apparatus in several details, and is now able to examine the gas under a pressure of a hundred atmospheres. The oxygen employed was prepared by electrolysis. The measurements of rotation are made by the well-known method in which white light, having passed through the polariser, observing tube, and analyser, is then examined by means of a spectroscope. A dark band is thus obtained traversing the spectrum, and the analyser is turned till this dark band coincides with the part of the spectrum corresponding to light of any desired wave-length. With currents between 35 and 65 amperes, the author is able to get rotations of from 3° to 4°. In the case of oxygen the results are very well expressed by the formula $\gamma = \frac{808 \cdot 028}{\lambda}\left(1 + \frac{0 \cdot 07202}{\lambda_2}\right)$ where λ is the wave-length in thousandths of a millimetre; the mean error in γ being ± 17·5. This formula is deduced from the formula $\gamma = \frac{c}{\lambda}\left(n - \rho\lambda\frac{\delta n}{\delta\lambda}\right)$ where n is the refractive index, given by Mascart. A series of measurements were also made on atmospheric air, and the values for nitrogen deduced by comparison of these numbers with those obtained for oxygen. The expression thus obtained for nitrogen is as follows:—

$$\gamma = \frac{560 \cdot 41}{\lambda}\left(1 + \frac{0 \cdot 32424}{\lambda^2}\right).$$

AN interesting series of experiments have been carried on by Mr. T. Andrews, on the influence of stress on the corrosion of metals, which may have considerable practical applications. Bars of iron or steel were subjected to different stresses, and were then placed in some electrolyte—generally a solution of common salt—and the difference of potential between them measured. It was found that tensile stress caused the production of an average E.M.F. of 0·016 volt between the strained and unstrained bars, the latter being positive. The effect of torsional stress was to produce an average E.M.F. of 0·012 volt in the same direction. Similar results were obtained with flexional strains. From the data obtained, the author deduces a number of interesting conclusions which bear on the corrosion of iron structures, for which we must refer to the original paper in the *Proceedings* of the Institution of Civil Engineers, cxviii. 4.

THE ever-increasing precision in the study of the geological distribution of fossils renders it necessary, from time to time, to recognise that a well-marked lithological division, though of the greatest value in geological mapping, does not represent a definite time-level, but may gradually rise or fall in time as it is traced along its outcrop. This fact is well illustrated in England by the Cretaceous beds underlying the true Chalk, and some of the questions involved have been discussed in two recent papers in the *Geological Magazine*. The first of these, by Messrs. Jukes-Browne and Meyer (November, 1894) deals with the Upper Greensand and Chloritic Marl. They point out that the latter term has been applied—and may justly be in its lithological sense—to various horizons up to the zone of *Belemnitella plena* (as at Beer Head), and they propose that if the name be retained it should be strictly limited to the zone of *Stauronema Carteri*, which may be regarded as the bottom bed of the true Chalk. They further point out that the well-known Warminster fossils are a mixture of two faunas—the majority coming from the summit of the true Upper Greensand, just below the *Stauronema* zone, though some are from that zone itself, the state of preservation being different in the two cases. Thus the confusion between Chloritic Marl and Warminster Greensand is due to a mixture of fossils from different levels—an accident that has often caused confusion in other formations—and a complete revision of the lists of fossils from these horizons must precede any further correlation. The second paper, by Dr. J. W. Gregory (March, 1895), deals with the Gault and Lower Greensand. After considering evidence of various kinds, he comes to the conclusion that the conformable passage from sandy beds into clay rises in time as it passes westward from Kent to Surrey, much as the upper limit of the clay sinks rther west towards Wiltshire. The lowest zone of the Gault in Surrey that has the typical clayey facies is equivalent to the fourth or higher zone of the Folkestone Gault, the lower zones being represented in the so-called "Folkestone Sands." Dr. Gregory indicates the levels at which, in Kent and Surrey respectively, the limits of the Albian, Upper and Lower Aptian, and Rhodanian formations of the Continent can be drawn; but insists on the necessity of continuing to recognise the old lithological divisions side by side with the new palæontological ones. He also gives a critically revised and extended list of fossils from the phosphate beds of Great Chart, near Ashford, Kent.

THE 1894 "Report of Observations of Injurious Insects and common Farm Pests," by Eleanor A. Ormerod, will not yield to any of its predecessors in interest, value, or variety. The general character of these Reports is so well known that it is unnecessary to dwell upon it; but the present part gives prominence to several considerations which have not hitherto received very much attention. The first of these is the undoubted fact that almost any of the 12,000 species of insects inhabiting the British Islands, except those which feed exclusively on other insects, may, under certain circumstances, or when unusually abundant, become entitled to a place in the category of injurious insects. Thus, the present Report opens with figures and descriptions of three species of *Lepidoptera*—the Eyed Hawk Moth, the Lappet Moth, and the large Tortoiseshell Butterfly—which are not generally so common in England as to be thought capable of causing serious injury; indeed, Miss Ormerod herself suggests that such pests might easily be got rid of by inviting an entomologist to clear them off. One of the most important insect visitations during the past year was that of the Antler Moth (*Charæas graminis*) in South Scotland, where the larvæ fed on the tender grass which sprang up over the districts previously devastated by the vole plague. Several pages are devoted to hay mites, which appear, however, though sometimes excessively abundant, to cause little real damage. Other interesting creatures noticed are the eel-worms (in her account of which Miss Ormerod has unintentionally in part anticipated Prof. Percival's important paper on the subject in *Natural Science* for March, as fully explained in an accompanying note), horse-warble, winter gnats, wasps, &c. It does not appear to be quite certain whether the horse-warble is the same species as the ox-warble. Warble in the horse appears to be of much less common occurrence than in the ox, and usually to occur only in small numbers in the same animal. But this may be due to the horse being a more carefully-tended animal than the ox. Two other points of interest deserve notice. Several species of carnivorous ground-beetles are stated to be very destructive to strawberries. More information is certainly required as to how far so-called carnivorous insects will also eat vegetable matter, decaying or otherwise. It appears that sea-gulls are sometimes in the habit of frequenting turnip-fields infested with the Diamond Back Moth, and in one instance a farmer attributed the destruction of his crop to the gulls. So easy is it to make a serious error in discriminating between the farmer's friends and foes.

A NEW and particularly convenient method of preparing the unsaturated hydrocarbon allylene, C_3H_4, has been discovered by Prof. Keiser and Miss M. B. Breed, as the result of an investigation concerning the action of magnesium upon the vapours of the alcohols. Preliminary experiments showed that when magnesium is heated with organic compounds such as alcohols, acids, and ketones, a reaction of considerable energy occurs at more or less elevated temperatures, accompanied by incandescence of the metal. The reactions between magnesium and the alcohols were then systematically studied. The magnesium, in the form of filings, was placed in a porcelain boat, and heated in a combustion tube through which the vapour of the alcohol was conducted. At a low red-heat the magnesium usually commenced to glow at one end of the boat, and the incandescence was then rapidly communicated to the whole quantity of metal, while large volumes of gas were evolved from the tube. When methyl alcohol is employed the action is extremely energetic, and the gases evolved consist mainly of about four-fifths hydrogen and one-fifth marsh gas. The residue in the boat is then allowed to cool in the vapour of the alcohol, when it is found to have the appearance of a black coherent mass. When this solid residue is placed in water a gas is slowly evolved, and if a few drops of ammonium chloride are added, the gas is liberated in a steady and moderately rapid current. The odour of the gas resembles that of acetylene, but when it is conducted through an ammoniacal solution of cuprous chloride the greenish yellow precipitate of cuprous allylide is produced, and with an ammoniacal silver nitrate solution the white crystalline precipitate of silver allylide is formed. These precipitates are highly explosive after separation and drying, a temperature of 150° being sufficient to bring about their explosion. When they are treated with dilute nitric or hydrochloric acids they dissolve with evolution of allylene. Ethyl alcohol behaves similarly towards heated magnesium, and the black residue left in the boat after the completion of the reaction is similarly decomposed by water with liberation of allylene, the rapidity of evolution of the latter being also largely augmented by the addition of a little ammonium chloride. The most convenient alcohol to employ, however, is propyl alcohol, for the black magnesium residue is in this case decomposed much more rapidly by water at the ordinary temperature, and the yield of gas is considerably larger. Prof. Keiser states that this method of preparing allylene for lecture purposes, by the reaction between magnesium and propyl alcohol, and subsequent decomposition of the product by water, is far preferable to the ordinary method of decomposing propylene bromide with alcoholic potash. Most of the other alcohols likewise afford magnesium residues which liberate allylene when brought in contact with water, but the gas is rarely so pure as that derived from the use of propyl alcohol.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mrs. Turner-Turner; an Azara's Fox (*Canis azaræ*) from Brazil, presented by Messrs. Edgar and Harold Turner; four Amadavade Finches (*Estrelda amandava*) from India, presented by Mrs. Faulkenor; a Chukar Partridge (*Caccabis chukar*) from India, deposited; a Sykes's Monkey (*Cercopithecus albigularis*, ♀) from East Africa, two Red-crested Pochards (*Fuligula rufina*, ♂ ♀) from India, purchased; a Great Kangaroo (*Macropus giganteus*, ♂), three Hunter's Spiny Mice (*Acomys hunteri*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SPECTRUM OF THE ORION NEBULA.—A full account of the photographs of the spectrum of the Orion Nebula, which were taken with Mr. Lockyer's 30-inch reflector at Westgate-on-Sea in 1890, has just been published in the *Philosophical Transactions* (vol. 186 A, p. 73.) Four hydrogen lines more refrangible than K are shown on the photographs, and in all 54 lines have been recorded. The line near wave-length 3730, first discovered by Dr. Huggins, is a very strong line, and among other prominent lines, is the well-known chromospheric line at wave-length 4471. It is shown that many of the principal lines are coincident with bright lines photographed in the spectrum of P Cygni at South Kensington, and with bright lines in planetary nebulæ and bright line-stars photographed by Campbell and Pickering, so that a close connection of these bodies is established. Other tables show a close relationship between the bright lines of the nebula and the dark lines in the so-called Orion stars, of which Rigel and Bellatrix are typical examples.

The following are the conclusions to which the investigation has led: (1) The spectrum of the nebula of Orion is a compound one, consisting of hydrogen lines, low temperature, metallic lines and flutings, and high temperature lines. The mean temperature, however, is relatively low. (2) The spectrum is different in different parts of the nebula. (3) The spectrum bears a striking resemblance to that of the planetary nebulæ and bright-line stars. (4) The suggestion, therefore, that these are bodies which must be associated in any valid scheme of classification is strengthened. (5) Many of the lines which appear bright in the spectrum of the nebula, appear dark in the spectra of stars of Groups II. and III., and in the earlier stars of Group IV.; a gradual change from bright to dark lines has been found. (6) The view, therefore, that bright-line stars occupy an intermediate position between nebulæ and stars of Group III. is greatly strengthened by these researches.

THE ECLIPSE OF THE MOON.—The earlier phases of the total eclipse of the moon on Monday morning were observed under very favourable circumstances in the neighbourhood of London. The penumbra was not distinctly visible until about ten minutes before contact with the shadow, and the whole disc of the moon remained clearly visible, even at the middle of totality, until clouds stopped observations about 4 a.m. The parts deeply immersed in shadow were intensely red throughout, and with the telescope all the principal formations could be easily distinguished. During totality the sky was exceptionally clear, and numerous occultations were observed without difficulty. For half an hour after the commencement of totality the following edge of the moon was pretty brightly illuminated, and presented a striking contrast with the redness of the advancing edge; at mid-eclipse, however, the whole of the disc was very red.

It is reported that nearly 140 observations of disappearances or reappearances of eighteen stars were secured at the Royal Observatory on Monday morning by the eleven observers who watched the progress of the eclipse.

THE NAUTICAL ALMANAC, 1898.—In the recently published volume of the British Ephemeris for 1898, we note several valuable additions. The places of eleven close circumpolar stars, four of which are in the northern hemisphere, are given for each day of the year, and the mean places of fifty-two additional stars for navigational purposes have been added. The improved explanations of the contents will also no doubt be generally appreciated. The publication of an abridged edition for the use of seamen is a step in the right direction.

PHYSICAL WORK OF HERMANN VON HELMHOLTZ.[1]

I

THE career we are to consider this evening was a career of singular distinction. In days when the range of "natural knowledge" is so vast that most workers are compelled to be content if they can add something to one or two of the subdivisions of one of the main branches of science, von Helmholtz showed us that it is not impossible to be at once a great mathematician, a great experimental physicist, and, in the widest sense of the term, a great biologist.

It was but eight months yesterday since he delivered his last lecture; it is six months to-day since he died, and the interval is too short for us to attempt to decide on the exact place which will be assigned to him by posterity; but making all allowance for the fact that each age is apt to place its own great among the greatest, making all allowance for the spell which his name cast over many of us in the lecture-rooms where we ourselves first gained some knowledge of science, I am sure that I only express the views of all those who know his work best, when I say that we place him in the very front rank of those who have led the great scientific movement of our time. This opinion I have now to justify. I must try to convey to you in some sixty minutes an outline of the work of more than fifty strenuous years, to give you some idea of the wide range of the multifold activities which were crowded into them, of the marvellous insight with which the most diverse problems were attacked and solved, and, if it may be, some image of the man himself. The task is impossible, and I can but attempt some fragments of it.

The history of von Helmholtz is in one respect a simple tale. There are no life and death struggles with fate to record. His work was not done with the wolf at the door, or while he himself was wrestling with disease. He passed through no crises in which success or failure, immortality or oblivion, seemed to depend on the casting of a die. He suffered neither from poverty nor riches. He was a hale strong man on whom external circumstances neither imposed exceptional disabilities, nor conferred exceptional advantages, but who, by sheer force of the genius that was in him, passed on from success to success till he was recognised by all as the admirable Crichton of modern science, the most widely cultivated of all students of nature, the acknowledged leader of German science, and one of the first scientific men in the world.

It is the more fitting that this evening should have been set aside for the consideration of the work of Helmholtz, in that England may claim some share in his greatness. Before her marriage his mother bore an English name—Caroline Penn; she was, as her name implied, of English descent. His father was a Professor of Literature in the Gymnasium at Potsdam, so that his early days were passed amid that plain living and high thinking which are characteristic of intellectual circles in Germany. The boy did well at school, and when the time came for choosing a profession, his passion for mathematics and physics had already developed itself. The course of his love for these sciences did not run quite smooth. The path of his ambition was crossed by the hard necessity which in some cases checks, in others fosters, but in all chastens the aspirations of youth. He had to make his livelihood. Science must be to him what the Germans happily call a "bread-study." Medicine offered a fair prospect of prosperity. Physics, in those days, was but an intellectual pastime. And so the young man took his father's advice, and became an army doctor. In this, as in so many other cases, "the path of duty was the way to glory."

It is possible that if von Helmholtz had been what—with a sad consciousness of the limitations it implies—I may call a mere physicist, he would have played a greater part in the development of some of those subjects, the study of which he initiated or helped to initiate, but did not thereafter pursue. It is possible that had he been a biologist, and nothing more, he would have followed up the early investigation in which he disproved the old theory that putrefaction and fermentation are chemical processes only, clearly indicating, if he did not actually demonstrate, that the decay which follows death is due to an outburst of low forms of life.

He might thus under other circumstances have done work for which he showed his competence, but which is now chiefly associated with other names; but it is certain that without the unusual combination of wonderful mathematical power and a professional knowledge of anatomy, he would never have accomplished the special tasks which it is his special glory to have achieved.

His first three papers, however, hardly displayed the fusion between his various powers which was afterwards so remarkable a characteristic of his work. The first two were on biological subjects. The third was the famous essay on the "Conservation of Force." I have told elsewhere the story of the dramatic circumstances under which it was given to the world, of the interest it excited among the members of the Physical Society of Berlin, the refusal of the editor of *Poggendorff's Annalen* to publish it, and the final triumph of the author and his views. (*Fortnightly Review*, November 1894.) Helmholtz was not, and did not claim to be an original author of the doctrine of the conservation of energy; but two young men, Sir William Thomson in England, and Helmholtz in Germany, independently, and within a month of each other, were the first persons who compelled the scientific world to regard it seriously.

There is one interesting fact which connects this essay directly with the Royal Institution. Four years after it was published, it was placed by Du Bois Reymond in the hands of one who was lost to science in the same year as von Helmholtz himself—the late Prof. Tyndall. He was much impressed, and has spoken of the incident as bringing him face to face with the great doctrine of the "Conservation of Energy." ("Introduction to Popular Lectures by Helmholtz," translated by E. Atkinson, 1873.) He translated the essay into English, and

[1] A discourse delivered at the Royal Institution, by Prof. A. W. Rücker, F.R.S., on Friday, March 8.

for many years made it his habit to place every physical paper published by Helmholtz within the reach of English readers.

And now, having brought you to the point at which Helmholtz may be said to have been fairly started on his life's work, let me first briefly describe his official career, before I consider his work in greater detail.

When his extraordinary abilities became evident, he was permitted to sever his connection with the army. At twenty-seven years of age he became Teacher of Anatomy in the Academy of Arts at Berlin. In the next year he was appointed Professor of Anatomy and Physiology at Königsberg, and he held similar posts in the Universities of Bonn (1855-58) and Heidelberg (1858-71). It was not till 1871 that his early love for physics was finally rewarded. When the chair of Physics was to be filled in the University of the newly-founded German Empire, in Berlin, it was felt that even in Germany—the land of specialists—no better occupant could be found than one who was then in his fiftieth year, and had been all his life a teacher of anatomy and physiology. The choice was universally approved and completely justified, and von Helmholtz held this post till his death.

In this connection I am, by the kindness of Sir Henry Roscoe, enabled to show to you a relic of remarkable interest. It is a photograph of the great teacher and investigator, taken at the very last lecture that he delivered—that, namely, on July 7, 1894.

For some years, that is, from the date of its foundation, von Helmholtz was the president of the Physikalisch-Technische Reichs-Anstalt in Charlottenburg. This institution, founded partly by the munificence of the late Dr. Werner Siemens, partly by funds supplied by the State, has no precise analogue in this country. It is devoted to the carrying out of systematic researches on questions of fundamental importance to which a long time must be devoted.

The most characteristic work of Helmholtz was, as I have already hinted, that in which his knowledge of physics and his knowledge of anatomy were both directed to a common end. He dealt in turns with the external physical phenomena, with the mechanism of the organs which the phenomena affect, with the relations between the mechanical effect on the organ and the sensations which it excites, and, lastly, with the connection between the sensations in those simple cases which can alone be investigated in the laboratory, and the complex laws of æsthetics and art.

The two books in which these problems were chiefly treated were the "Physiological Optics," and the "Sensations of Sound." It is impossible to do more than lay before you a sample which may afford some idea of the intricacy of the problems with which he dealt, and of the pitfalls amongst which he walked so warily. For this purpose I have chosen one branch of his work on "Sound."

I have deliberately selected that particular portion which has been most questioned, that on which the verdict of most of those who have sat in judgment on his views has been against him.

In discussing this question I must give a general description of the principal phenomena; but if I were to attempt an exhaustive catalogue of all the facts disputed and undisputed, and of all the theories which have been based upon or upset by them, not only would time fail me, but those who have not given special attention to the subject would, I fear, become hopelessly confused amid the chaos of opposing statements and views. Another reason which urges me to be brief, is that a few years ago Prof. Silvanus Thompson explained the whole subject to the members of the Royal Institution, having kindly consented to act as the mouthpiece of the celebrated instrument maker, König, who has played so large a part in these controversies.

Among the chief achievements of Helmholtz was an explanation of the physical difference between pairs of notes which we recognise as concords and discords respectively. When two neighbouring notes are sounded, alternate swellings and fallings off of the intensity are heard, which are called beats. These produce an unpleasant effect, which depends partly on their number, partly on the relative pitches of the beating notes. When two notes beat badly, they form an intolerable discord. When they become separated by a wider interval, the beats are so rapid that they cease to be unpleasant.

The sense of dissonance produced by many of these wider intervals, such as the seventh (4 : 7), requires further explanation. In general, the fundamental musical note is only the first and loudest of a series of so-called partials, whose vibration frequencies are 2, 3, 4, &c., times that of the fundamental, and the consonance and dissonance of two notes is shown to depend on the presence or absence of beats between important members of these series. Thus in the case of the seventh the frequencies of the octave of the lower note and that of the upper note would be in the proportion 8 : 7, which are sufficiently near to make the beats very prominent and disturbing.

In cases where the notes are pure, that is, are not accompanied by upper partials, the explanation of dissonance is based upon another phenomenon.

When two notes are sounded simultaneously a third tone is often perceived, the frequency of which is equal to the difference of their frequencies. The number of vibrations of this tone is equal to the number of beats, and as there has been controversy as to whether the beats when they become rapid can produce a note, and if so, whether this note is or is not the same thing as the difference tone, it is necessary to distinguish between the two. This distinction is to be found in the mode of their production; but for the moment it is sufficient to remember that they may be distinguishable, and to reserve for them two names, viz. the beat-note, and the first difference tone respectively.

Helmholtz drew attention to the fact that together with the difference tone there is also produced a note, the frequency of which is equal to the sum of those of the two primaries, and this he called the first summation-tone.

Together with these he believed that there existed summation and difference tones of higher orders, the whole series being included under the name of combination tones. Our sense of dissonance between pure notes was explained as dependent on beats produced by the combination tones.

Up to the time of Helmholtz it was generally thought that these tones were produced in the ear itself, and had no objective existence in the external air. They are thus often called subjective, but as that adjective is usually reserved for impressions produced in the brain itself, it is better to say that they were regarded as *ear-made*. Helmholtz himself gave a theory, which showed that it is probable that a membrane like the drum-skin of the ear, which is forced out of shape by pressure, and that bones, like those in the ear, which can rattle, would, if acted upon by two notes, manufacture by their own proper movements all the varied combinational tones which his theory postulated. He therefore believed that combinational tones were largely ear-made.

You will observe that his theory of discord is quite unaffected by the question whether the combination tones are or are not sometimes objective. Provided only they are produced at all, it is immaterial whether they are produced in the ear itself. Von Helmholtz admitted that the phenomena we observe are in most cases ear-made tones; but he also asserted that they were sometimes objective, and could set bodies tuned to vibrate with them in resonant motion. This latter statement has been denied with singular unanimity, sometimes, I think, without due regard to the limitations which Helmholtz himself placed on the conditions under which the objective character of the notes can be realised.

All ordinary calculations as to the production and mingling of different waves of sound are based upon the supposition that the displacements of the particles of air, or other body through which the sound is travelling, are very small. If this is so, the force which tends to restore each disturbed particle to its ordinary position of equilibrium is accurately proportional to the amount of the displacement.

In von Helmholtz' view, objective combination tones were in general produced when the disturbance was so great that this condition was no longer fulfilled. Violence is of the essence of the explanation. Hence the siren, where both sets of holes open into the same small wind-chest—the harmonium, in which two reeds alternately close and open slits in the same enclosure, are the instruments best suited to produce them. Of these the siren is the more efficient. Von Helmholtz convinced himself that the combination tones produced by the harmonium are for the most part ear-made. He expressly stated that "when the places in which the two tones are struck are entirely separate and have no mechanical connection, as, for example, if they come from two singers, two separate wind instruments, or two violins"—to which we may add two tuning-forks—"the reinforcement of the combinational tones by resonators is small and dubious." ("Sensations of Tone," translated by Ellis, p. 157.)

Now this reinforcement by resonators has been altogether denied by most of those who have taken an interest in the matter, while, if an exception is allowed, it is in favour of the beats of a disturbed unison, the observed effects being ascribed to the beats, and not to the difference tone.

Some writers make no exception whatever in their denial of the objective reality of what may be broadly termed secondary tones. Thus Mr. Bosanquet, who made a most careful series of experiments some fourteen years ago, stated that "the ordinary first difference tone . . . is not capable of exciting a resonator. . . . In short, the difference tone of Helmholtz . . . as ordinarily heard, is not objective in its character." (*Proc. Phys. Soc.* iv. 1881, p. 233.)

Prof. Preyer, too, using very sensitive tuning-forks, found that the differential tone given by two forks did not affect a fork the frequency of which corresponded with its own, except in cases where the difference tone was itself a partial of one of the forks.

It must be remembered that the assertions of Helmholtz as to the experimental proof of the objective nature of the tones were made with reference to those instruments which he regarded as most likely to produce objective notes, viz. the siren and the harmonium, and that, therefore, experiments with forks hardly affect his position.

Let us now try with the siren whether it is possible to confirm or to disprove the validity of his views.

For this purpose the rather bulky apparatus which you see before you has been constructed. I should hardly have been able to realise the idea embodied in it, at all events in time to show it to you this evening, if I had not been favourably situated in two respects. In the first place, I have had the zealous co-operation of one of my assistants, Mr. Edwin Edser, who has not only made all the parts of the apparatus that required to be newly made, but has thrown himself into the investigation with the utmost energy, working at it late and early, and making many valuable suggestions and improvements. In our joint work we have been helped by some of my senior students, and notably by Messrs. Cullen and Forsyth. In the second place, I have had at my disposal the magnificent collection of acoustical apparatus in the National Museum at South Kensington, some of which I am allowed, by the kindness of the Department of Science and Art, to bring here this evening.

wave-length of light, the path of the ray which falls upon it is shortened by a whole wave-length, and the position of each band is shifted to that previously held by its neighbour. If the fork vibrates with an amplitude of this almost infinitesmal amount, the bands will disappear, or will alternately appear and disappear according to circumstances. The fork may therefore be used to detect by resonance the presence of vibrations, the frequency of which is 64 *per second.*

A priori, there were two difficulties of opposite kinds which made it doubtful whether the fork would be an efficient weapon for the purpose for which it was to be used.

In the first place it would feel tremors of any sort, and it was doubtful whether it would be possible to discriminate between mere shakes and the vibrations which were to be studied. This difficulty has been very largely overcome.

The table on which the apparatus stands rests on india-rubber. On the table are a pair of library steps; these support two pieces of wood, which are heavily weighted and rest on india-rubber balls. From these two beams hang steel wires, which carry india-rubber door-fasteners, and these in turn support two rods on which the paving-stone is placed. By this alternation of elastic and of heavy bodies we can make the bands absolutely steady, unless the disturbances are violent. The quiet movements necessary for working the apparatus, the blowing of the bellows, and the like, produce no effect. On the other hand, the shutting of a door in a distant part of the building, the rumble of a cart in the street, will cause the bands to disappear. A great deal of the work on which we rely has been done at South Kensington between midnight and three o'clock in the morning. Trustworthy observations have indeed been made at other times, but it is only in the still small hours that the apparatus is at its best.

The second doubt was of a different kind. It was certain that the instrument would be more or less shaken; it was not quite certain whether the fork would respond to vibrations of the given period. It is easy to set a tuning-fork in vibration by resonance when it is mounted on a sounding-box, but in that case the vibrations of the enclosed mass of air are communicated through the box to the fork. When the stalk of the fork is held rigidly, a tuning-fork is notoriously difficult to excite by resonance. This objection is, of course, to some extent counter-balanced by the extraordinary sensitiveness of the means of detecting the vibrations, but it is necessary to supplement this by other devices. The instrument used is a siren (S). In front of it is placed a hollow wooden pyramid, the narrow end of

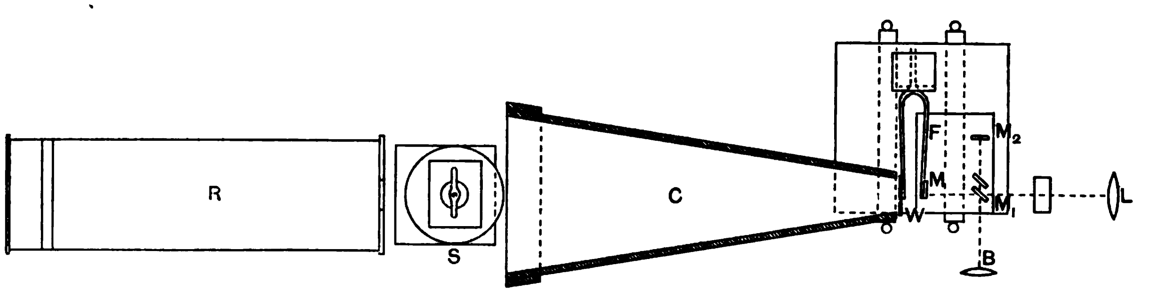

FIG. 1.

The essential part of the apparatus, Fig. 1, is a tuning-fork, F, to one prong of which is attached a mirror, M, and to the other a square of thin wood, strengthened by ribs, which is of the same weight as the mirror. The fork thus loaded has been compared with one of König's large standards by means of Lissajous' figures. Its frequency does not differ from 64 complete vibrations per second by more than one vibration in two minutes. The shank is supported by a mass of lead, which in turn is placed upon a paving-stone. Upon this stone also rest the other mirrors necessary for producing Michelson's interference bands. The mirror, M_1, is silvered so thinly that half the light which falls upon it is reflected, and half is transmitted.

A ray proceeding from the lantern, L, will be divided at M_1, into two, which follow the paths $LM_1M_2M_1B$ and LM_1MM_1B respectively. Interference bands are thus produced, which can be projected on to a screen, so as to be rendered visible to a large audience.

If the prong of the tuning-fork moves through the eighty-thousandth of an inch, that is, through a distance equal to a half

which is near to, and is of the same area as the wooden plate attached to the tuning-fork. This serves to collect the waves of sound, and to concentrate them on the fork. Behind the siren is a large resonator by König, timed to respond to 64 vibrations per second.

In some respects the apparatus requires careful handling. Of course if you blow down the collecting cone the fork may be disturbed, and sometimes a particular note of the siren appears to affect the fork for no very obvious reason. Probably the resonance of the air in the cone, or the vibrations of the wooden disk, may at times be the causes of such effects. We have, however, found that whatever they may be due to, they differ in appearance from those produced by vibrations synchronous with the periodic time of the fork, and they can in general be got rid of by a very slight readjustment of the apparatus. The fact that our main conclusions do not depend on any such nicety, is proved by the fact that the instrument has been set up twice in the laboratory, and once in the lecture-room in the College. In each case all the experiments have been successful, and on one occasion only were we troubled by a disturbance due to a note (of about 253 vibrations) when sounded alone. A slight readjustment of the cone, however, eliminated this effect entirely.

Such difficulties make it no easy matter to set up the apparatus in a hurry, and the most I can hope to do this evening is to demonstrate to you the methods of using it. I cannot undertake to make the actual measurements before you.

It is, however, desirable to illustrate the sensitiveness of the apparatus to vibrations of 64 per second, and its insensitiveness to other sounds.

Provided the current of air does not travel directly down the cone, organ-pipes may be blown just outside it without producing any effect. One of Konig's large tuning-forks may be bowed strongly without effect.

If, however, the exciting fork be tuned to 64 vibrations per second, and if it be struck as lightly as possible with the handle of a small gimlet, used as a hammer, the handle having been previously covered with india-rubber, the bands will immediately vanish, though the note produced is often quite inaudible, even to a person whose ear is placed close to the fork.

Let the weights on the fork be shifted so that it makes 63·5 vibrations per second, then the resonating fork beats, and the bands regularly appear and disappear every two seconds.

Having thus explained the construction and working of the apparatus, let me show you how we have tested whether it responds to a difference tone. When the proper rows of holes are opened, the siren will give simultaneously the *c′* of 256 and the *e′* of 320 vibrations. The interval is a major third, the difference tone is 64 vibrations. The pitch is determined by the beats between the upper note and a standard tuning-fork which gives *e′*. Sounding the upper note alone no effect is produced on the interference bands, as the beats first appear, then die out, and are finally heard again when the note given by the siren is too high.

It could be shown in like manner that the 256 note alone produces no effect, but if, when the standard fork of 320 vibrations and the upper note of the siren are judged to be in exact accord, the 256 note be also produced, the bands immediately disappear. Sometimes, of course, a small error is made in the estimate of the pitch, and the effect is not instantaneous, but in every case the bands disappear when the beats between the two notes are so slow that they cannot be distinguished.

It is therefore evident that Helmholtz was right when he asserted that the difference tone given by the siren is objective. It exists outside the ear, for it can move a tuning-fork.

(*To be continued.*)

JAMES WATT AND OCEAN NAVIGATION.[1]

IF it be asked what James Watt did during his long, busy, and eventful life to improve ocean navigation, or to adapt the steam engine to the work of propelling ships, I am obliged to reply that I am not aware he personally did anything, or even that he concerned himself much about the matter. He took no active part that we know of in applying or adapting his steam engine to the propulsion of ships. The reason probably was that after his attention was first directed to the subject of the steam engine, or fire engine, in 1759, his whole energy was expended, first in improving the steam engine and making its manufacture commercially successful, and afterwards in executing the orders that came for pumping and other engines that were required for mines and manufactures. In the case of most of the greatest mechanical inventions—Watt's among the number—it has not been the ideas or the inventions by themselves that have brought success, prosperity, or even satisfaction to their owners. These results have had to be painfully and slowly evolved out of long and costly practical demonstrations and experience of the alleged merits of the invention. James Watt toiled, suffered and endured for more than twenty years after his discovery of separate condensation in 1765, before he could see that his steam engine would ever bring him anything but disappointment, loss, and misery. It is highly characteristic, however, of Watt's fertile and original genius, and significant of what he might have done to develop the marine engine at the commencement of its history, had he taken the matter up, that upon the two principal occasions we know of when he applied his mind to the subject, he made very pregnant suggestions. Thus, when Watt sent drawings of his engines to Soho in 1770 for Mr. Boulton to construct one for experiment, and had been told that it was intended to make an engine to draw canal boats, Watt wrote, "Have you ever considered a spiral oar for that purpose, or are you for two wheels?" and to make his meaning clear he sketched a rough but graphic outline of a screw propeller. This is, perhaps, the earliest suggestion of a screw propeller, except that it was proposed by Daniel Bernoulli, the mathematician, in 1752. Again, in 1816, four years after the first Clyde steamboat, the *Comet*, was built at Port Glasgow, when Mr. Watt was upon his last visit to Greenock, he went to Rothesay and back in a steamboat. At that time the engineer did not reverse his engines, but merely stopped them some time before the vessel reached her mooring-place, and let her gradually slow down. James Watt, then an old man of eighty, tackled the engineer of the boat, and showed him how the engine could be reversed. He tried to explain this with the aid of a foot rule, but not being successful in doing it to the complete satisfaction of the engineer, he is said to have thrown off his overcoat and given a practical demonstration. Although Watt never took up the subject of steam navigation and never made a marine engine, still he was in reality its originator, because he discovered and provided the means by which it could be applied with advantage to the propulsion of ships. Each of his great improvements upon the old engine that worked by atmospheric pressure and condensed its steam in the cylinder—such as the separate condenser, the working by steam pressure as well as by pressure obtained by vacuum, the double action of the steam in the cylinder on both sides of the piston, working the steam expansively, the centrifugal governor for automatically regulating the speed of the engine, and many others—was a direct adaptation for marine purposes.

There is one point in the history of shipping at which we can draw a definite line between old and new when changes were made so radical in their nature, and so rapid and universal in their operations, that all which came after is fundamentally different from what existed before. The period of transition falls in the early part of the present century, when the propulsion of ships by steam power was substituted for propulsion by the wind—the motive power that had been employed from time immemorial—and when the material out of which their hulls were built was changed from wood to iron. The lateness of this period and its near proximity to the present, is illustrated by the fact that it was not till after the accession of H.M. Queen Victoria that steamships and ships built of iron came to be regularly employed in ocean navigation. At the close of the first third of the nineteenth century, the over-sea trade of the world was carried on with ships that were all built of wood and propelled by sails. Only about 200 of these were over 500 tons in burden, or much over 100 feet long. Nothing approaching to such a rapid and complete revolution as these two great changes brought about in the dimensions, forms, and all the characteristics and qualities of ships, in the conditions of life on board ship, and in travelling by sea, was ever experienced before in the known history of shipping. All the old ships of which we have any knowledge—and by old ships I mean all that existed prior to the introduction of steam—were built and fashioned entirely by manual power, with the aid of very simple tools; and they were either propelled through the water by manual labour, or by sails that could be worked in the simplest manner by the crew. One of the broadest distinctions between the ships of the past that were built of wood and propelled by sails and those of the present that are built of iron or steel and propelled by steam, is that everything had to be done in the former by the hand of man, without any aid from machine tools or other modern labour-saving and labour-helping appliances. And this was so both in preparing the materials used in building the hull and shaping them to their requisite form, putting them in position, fastening them together, and in working the ship at sea and handling the sails so as to make the pressure of the wind most effective for propulsion. In modern ships, almost everything is, on the other hand, done by steam-power in its various applications. It is by this means the plates which form the hull are first of all rolled

[1] Abstract of the Watt Lecture, delivered by Dr. Francis Elgar at Greenock, on January 18.

and are afterwards cut, drilled, bent to the required form, and many of them riveted; and it is by steam-power also that ships, after they are built, are propelled through the water, steered, pumped and drained, ventilated, lighted, loaded and discharged; the anchor is weighed, guns are trained, loaded and fired, and all the principal working operations are carried on. There could have been no great difference in size between the ships of 2000 years ago and the trading vessels of the last century. It is the application of steam-power to propulsion and to manufacture that has enabled vessels to be produced the dimensions and proportions of which were formerly unapproachable. The employment of iron and steel as the material of construction would have been impossible without the aid of steam-power; and it is the extra strength of hull obtained by these means which enables ships to be built of the large size that has now become common. Steam-power has thus not only furnished a mode of propulsion certain and regular in its action, and enabled ships to make their voyages with little or no regard to wind or weather, but it has, in manufacturing the raw material out of which ships are built, permitted the dimensions to be very largely increased, and that not only without risk and inconvenience, but with very great increase of accommodation, comfort, and safety. It is sometimes thought that the largest ships are essentially more unsafe than those of smaller size; the fact is, increase of size enables a vessel not only to be made easier in her movements at sea and less affected by the waves across which she is travelling, but it also enables the largest ships to be divided into so many separate water-tight compartments as to be practically unsinkable by the action of the heaviest seas, or by the worst effects of a collision. I do not say that all large ships are constructed so as to possess this high degree of safety, but many of the latest ones are, and it is perfectly practicable to obtain in cases where safety is the principal consideration. In small vessels the same degree of safety could not always be obtained. Safety is a quality that can be much increased by growth in dimensions.

Although James Watt may not have helped actively in the application of steam-power to ships, it is really to him and his inventions we have to look as the source whence all the great modern improvements in ocean navigation have been derived. We find in James Watt the typical engineer. He was a great philosopher and a great mechanic. He possessed just the combination of qualities and the temperament requisite to enable a man to ascertain what may be learned of the forces of nature and their mode of operation, and to utilise and apply these in the most direct way for producing a required result. He formed that happy union of what is commonly called the "theoretical" with the "practical" man. For as there was no better practical mechanic than Watt in the country, so was there no more diligent student of the sciences related to the subjects of his work, or a more patient and thorough investigator of the principles or theories upon which it depended. He tested everything by experiment; and it is said that when asked an opinion of a novel invention or proposal, his reply invariably was, "Make a model." But having ascertained by experiment all he could learn of the facts connected with any subject he was investigating, he was never satisfied till these could be explained by some physical law with which they could be shown to accord. His mental attitude towards the great mechanical problems he took in hand was that of one engaged in a close and desperate struggle with nature herself, questioning, cross-examining, testing by experiments, attacking from all sides, and refusing to give in till he had succeeded in discovering the particular secret he required to know. A favourite saying of his was, "Nature can be conquered, if we can but find out her weak side."

We thus see what are the qualities necessary to make a great engineer. They are mechanical skill and experience, scientific knowledge and capacity, great powers of observation and original investigation, energy, patience, and untiring perseverance. There have been great engineers who have exhibited certain of these qualities in a very high degree, but none who possessed all together in such full measure and such harmonious blending as we see in the case of Watt. No one man could otherwise, in a few years, have transformed so rude and imperfect a machine as the steam-engine was when Watt first took hold of it into the most perfect instrument that the working capabilities of the time admitted. The proof of Watt's great power as a mechanic and philosopher combined are to be found in the fact that he perfected in such a short time, within the limitations that were imposed by the quality of the materials and the workmen of the day, the greatest work that has been performed by any engineer of modern times.

We often hear the question asked by anxious parents or aspiring youths: How can my son, or how can I, as the case may be, become an engineer or a naval architect? This is sometimes asked as though the making of an engineer or a naval architect were perhaps a matter of three or four years' work in an office, combined with a certain amount of study of books, or attendance at lectures. There are few persons not belonging to one of the many branches of the engineering profession who know what this question really means. Engineering—and when I say engineering, I include in the term shipbuilding and all other branches of that grand profession, "whereby the great sources of power in nature are converted, adapted, and applied for the use and convenience of man"—engineering has of late become somewhat fashionable, and has attracted the notice of classes in the community who at one time would have despised it as a base, mechanic art, and turned their backs upon it. It has apparently acquired the reputation of being a well-paid profession and of being worth belonging to, in a money sense. To the general body of inquirers who thus look to engineering as offering better financial prospects than the army or navy, than the law, medicine, or the Church—including some who think there might be a chance in that direction after failing to qualify for one of the professions named—let me say that the prospects of success are very remote unless he who enters upon it is gifted with mechanical aptitude and skill, is willing to gain experience by a long course of hard work, and at the same time has the capacity, the taste, and the time for acquiring a sound knowledge of the mathematics and the physical sciences that relate to the particular branch of engineering he may think of taking up. Competition is now very keen in all departments of engineering, and what prizes there may be to strive for in them, can only fall to those who are exceptionally gifted with knowledge, experience, energy, and determination. An ordinary student or apprentice who can only learn what some one teaches him, and has not much faculty for independent observation, or for reflecting upon and discovering the causes of the many things he sees going on all around him, is never likely to be more than a subordinate in the ranks of the profession, a hewer of wood and a drawer of water, for others who have greater power of acquiring knowledge, of thinking for themselves, of observing and investigating closely and accurately the causes of defects and difficulties that arise out of their work, and of devising the necessary means of overcoming them.

If poets "are born and not made," I am sure it is equally the case with a great engineer like James Watt. His wonderful mechanical skill and ingenuity were natural to him, and were the means of determining the course his life would take. But even with all that, it is quite clear he could never have made his great discoveries and improvements had he not been a naturally gifted and diligent student, and acquired all the knowledge that was obtainable at the time of mathematics and natural philosophy. It is true that scientific study alone cannot make an engineer; but with the example of such a great mechanic as James Watt before us, it would be very presumptuous for any to say of himself that his own practical knowledge and judgment are sufficient to make him a fully-qualified engineer without studying what others have said or done upon the subjects of his work, or the physical laws that underlie the whole fabric of his practice and ideas. I would be the last to encourage any young man to suppose that a short course of study, or even great progress in mathematics and the physical sciences, would justify him in thinking himself an engineer; but I am at the same time perfectly sure that no one, however great his mechanical skill and ability might be, could ever become an engineer in the true sense of the term without following Watt's example of studying, thinking, and diligently acquiring all the knowledge of nature and nature's laws he can obtain; and applying such knowledge to the better understanding of the principles which relate to his work, and upon which the degree of success he may achieve in it depends.

One other remark with regard to James Watt. I have spoken of the great benefits we have derived in this country from the application of his steam-engine to ocean navigation by drawing the various parts of the world closer towards us, and converting the sea into a broad highway that unites us to the different continents and islands upon it in a neighbourhood which is becoming nearer and more intimate every year. We often speak complacently of the advantage this is to our own country in particular—of what it has done in enormously increasing the wealth and prosperity of the rich, and ameliorating and brightening the lives of the poor—in promoting the growth of our manufacturing trades—in enabling food to be imported from abroad in large and regular supplies at much cheaper rates than we could produce it ourselves in these islands, and in the great increase of population that the growing prosperity of the country and the easier conditions of life have thus brought about. All this is true, and it represents an extent of change and of progress during a short space of time that we can only look and marvel at, as being due to so large an extent to the results of one man's inventions. But there are other feelings with which we do well to regard the matter besides those of wonder and admiration, and of self-satisfaction with the great prosperity and the numerous advantages the country has reaped. We have been favoured above most other peoples by all these great changes, and have been blessed in very bountiful measure. We must not forget, however, that among the privileges we thus enjoy, that of immunity from danger and harm is not included. There are few pleasures or privileges to be had without alloy; and we now find, as a set-off against the benefits obtained through the improvements in ocean navigation, that we have much greater responsibilities and difficulties in protecting ourselves against danger, and in preserving unimpaired for the future the heritage of power and prosperity that has been handed down to us. The same causes that make ocean navigation easy, swift, and certain for us, make it easier also for any possible enemies to attack us. The great increase of population, due to the recent growth of wealth and prosperity, requires for its existence constant supplies of raw material to be kept up from abroad, in order that our surplus hands may be profitably employed in manufactures, and it requires also large and continuous food supplies from outside in order that it may be fed. Hence the great problem of the time for this country—how to protect ourselves against the dangers and drawbacks of the new state of things, while enjoying for the time its advantages and reaping its rewards; and how to effectually shield the vulnerable points in our armour that have arisen out of changes and improvements which brought so much good in other ways. It is upon the sea that any real danger to England would arise; and upon the sea it would have to be met. Let us hope that the nation which has covered all the seas of the world with its ships will not now fail in energy and enterprise, or be slow in providing and maintaining adequate defence of what it has produced with such success, and out of which it has reaped such rich reward. If we were to fail thus in our duties, and so shirk our responsibilities, the improvements and benefits we owe so largely to the genius of James Watt might, after all, prove a curse instead of a blessing; and we should be unworthy of the country and the race which produced the great engineer who taught his contemporaries, more than one hundred years ago, how to manufacture Power.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. Francis Gotch, F.R.S., Holt Professor of Physiology in University College, Liverpool, has been elected to the Waynflete Professorship of Physiology, vacated by the appointment of Dr. Burdon Sanderson to be Regius Professor of Medicine. Prof. Gotch is no stranger to Oxford, having been for some years assistant to his predecessor in the Waynflete Chair.

CAMBRIDGE.—Dr. W. S. Lazarus-Barlow, of Downing College, has been appointed Demonstrator of Pathology in the room of Dr. J. Lorrain Smith, who has been elected Lecturer in Pathology at Queen's College, Belfast.

The Examination in Sanitary Science for the University Diploma in Public Health will begin on April 2.

Hitherto one of the conditions which had to be fulfilled before the Science and Art Department made payments to the Committees of schools or classes, for the instruction of students, has been that the parents of a student should not have an income exceeding £400 a year from all sources. A Blue-paper now informs us that the Lords of the Committee of Council of Education have decided to enlarge this limit to £500 per annum. In future, therefore, the student on account of whom a claim is made must belong to the category of "persons in the receipt of not more than £500 a year from all sources, that is, who are allowed an abatement of the income-tax; and their children if not gaining their own livelihood." This example could be followed with advantage by the Technical Education Committees of those County Councils that restrict their Scholarships to competitors whose parents are in receipt of less than £120 a year.

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, No. 1.—Is the declination indicated by a compass independent of its magnetic moment? by Ch. Lagrange. According to Gauss's theory it may be assumed that the magnetic axis of a magnet lies in the direction of the lines of force of the field, whatever its magnetic moment may be. But in practice it is found that the orientation of a magnet depends upon the strength of its magnetisation. Since these systematic differences are not due to magnetic force, they must be due to some other force, probably a force hitherto unknown. Hence the magnetic chart of the earth calculated by Gauss's theory cannot be considered rigidly correct. A new constant must be introduced, depending upon the declinometer. The author foreshadows an explanation of these facts, based upon the "circulation of the ether," and intimately associated with the physics of the globe.—Double decompositions of vapours, by Henryk Arctowsky. It is not necessary that two substances should be dissolved in water to bring about their mutual decomposition; or their "ionisation," in terms of the electrolytic theory, is not altogether dependent upon water. Freshly sublimated mercuric chloride and flowers of sulphur were placed in small vessels inside a Bohemian glass tube over an organic combustion furnace. A current of pure dry hydrogen was introduced, which on heating formed sulphuretted hydrogen with the sulphur. This gas and the vapour of $HgCl_2$ gave a precipitate of mercuric sulphide on the walls of the tube. This reaction, which is contrary to Berthelot's principle of maximum work, does not take more time than the corresponding reaction in water. To prove that it was a true double decomposition, CO_2 was substituted for the hydrogen, when it was found that the sulphur vapour alone was unable to attack the mercuric chloride.

Bulletin de l'Académie des Sciences de St. Pétersbourg, fifth series, vol. 1, No. 4, 1894.—Minutes of proceedings for October last.—On derived functions of superior orders, by N. Sonin (in Russian).—Crustacea Caspia: contributions to the knowledge of the Carcinological fauna of the Caspian Sea, by G. O. Sars (in English, with eight plates). The Gammarideæ are continued, and the following species, mostly new, are described and figured: *Gammarus Warpachowskyi*, *minutus*, *macrurus*, *compressus*, *similis*, *robustoides*, *crassus*, *abbreviatus*, and *obesus*, and *Niphargoides caspius*, Grimm.—On the transformation of Periodical Aggregates, mathematical paper by H. Gyldén (in German).—On Free Energy, by B. Galitzine (in Russian).

SOCIETIES AND ACADEMIES.

LONDON

Royal Society, January 24.—"Notes of an Inquiry into the Nature and Physiological Action of Black-damp, as met with in Podmore Colliery, Staffordshire, and Lilleshall Colliery, Shropshire." By Dr. John Haldane.

Black-damp, sometimes also called choke-damp, or "stythe," is one of the gases frequently found in the workings of coal mines. It is distinguished from fire-damp by the fact that it is not explosive when mixed with air, but extinguishes flame; and from after-damp by the fact that it is not the product of an explosion, but collects in the workings under ordinary conditions. Like after-damp and fire-damp, it produces fatal effects when inhaled in sufficient concentration. A further distinction has been drawn between black-damp and white-damp, which latter is described as capable of supporting combustion, while at the same time acting as a poison when inhaled.

The author has made a number of observations on concentrated black-damp from two pits, the first being in a fiery and the second in a non-fiery district. The conclusions arrived at are as follows:

(1) The specimens of black-damp consisted when undiluted of nitrogen containing an admixture of a seventh to an eighth of its volume of carbonic acid.

(2) Air containing just sufficient black-damp to extinguish a candle or oil lamp produced no immediately sensible action on a man. A mixture of about 16 per cent. of the black-damp and 84 per cent. of air extinguished candles and lamps, whereas a mixture of about 60 per cent. of the black-damp and 40 per cent. of air would be required to produce immediate danger to life.

(3) The dangerous physiological action of black-damp is due to deficiency of oxygen, not to excess of carbonic acid. The effect first appreciable when increasing proportions of black-damp are breathed is, however, due to carbonic acid alone.

February 21.—"The Composition of the Extinctive Atmospheres produced by Flames." By Prof. Frank Clowes.

In a former paper (*Roy. Soc. Proc.*, vol. lvi.), the author communicated the results obtained by mingling gases, which were extinctive of flame, with air, until a flame burning in the air was just extinguished. The gases used in the experiments were carbon dioxide and nitrogen. Each of these gases was separately introduced into the air, and the composition of the atmosphere thus produced, which just extinguished flame, was determined by chemical analysis.

The general results arrived at were:—

(1) That wick-fed flames require atmospheres of very similar composition to extinguish them: while gas-fed flames require atmospheres of widely differing composition.

(2) That nitrogen must be added in larger proportion than carbon dioxide, in order to extinguish the same flame.

(3) That the minimum proportion of extinctive gas which must be mingled with air in order to extinguish a flame is independent of the size of the flame.

A supplementary series of experiments has now been undertaken in order to determine the composition of the atmosphere extinctive of each flame, which is produced by the flame itself when burning in an enclosed volume of air at atmospheric pressure. The apparatus used and the method of experimenting are fully described.

As in the previous series of experiments (*loc. cit.*) the combustible substances used were chiefly those which are burnt for ordinary heating and lighting purposes—namely, alcohol (absolute), alcohol (methylated), paraffin (lamp oil), colza and paraffin, candle, hydrogen, carbon monoxide, methane, and coal-gas.

Determinations were made of the percentage composition of the residual atmospheres left by the flames, and these were compared with the composition of the artificial atmosphere in which flame is just extinguished, and with the composition of atmospheres which are respirable according to the recent experiments of Dr. Haldane (*Proc. Roy. Soc.*).

The conclusions drawn from the tabulated results of the experiments published in the paper are that:—

(1) The flames of the combustible gases and liquids, which were experimented upon, produce, at the point of extinction in an enclosed atmosphere, a change in the proportion of oxygen in the air generally corresponding to that produced by preparing extinctive atmospheres by artificial mixture.

(2) The flames of candles and lamps, when they are extinguished by burning in a confined space of air, produce an atmosphere of almost identical composition with that of air expired from the lungs.

(3) The extinctive atmospheres produced by the combustion of the flames of candles and of lamps, and the air expired from the lungs after inspiring fresh air, are respirable with safety.

(4) The extinction of an ordinary candle or lamp flame is not necessarily indicative of the unsuitability of an atmosphere to maintain life when it is breathed.

Geological Society, February 6.—Dr. Henry Woodward, F.R.S., President, in the chair.—On bones of a Sauropodous Dinosaur from Madagascar, by R. Lydekker, F.R.S. The bones described in the paper were collected by Mr. Last to the east of the town of Narunda, on the north-eastern coast of Madagascar. They include vertebræ, limb-bones, and portions of pectoral and pelvic girdles. These bones were described in detail, and the animal which possessed them was referred to the genus *Bothriospondylus*, Owen; a dorsal vertebra, described in the paper, being taken as the type of the new species. The identification of the Malagasy reptile with a type occurring in the Jurassic rocks of England harmonises with the reference of some of the strata of the island to the Jurassic period.—On the physical conditions of the Mediterranean basin which have resulted in a community of some species of freshwater fishes in the Nile and the Jordan waters, by Prof. E. Hull, F.R.S. The author summarised the evidence in favour of the existence of barriers in post-Miocene times, separating the Mediterranean area into a chain of basins. He brought forward arguments in support of his contention that the waters of the eastern (Levantine) basin became fresh during a period when the area of evaporation was smaller, and the supply of river-water greater, than at present. Into this freshwater lake the waters of the Nile would flow directly. He had elsewhere given reasons for believing that the Jordan Valley from Lake Huleh to Arabah was the bed of a lake over 200 miles long, and at least 1300 feet above the present level of the Dead Sea. He suggested that the waters of this lake escaped into the Levantine basin through the plain of Esdraelon. With such physical conditions existing, the fauna of the Levantine basin would have had a means of spreading throughout the whole system of waterways connected with it. In conclusion the author added some observations on the changes which occurred in the Mediterranean area subsequent to the post-Miocene epoch of earth-movement.—On the loess and other superficial deposits of Shantung (Northern China), by S. B. J. Skertchly and T. W. Kingsmill The following deposits were described in the order of their antiquity:—(1) Recent fluviatile deposits. (2) Marine sands with *Cardium*, *Ostræa*, and *Bulla*, extending to a height of 200 feet above sea level, and indicating former submergence to that amount. (3) Old river gravels, often resting on loess, and possibly contemporaneous with the marine gravels. They furnish part of the evidence relied on by the authors for supposing the existence at that time of a climate moister than the present one. (4) Loess. (5) Basement-gravels having the same relation to the loess that the Upper Greensand bears to the Chalk. The loess east of the Pamirs is extensively developed over an area of over one million square miles. It is sometimes over 2000 feet thick, and occurs up to several thousand feet above sea-level. Evidence was brought forward by the authors with the intention of establishing the absolute want of connection between the Chinese loess and the present river-systems, its original stratified condition (as shown by variation of tint and horizontality of layers of concretions), and its subsequent rearrangement to a great extent. The absence of marine shells was discussed, and the suggestion thrown out that the shells had been destroyed by percolating water. The authors gave their reasons for supposing that the loess is a marine formation, and stated that the sea need not have reached to a higher level than 600 feet above the present sea-level, for the Pamir region where it occurs, 7000 feet above the sea, is an area of special uplift. They maintained that there are no proofs of the glaciation of Northern and Eastern Asia, so that Chinese loess could have no connection with an area of glaciation. They stated that the zoological, ethnological, historical, and traditionary evidence alike pointed to the former depresssion of Asia beneath the sea, and the subsequent desiccation of the land, consequent upon re-elevation.

Mathematical Society, February 14.—Mr. A. B. Kempe, F.R.S., Vice-President, in the chair.—The chairman announced the decease, since the January meeting, of Prof. Cayley, F.R.S., and Sir J. Cockle, F.R.S., and stated that the Society had been represented at the funeral of the former by the President, himself, and Profs. Elliott, F.R.S., and Henrici, F.R.S. Messrs. Walker, F.R.S., Glaisher, F.R.S., and Elliott, F.R.S., paid tributes to the memory of the deceased gentlemen, and a resolution was passed unanimously that the President (Major Macmahon, F.R.S., who was absent owing to a domestic affliction) be requested to convey, in such form as he should think fit, votes of condolence from the Society to Mrs. Cayley and Lady Cockle.—Dr. Hobson, F.R.S., gave a brief sketch of a paper, by Mr. H. M. Macdonald, on the electrification of a circular disc in any field of force symmetrical with respect to its plane.—Prof. Elliott read a paper on certain differential operators, and their use to form a complete system of seminvariants of any degree, or any weight.—Prof. W. Burnside, F.R.S., sent notes on the theory of groups of finite order, iii. and iv. Herr Hölder, in a paper in the *Math. Ann.* vol xl., and Dr. Cole, in a paper in the *American Journal of Mathematics*, vol. xv., have determined all the simple groups whose orders do not exceed 660. The only other known results in connection with the question as to whether there is a simple group corresponding to a given order are as follows. There is no simple group whose order is the power of a prime, or whose order contains two or three prime factors; and the only simple group whose order contains four prime factors is a group of order 60. The latter result was established in a paper published in vol. xxv. of the *Proceedings* of the Mathematical Society. The present paper aims at an extension of these results. If $p_1, p_2, \ldots p_n$ are distinct primes in ascending order, it is shown that in a group of order

$$p_1 p_2 \ldots p_{n-1} p_n^m$$

the number of operations whose orders are divisible by p_s and by no lower prime is

$$(p_s - 1)p_{s+1} \ldots p_{n-1} p_n^m,$$

from which it follows at once that a group whose order is of this form can neither be simple nor contain a simple sub-group.[1] It is also shown that a group whose order is of the form

$$p_1^2 p_2 \ldots p_{n-1} p_n^m$$

cannot be simple, and cannot contain a simple sub-group, with the exception of the case in which it contains a tetrahedral sub-group; in which case $p_1 = 2$, $p_2 = 3$. Thirdly, it is shown, with certain limitations, that if no prime entering in the order of a group, except the greatest, appears to a higher power than the second, the group cannot be simple. Fourthly, it is proved that no groups whose orders are of the forms

$$p_1^m p_2 \text{ or } p_1^m p_2^2$$

can be simple. A deduction from these results of general form, aided by the consideration of certain more particular cases, is that the only simple groups whose order is the product of five primes are the known simple groups of orders 168, 660, and 1092. Finally, it is shown that if in a group of order

$$p_1^{m_1} p_2^{m_2} \ldots p_{n-1}^{m_{n-1}} p_n^{m_n}$$

the sub-groups of order

$$p_1^{m_1}, p_2^{m_2}, \ldots p_{n-1}^{m_{n-1}}$$

are all cyclical, the group cannot be simple, and cannot contain a simple sub-group.

Entomological Society, February 20.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. W. M. Christy exhibited specimens of *Lycæna agestis*, caught in Sussex, last summer, which had a white edging round the black discoidal spot. He said the specimens might, perhaps, be identical with the northern form of the species known as the variety *salmacis*.—Mr. H. Goss exhibited a small collection of Lepidoptera from the South of France, made by Mr. Frank Bromilow.—Prof. Meldola invited discussion upon the address delivered by Mr. Elwes, as retiring president, on the "Geographical Distribution of Butterflies," at the last annual meeting. He remarked that he had not himself had time to consider the paper in an adequate manner, but he thought that the discussion might lead to a useful expression of opinion if the speakers would deal with the question as to how far the scheme of distribution advocated by Mr. Elwes was borne out by a comparison with other orders of insects. He was of opinion that in considering schemes of geographical distribution, the results arrived at were likely to be of greater value the wider the basis on which they rested, and he therefore suggested that the question might also be taken into consideration as to how far it was justifiable to draw conclusions from the consideration of one division or one order only. Dr. Sharp, F.R.S., remarked that geographical distribution consisted of two divisions; firstly, the facts; secondly, the generalisations and deductions that may be drawn from them. He thought that as regards insects generally our knowledge of the facts was not yet sufficient to warrant many generalisations. Still the impressions of those who have paid attention to particular groups of insects are even now of some importance, though at present based on incomplete knowledge. He thought the Rhopalocera would prove to be a somewhat exceptional group in their distribution. Notwithstanding that Australia and New Zealand are so poor in them, this was by no means the case with their Coleoptera, Australia being very rich, and its fauna of Coleoptera being very distinct. He thought that if Lepidoptera generally were well collected in Australia and New Zealand, it would be found that this order was not so poor in species as was supposed. He instanced the case of the Sandwich Islands, where it was supposed that there were very few species of Lepidoptera, and yet some 500 species, or perhaps more, had been recently found there by Mr. R. C. L. Perkins, who had been sent to investigate the islands by a committee appointed by the Royal Society and British Association.—Mr. McLachlan, F.R.S., said he was of opinion that no definite demarcation of regions existed, but that all the regions over-lapped; in any case the retention of Palæarctic and Nearctic as separate provinces was not warranted on Entomological data. He believed that at the close of the Glacial period some insects instead of going north were dispersed southwards, and that the present geographical distribution of some forms might thus be accounted for. The discussion was continued by Mr. Osbert Salvin, F.R.S., Mr. J. J. Walker, Herr Jacoby, Mr. Champion, Mr. Elwes, and Prof. Meldola.—The Rev. T. A. Marshall contributed a paper entitled "A Monograph of British Braconidæ, Part vi."—Mr. J. W. Tutt read a paper entitled "An attempt to correlate the various systems of Classification of the Lepidoptera recently proposed by various authors." In this paper he criticised the opinions recently expressed by Mr. G. F. Hampson, and Dr. T. A. Chapman, in certain papers published by them. A discussion ensued, in which Mr. Elwes, Prof. Meldola, and Mr. Tutt took part.

Zoological Society, February 19.—Sir W. H. Flower, K.C.B., F.R.S., President in the chair.—Mr. F. E Beddard, F.R.S., read a paper in which he gave a description of the brain of the Glutton (*Gulo luscus*).—A second paper by Mr. Beddard contained a description of the brain of different species of Lemurs that have died in the Society's Gardens, pointing out the range of variation to be observed in the cerebral convolutions of this order.—A communication was read from Mr. C. Davies Sherborn and Dr. F. A. Jentink, in which was given the dates of the publication of the parts of Siebold's "Fauna Japonica" and Giebel's "Allgemeine Zoologie" (first edition).—A communication was read from Dr. J. de Bedriaga, "On the Pyrenean Newt, *Molge aspera*, Dugès," dealing with the external, osteological, and larval characters of this imperfectly-known Batrachian, and giving an account of its habits.

Linnean Society, February 21.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. J. H. Vanstone exhibited specimens of some nearly allied Hydrozoa, namely, *Bougainvellea ramosa* and *B. musca*, and after demonstrating their structure, gave reasons for concluding that although the latter had been described as distinct by Prof. Allman, the characters relied upon were not of specific value but simply varietal.—Mr. George Brebner exhibited some lantern slides of *Glœosiphonia capillaris* and other Algæ, with accompanying descriptions, and gave an interesting account of his method of preparing slides in colours.—On behalf of Mr. J. Boerlage, the President demonstrated the chief points in a paper communicated by him on the identification of *Chionanthus Ghæri*, an obscure species figured by Gaertner at the end of the last century in his famous work "De fructibus et seminibus Plantarum," but hitherto undetermined. From the researches of Mr. Boerlage it now appeared that it was evidently referable to *Seitpodendron costatum*, Kurz. This was made clear by the excellent drawings which accompanied the paper, as well as by the specimens which were exhibited.—A paper was then read by Mr. E. M. Holmes, on new marine Algæ from Japan. The author pointed out that up to the present time the known species of Algæ from that country did not exceed 300, or about half the number found in Great Britain; but that the districts around three centres only had been explored, namely Hakodadi, Tokio, and Nagasaki, notwithstanding the fact that seaweeds are largely used as food by the Japanese, and form an important article of commerce. The paper included descriptions of twenty-three new species (the structure of which was shown by means of the oxyhydrogen lantern) belonging to the genera *Cladophora*, *Codium*, *Dictyota*, *Dictyopteris*, *Polyzonias*, *Chondrus*, *Gracilaria*, *Grateloupia*, *Gymnogongrus*, *Halymeria*, *Lethershedtia*, and *Padina*.

[1] It has been pointed out to the author since the paper was communicated to the Society, that this first result is contained in a paper by Herr G. Frobenius, *Berliner Sitzungsberichte*, 1893.

CAMBRIDGE.

Philosophical Society, February 25.—Mr. R. T. Glazebrook, Treasurer, in the chair.—On binocular colour mixtures, by Dr. W. H. R. Rivers. Two methods of producing binocular colour mixture were shown—by Wheatstone's stereoscope and by a modification of Hering's method devised by Mr. E. T. Dixon. Colour mixture and rivalry were described as occurring in the after-image following binocular combination of coloured patches.—On a new parasite probably allied to Echinorhynchus, by Mr. A. E. Shipley. The specimens described came from the skin of a bird *Hemignathus procerus*, taken by Mr. Perkins in the Island of Kauai, one of the Sandwich Islands.—Notes on Pachytheca (with exhibition of specimens), by Mr. A. C. Seward. The genus *Pachytheca* from Silurian and Devonian rocks of Britain and Canada has been a subject of discussion among palæontologists ever since its discovery in 1853. Several writers have placed the fossil among Algæ, and this position has been assigned to it on the grounds of a supposed resemblance of its histological structures to that of certain recent genera. An examination of a series of microscopic sections prepared by Mr. Storrie, of Cardiff, has led the author to doubt the sufficiency of the evidence on which the comparison with any existing alga has been based, and to regard *Pachytheca* as an organism of uncertain position which might well receive attention at the hands of zoologists.

PARIS.

Academy of Sciences, March 4.—M. Marey in the chair.—The life and works of Admiral Pâris, member of the Geography and Navigation Section, by M. E. Guyou.—Axoïds of two plane lines, by M. H. Resal.—Prophylactic remedy for marsh-fevers, by M. d'Abbadie. The use of a daily fumigation of the body with sulphur is urged as a preservative against intermittent fevers in malarial districts.—On the interior pressure and the virial of the interior forces in fluids, by M. E. H. Amagat. A mathematical paper in which the variations of certain theoretical constants, deduced from the results of the experimental determinations of the properties of gases under high pressures, are discussed.—Observation of Wolf's planet BP, made at Toulouse Observatory, by M. F. Rossard.—Rectification of some arithmetical theorems, by P. Pepin.—The month of February, 1895, at Parc de Saint-Maur Observatory, by M. E. Renou. A discussion of the meteorological conditions obtaining in the neighbourhood of Paris. It is shown that a continued low temperature is very rare in February. The mean temperature of the month is given at $-4°\cdot45$. The minimum temperature was reached on the 7th at Parc de Saint-Maur $-15°\cdot4$, and at Châteaudun $-14°\cdot6$, and on the 9th at Vendôme $-19°\cdot4$. At the first-named station the earth was frozen beneath turf to a depth of 0·53 metres, and in the kitchen-garden to a depth of 0·65 metres.—Panoramic views obtained with the repeating twin-camera, by M. J. Carpentier.—Basic and acid oxides and sulphides. Zinc sulphide, by M. A. Villiers.—Calorimetric researches on dilute solutions. Sodium acetate, by M. E. Monnet. The heat of solution of sodium acetate augments with the concentration of the solution.—On hexamethylene-amine; ammonium salts; action of acids; production of primary amines, by M. Delépine. The reaction of acids on the ammonium iodides of hexamethylene-amine. $C_6H_{12}N_4.RI + 6H_2O = 6CH_2O + 3NH_3 + NRH_3I$, is given as a new method of forming primary amines. The use of bismuth potassium iodide for the isolation of these primary amines is noted.—On the composition of French and foreign oats of the 1893 crop, by M. Balland.—New considerations on the comparative anatomy of the limbs, by M. J. P. Durand (de Gros). M. Edmond Perrier followed up this paper with a discussion of the theory of the compound nature of the higher animal organisms.—On a disease of the spiny lobster, by MM. E. L. Bouvier and Georges Roché.—On the formation of the shell of molluscs, by M. Moynier de Villepoix.—On the diffusion of perfumes, by M. Jacques Passy.—Researches on the fertilising materials required by the vine, by M. A. Müntz. The following conclusions have been arrived at: (1) In all vineries the absorption of nitrogen and potash is much more considerable than that of phosphoric acid. (2) Nitrogen is absorbed in large quantity by the vine, and, contrary to widely received opinions, nitrogenous manures ought to be used; these are in other respects the most effective. (3) In the southern vineyards, nitrogen is absorbed in greater proportion than potash; in more northern regions potash is most absorbed. (4) Notwithstanding the enormous difference in yield, the southern vine requires no greater amount of nutritive materials than the vines of more temperate climates. (5) The quantity of fertilising elements used by the vine per hectolitre of wine produced is three or four times more considerable in the more northern districts than in the south.—On the abnormal partitions of the fronds of ferns, by M. Adrien Guébhard.

MODERN BACTERIOLOGY.

Lehrbuch der Bakteriologischen Untersuchung und Diagnostik. By Dr. Ludwig Heim, Crown 8vo. Pp. 528. (Stuttgart: Verlag von Ferdinand Enke, 1894.)

THE writer of this volume takes care to leave us in no doubt as to its purpose. We are told in the preface, "Für den Praktiker ist dieses Buch geschrieben." Again, "Ein Lehrer und ein Führer soll dies Buch sein." Even the unfortunate student, who, in spite of attending a practical course on bacteriology, has failed to carry away an adequate knowledge of his subject, is to turn to this book for consolation, where "he may yet arrive by its assistance at his goal, providing he follow step by step and point by point the instructions which it contains."

But after a careful perusal of this bulky octavo volume, we find ourselves unable to agree with the author's estimate of his book. It contains a mass of facts, a bewildering maze of detail through which we think no student would have the patience to thread his way, much less the student who has failed in spite of passing through a course of practical instruction. Possibly Dr. Heim knows too much, or is too generous in giving his knowledge away. A little more reticence would have not only made his book less unwieldy in dimensions, but the whole treatment of the subject would have gained in simplicity.

The excessive love of minute detail is characteristic of most German text-books, but we do not think the following example of it will easily be surpassed: "Smokers must put their cigars or cigar-ends so down that the burning part rests on the table, the mouth-piece remaining free. Eating must not under any circumstances be carried on in the laboratory. The moistening of the fingers in the mouth is to be rigidly avoided. Gum labels must only be wetted with water." We can only say that if the student approaches his subject with as little feeling for it as the necessity of these instructions implies, he will, we predict, never do much, however often he may read through Dr. Heim's volume!

The work is divided into three parts—bacteriological manipulations, including microscopic investigations; the preparation of culture media, and experiments on animals. The latter section is given in greater detail than in most text-books, and is very clearly described. Secondly, the morphological and other characteristics of bacteria, containing an admirable though brief account of the subject of immunity and the latest developments of serum therapeutics. Thirdly, the diagnosis of bacteria in disease, as well as their demonstration in our surroundings. The information imparted is, in nearly all cases, gathered from the most recent publications in Germany; but on consulting the list of journals referred to in the text, the only foreign publication considered worthy of notice is the *Annales de l'Institut Pasteur*, English periodicals being completely ignored, as well as the excellent *Annali dell' Istituto d'Igiene Sperimentale*, published in Rome, and the official reports, published in St. Petersburg, of the work carried out in the Imperial Institute of Experimental Medicine.

This accounts for the omission of all reference to Palermo's most interesting experiments on the attenuation of the pathogenic properties of the cholera bacillus through exposure to sunshine. In the section describing the methods which may be adopted for reducing and increasing the virulence of particular bacteria, mention is made of Arloing's isolated investigation on the attenuation of the disease-producing powers of the anthrax bacillus through three hours' insolation; but the fact is passed over, that Palermo succeeded in reducing cholera bacilli to the condition of vaccine through the action of sunshine, so that guinea-pigs, when inoculated first with *insolated* cholera bacilli, and then with ordinary virulent cholera bacilli, instead of dying, as usual, in about eighteen hours, remained alive.

The survey of the present state of our knowledge on the question of immunity is, perhaps, the most interesting and best-written portion of the book. Theoretical considerations of the subject are kept in abeyance, and prominence is only given to the practical outcome of the investigations which have been made. The results of Roux's application of serum in the treatment of diphtheria in the Paris hospitals appeared too recently to admit of incorporation here. In the section on the production of spores, the author throws doubt on Roux's method for obtaining anthrax bacilli permanently deprived of their power of producing spores, so-called *asporogene* anthrax. He states that he has not been able to succeed in procuring such a race of anthrax bacilli, although he has made numerous attempts with the utmost regard to Roux's recipe. The method devised by Phisalix is preferred, which consists in prolonged exposure of anthrax cultures to a temperature of from 30° to 42° C.; but this device only answers as long as the bacilli are kept in ordinary culture media, for even when introduced into broth containing a fraction of guinea-pig's blood, they are at once sufficiently revived to produce spores.

In describing the capacity for multiplication possessed by bacteria, an interesting experiment is cited, which we do not remember having seen elsewhere, showing that 149 cholera bacilli kept at 37° C. had within three hours increased to as many as 96,000, and that the minimum time occupied by these bacilli in the production of a new generation was twenty minutes. This involves, however, the assumption that in the process of multiplication from every individual cell two new ones are started, never more or less.

The concluding portion of the volume, which deals with bacteriological diagnosis, and occupies close upon 200 pages, is helpfully illustrated by photographic plates of many pathogenic micro-organisms. In this section, in speaking of the vexed question of the microbic origin of scarlet fever, Dr. Heim considers that the cause of this disease has not yet been discovered, and that the streptococci which have been found by various observers must be regarded as a secondary and not primary infection; in his own words, "man muss sich wohl hüten dabei die Grundkrankheit zu übersehen." According to Doehle, scarlet fever may be with more likelihood ascribed to protozoa; and this authority is of opinion

Y

that similar organisms may very possibly be found to be the exciting cause of both measles and small-pox. In malaria protozoa are now accepted as the origin of the disease, and a similar suggestion has been made to account for yellow fever in the absence of all trustworthy microbic evidence. The examination of air, water, &c., for micro-organisms, is, of course, only dealt with in a very cursory manner. In the small section devoted to water-bacteriology, we are glad to find Dr. Heim calling attention to the errors which may so easily occur in the correct numerical estimation of bacteria in water.

Dr. Heim has spent an immense amount of patient labour on the compilation of this volume, and he approaches his subject invariably from the point of view of a man who has worked out things and problems for himself; it is thus that his book acquires an original flavour, which, whilst making it more palatable to the teacher, renders it less likely to find favour, or prove useful to the student. We venture to think that it will, in the concluding words of the preface, "sich den Herrn Kollegen nützlich erweisen"; and it must in any case be regarded as a responsible and noteworthy contribution to the bacteriological text-books, now fairly numerous, already in existence.

G. C. Frankland.

CHEMICAL ANALYSIS.

Die wissenschaftlichen Grundlagen der analytischen Chemie. Von W. Ostwald. (Leipzig: Wilhelm Engelmann, 1894.)

THE Professor of Chemistry in the University of Leipzig has taken so assiduously to the making of books that, as regards the fruitfulness of his pen, he may well take rank with even the more prolific of our writers of fiction. Despite this fact, it is not too much to say that none of his productions will appeal to a larger section of the chemical public than the little volume under notice. For although it is professedly a work on general analytical chemistry, it will mainly make its mark as a concise exposition of qualitative analysis, based upon the most recent developments of chemical theory.

The author first deals with the modes of recognising substances—*Zustands-* and *Vorgangseigenschaften*—and the modes of separating substances prior to recognition. Amongst other things the theory of filtration and washing is discussed, together with the complication introduced by "adsorption"—that curious property in virtue of which the concentration of a solution near the surface of an immersed solid is greater than the average concentration. Separation, it is emphasised, must always be mechanical, and if it cannot be effected directly by the physical methods described, such as distillation or the action of solvents, chemical operations, such as form the subject-matter of qualitative analysis, have first to be performed.

At this point we meet with views which are novel in an analytical text-book. The theory of analysis, it is urged, is now upon a new platform. With van't Hoff and Arrhenius, we must regard the properties of dilute solutions of acids, bases, and salts as mainly those of their ions; and herein lies a simplification of the utmost importance, for it is possible to express in terms of the properties of, say, 50 anions and 50 cathions the properties of the 2500 odd salts to which they may give rise. A digest of the new theory of the constitution of solutions is here given, and of the mode in which the law of mass action may be extended to analytical reactions by regarding the ions as individual substances.

A precipitate in its mother-liquor we are to regard as a system in equilibrium. Precipitation is never complete. On precipitating $BaSO_4$, for example, a small amount remains in solution, and portion of this is dissociated into the ions Ba and SO_4. The precipitate is in equilibrium with the soluble $BaSO_4$, while it in turn is in equilibrium with the ions. Now the active mass of a solid is constant, hence for equilibrium the product of the concentrations of the ions in the solution must have a definite value—the solubility product. If the product be raised above this definite value, more precipitate must form; if it be lowered, more precipitate must dissolve. We have here a reason for the common practice of adding an excess of precipitant in order to ensure complete precipitation. In the case quoted the solubility product of the $BaSO_4$ will be partly kept up to the necessary value by means of the Ba ions of the excess of precipitant, and hence less $BaSO_4$ will require to remain in solution. This is a particular instance of the general rule that the solubility of a substance is diminished by the presence of another having an ion in common with it.

We can thus formulate a theory of precipitation. It is in general the result of interaction between ions; consequently, if on mixing two solutions ions are present which can form a substance having a sufficiently small solubility product, that substance is precipitated, and causes which affect the solubility product are the causes affecting the precipitation. Here are one or two instances of this method of treating analytical reactions.

The solubility of $Mg(HO)_2$ in water is regulated by the solubility product of Mg and HO ions. If hydrochloric acid, which is almost completely dissociated, be added to the water, the H ions of the acid at once unite with the HO ions of the dissolved $Mg(HO)_2$ to form water, because water is practically undissociated. In this way the solubility product of the $Mg(HO)_2$ is diminished, and more solid $Mg(HO)_2$ must dissolve in order to maintain the product at the value necessary for equilibrium. If sufficient HCl be present, all the $Mg(HO)_2$ will pass into solution.

The following case of precipitation is more complex:—If CO_2 be passed through a solution of $Pb(NO_3)_2$, little or no precipitate is obtained, whereas two-thirds of the lead is thus removed from a solution of $Pb(C_2H_3O_2)_2$. In solution carbonic acid is but slightly dissociated into its ions 2H and CO_3; yet if $Pb(NO_3)_2$ be present, the product of the concentrations of the Pb and CO_3 ions is greater than the solubility product of $PbCO_3$; hence a precipitate forms. At the same time, however, HNO_3 is produced, and H and NO_3 ions accumulate in the solutions, since HNO_3 is strongly dissociated. Now H ions diminish the electrolytic dissociation of the H_2CO_3 just as excess of NH_3 or HCl diminishes the ordinary dissociation of NH_4Cl. The solubility product of the CO and Pb ions is thus diminished, and but a small quantity of HNO_3 has to accumulate, that is, but little decomposition has to take place, before the solubility product is reduced to the critical value, and no more precipitate is produced.

If $Pb(C_2H_3O_2)_2$ be used, since acetic acid is but feebly dissociated, much more precipitate can be produced before the H ions introduced into the solution by the acetic acid are numerous enough to reduce the solubility product to the critical value, and thus stop further precipitation.

Reactions may also be due to the formation of complex ions. Alumina in presence of water is in equilibrium with the ions Al and 3OH. If KOH be added, K_3AlO_3 is produced, of which the ions are 3K and AlO_3. The latter is not available for equilibrium with alumina, hence the solubility-product is reduced, and more alumina must dissolve.

With a chapter on quantitative estimations, such is the subject-matter of the theoretical part of the book. The second, or practical part, is concerned with the important reactions of qualitative analysis, treated as much as possible from the above standpoints.

The book is not written for the beginner, but to supply adequate theoretical support to the routine work of general analytical chemistry. Enough has been said to show that it is in great part unique, and throughout it is refreshing and profitable reading; indeed, it affords the easiest means yet offered to the general reader of getting the gist of current views, not only of the theory of analytical processes, but of the constitution of solutions, and of chemical mechanics—the law of mass action and the velocity of chemical change.

The ideas put forward relating to the nature of analytical processes are, of course, open to differences of opinion. The time has no doubt passed when the conceptions of ions and electrolytic dissociation were regarded as but the vain imaginings of mathematicians who had dabbled in chemistry. Nevertheless the view is still widely spread, at any rate in this country, that although they serve as a means of correlating otherwise isolated properties, and of predicting phenomena in solution, they are altogether too artificial to be anything but the crudest picture of what actually exists. Be this as it may, the book before us serves a good purpose, inasmuch as it puts in a clear light the fact that the direction of analytical reactions is determined by the solubility of the possible products of the interaction, and that when the reaction has run its course we have a system in equilibrium again governed by solubility.

In the common method of presenting qualitative analysis to the student, theoretical considerations are either entirely ignored, or are supposed to be supplied by statements asserting that a precipitate AB is formed in a given solution because the affinity of A for B is greater than its affinity for the other radicles present. It is this system, coupled with the abuse of the ordinary chemical equation, whereby all reactions are regarded as perfect, that fills the ranks of budding chemists with disciples of Bergmann, the gospel according to Berthollet, Wenzel, and Guldberg and Waage, notwithstanding.

J. W. RODGER.

ANALYTICAL GEOMETRY.

An Introductory Account of certain Modern Ideas and Methods in Plane Analytical Geometry. By Charlotte Angas Scott, D.Sc., Professor of Mathematics in Bryn Mawr College, Pennsylvania. Pp. xii. + 288. (London: Macmillan and Co., 1894.)

DR. SCOTT'S treatise is a welcome addition to the many excellent text-books on analytical geometry which have been published during the last few years. But while most of the text-books in use at the present time adequately explain the initial difficulties of the subject, scarcely one can be regarded as a satisfactory book for those students who wish to go beyond the elements as treated with the use of Cartesian coordinates. For such students Salmon's "Conics" is still the standard work. But although every fresh edition of this is carefully revised to meet modern requirements, there are many beautiful geometrical methods and theories which are only briefly noticed, but which should be fully discussed in a standard work. The book under review does not, indeed, aim at replacing Salmon's, but it is admirably adapted to be used as a companion to it. It aims at giving a concise account of the principal modern developments due to Cayley, Clebsch, Reye, Klein, and a few other continental geometers. As an introduction to the study of the higher branches, it may be confidently recommended to students as a clear, full, and well-arranged exposition of the leading principles of the subject. At the same time the book is something more than a text-book for students. Those who wish to keep up their mathematics, and have no time to spare to read the various papers and memoirs that are published every year, will find much that will interest them—many beautiful geometrical ideas that are here published for the first time in an English text-book.

The author starts with the general idea of coordinates, and develops simultaneously the theory of point-coordinates and line-coordinates, with a full explanation of the special peculiarities of the two systems. The principle of duality is then explained, and the descriptive properties of curves discussed. After a short but adequate chapter on curve tracing, the theory of projection and homography is introduced, leading up to the theory of correspondence. The chapter devoted to this theory is very well written, and is in fact one of the principal features of the book. In it will be found a full discussion of quadric inversion, based on a memoir by Dr. Hirst. The remaining chapters are devoted to a discussion of the generalisation of metrical properties of curves obtained by replacing the circular points by a conic, and a brief explanation of the connection which subsists between geometry and the algebraical theory of invariants.

The treatise is confined to plane geometry, in which figures are considered as combinations of points and straight lines. In constructing a system of coordinate geometry for such figures, two theories naturally present themselves; the two in which the point and the straight line are, respectively, the *primary* elements, and the straight line and point the *secondary* elements. But although Dr. Scott states that any other geometrical entity might be taken as the primary element, she makes no allusion to any such theory. We wish that she had found it possible to introduce a brief notice of the analytical theory in which the circle is taken as the primary element in view of the fact that most of the properties of an important class of curves—bicircular quartics—are best discussed by expressing the equations of these curves in terms of *circular* coordinates.

It is also a matter of regret that the use of trilinear coordinates is retained, although results are usually given in terms of areal coordinates as well. The use of both systems is confusing to students, and the use of the areal system has a double advantage; firstly, the fundamental metrical formulæ are more easily proved, and secondly, the areal system is intimately connected with the tetrahedral system in solid geometry. For the latter reason, if for no other, it is very desirable that the use of trilinear coordinates should disappear from our text-books on plane geometry. In this book the proofs of two fundamental results (§§ 20, 21) are long and tedious.

The only other point we have to find fault with is that harmonic relationship and involution are introduced as particular cases of cross ratio and homography. The author herself admits (p. 160) that this view disguises the real difference between the two conceptions, and explains that while cross ratio and homography relate to different spaces, harmonic relationship and involution relate to pairs of elements in the same space. The theories are developed independently, but we should have preferred that the theory of harmonic groups and the theory of involution should have been developed before the introduction of the idea of cross ratio and homography.

The examples chosen by the author to illustrate various theorems have been very carefully selected, and should be found quite sufficient for the use of students. Among them will be found many theorems of independent importance, which could scarcely be said to come within the scope of the book. We may add that an excellent index is provided. R. L.

OUR BOOK SHELF.

Les Aurores Polaires. By Alfred Angot. Pp. 318. (Paris: Félix Alcan, 1895.)

FRANCE has made two important contributions to the knowledge of auroræ. Perhaps the first work devoted entirely to the study of auroral phenomena was the "Traité physique et historique de l'aurore boréale," by Mairan, published by the Paris Academy of Sciences in 1733. A century later a volume was published containing the results of aurora observations made on the *Recherche* during the scientific expedition to Lapland. The plates which illustrated the observations then made have been laid under tribute by M. Angot for the present volume. Since the publication, however, of the "Aurores Boréales" which resulted from the 1838–39 expedition, we have it on the authority of M. Angot that no work dealing wholly with the subject has appeared in France. This volume, therefore, stands as practically the only one in which our neighbours on the other side of the Channel can find a popular account of auroræ, written by one of their own countrymen.

M. Angot has treated the subject lightly, yet scientifically. He traces the history of aurora observations from the time of Aristotle; describes the apparently adventitious forms assumed by the phenomena; explains the facts as to the extension, position, frequency, and periodicity of auroræ; develops the relations between auroral and terrestrial magnetism and electricity, and connects them with meteorological phenomena; and, finally, he presents the cosmical, optical, magnetic, and electrical theories put forward to account for the phenomena.

A list is appended, giving in chronological order all the auroræ seen in latitudes above 55° North from 1700 to 1890, with the names of the places at which observations were made. Eighteen rather coarse illustrations are distributed through the book. Altogether, the volume is a valuable summary of the growth of knowledge of auroræ.

A Few Chapters in Astronomy. By Claudius Kennedy, M.A. (London: Taylor and Francis, 1894.)

IN these 150 pages are discussed four or five of the numerous problems in astronomy, and these are handled in such a manner as to make them full of interest, both for the general reader and for the student. This book, unlike many others, is not written for the sole purpose of pouring condensed knowledge into the student's head, but for those who wish to sit down for half an hour or so and read for recreation, and so gain a fair understanding of some of the discussions contained in them, without going into too great detail. The points chiefly referred to, are, visual illusion affecting certain astronomical phenomena; the effect of the earth's rotation on certain moving bodies, as projectiles, paths of projectiles, Foucault's Pendulum and the Horizontal Pendulum; the causes of the tides; the moon's variation; and the parallactic inequality. In the last two chapters the text is accompanied by several figures.

As a supplement to the ordinary text-books on astronomy, this small volume will be found especially useful, as it deals with subjects not generally referred to in them, or at least only briefly mentioned.

Mechanics for Colleges and Schools: Statics. By R. T. Glazebrook, M.A., F.R.S. Pp. 180. (Cambridge University Press, 1895.)

THIS addition to the physical series of the Cambridge Natural Science Manuals will hardly add to the reputation of the assistant director of the Cavendish Laboratory. The only noteworthy feature is the prominence given to the experimental verification of statical principles; but excepting this, little can be found to distinguish the book from others of a similar type. Many of the experiments described are intended to be performed by the students, and the theoretical consequences are, when possible, deduced from experiments. This is undoubtedly the right line to go upon, but we are afraid that few of our schools or colleges possess at present sufficient apparatus for the laboratory work described. The text is clear and concise, and sufficiently illustrated; and the examples are numerous.

The Telegraphist's Guide. By James Bell, A.I.E.E. Pp. 101. (London: *Electricity* Office, 1895.)

TELEGRAPHISTS in the Government service have now to submit themselves to a technical examination before they can obtain promotion. Herein we have a guide in which the subjects of the new examination are considered in the order laid down by the Postmaster-General. The aspiring telegraphist will find the book a means of acquiring the knowledge he needs; and students of telegraphy not directly connected with the service, may obtain from it useful information on the practical working oftelegraphic systems.

LETTERS TO THE EDITOR.

Corrections of Maximum and Ex-Meridian Altitudes.

IN navigation the error introduced by taking the maximum altitude of a heavenly body for its meridian altitude is not sufficiently great to need correction when it is due to variation of declination alone, as it is then much within the probable errors of observation. When, however, a ship is steaming at a high speed, the error is considerably increased by the variation of latitude, especially when this is of opposite sign to the variation of declination.

The formula giving the correction in seconds of arc to be applied to the zenith distance of a body for reduction to the meridian is

$$x = \mathrm{C}h^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where, with the usual notation $\mathrm{C} = \frac{\cos l \cos \delta}{2 \sin (l \mp \delta)} \cdot \frac{\sin^2 15'}{\sin 1''}$, and h is the hour angle in minutes of time. Thus, if z be the zenith distance, we have the equation

$$z - \mathrm{C}h^2 = l \mp \delta,$$

the upper or lower sign being taken according as l and δ are of the same or of opposite sign. Since we may consider z, h, l, and δ as functions of the mean time t and C constant, we have on differentiation, if z be a minimum,

$$-2\mathrm{C}h\frac{dh}{dt} = \frac{dl}{dt} \mp \frac{d\delta}{dt}.$$

Let H and H′ be the hour angles of the body and the ship's zenith measured from some fixed meridian, and let u, v denote the northerly and westerly components of the ship's velocity in knots; then $\frac{dh}{dt} = \frac{d\mathrm{H}}{dt} - \frac{d\mathrm{H}'}{dt}$ and $\frac{dl}{dt} = v$. Also if the body's projection on the Earth's equator moves round at the rate of U knots,

$$\frac{d\mathrm{H}'}{dt} \Big/ \frac{d\mathrm{H}}{dt} = u \sec l/\mathrm{U};$$

and the above equation becomes

$$-2\mathrm{C}h\frac{d\mathrm{H}}{dt}(1 - u \sec l/\mathrm{U}) = v \mp \dot{\delta} \quad . \quad . \quad . \quad (2)$$

Now this equation will assume different forms according as the body under consideration is the Sun, a star, or the Moon. For, since the motion of the ship is expressed in mean solar time, the motion of the body must likewise be expressed in that time.

The unit of time being a minute of mean time, and the unit of arc a second of arc, we have for the Sun

$$\frac{d\mathrm{H}}{dt} = 1 \text{ and } \mathrm{U} = 900,$$

so that (2) becomes

$$-2\mathrm{C}h(1 - u \sec l/900) = v \mp \dot{\delta}.$$

For latitude 60° and $u = 20$ the value of $u \sec l/900$ is about ·04, so that we see for ordinary speeds and ordinary latitudes reached the term involving u may be neglected, and the equation reduces to

$$-2\mathrm{C}h = v \mp \dot{\delta} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

For a star

$$\frac{d\mathrm{H}}{dt} = \frac{\text{length of mean solar day}}{\text{length of sidereal day}} = 1$$

with sufficient accuracy, and as before we obtain equation (3).

For the Moon

$$\frac{d\mathrm{H}}{dt} = \frac{\text{length of mean solar day}}{\text{length of lunar day}} = \frac{1}{1{\cdot}035}$$

and

$$\mathrm{U} = 869,$$

so that in this case (2) becomes

$$-2\mathrm{C}h = 1{\cdot}035\,(v \mp \dot{\delta}).$$

On giving C its proper value, and putting w for the velocity compounded of the velocity in latitude of the ship and the velocity in declination of the body (3) becomes

$$h = -w(\tan l \mp \tan \delta) \sin 1'' \operatorname{cosec}^2 15' \quad . \quad . \quad (5)$$

The reduction is therefore from (1)

$$x = -\frac{w^2}{2}(\tan l \mp \tan \delta) \sin 1'' \operatorname{cosec}^2 15' \quad . \quad . \quad (6)$$

Equations (5) and (6) therefore give the hour angle (from the ship's meridian) and reduction for the Sun or a star at the maximum altitude. For the Moon $1{\cdot}035w$ must be substituted for w. The form of these equations has suggested the construction of the accompanying table, which gives the value of

°		°		°	
1	·004	21	·098	41	·221
2	·009	22	·103	42	·229
3	·013	23	·108	43	·237
4	·017	24	·113	44	·245
5	·022	25	·118	45	·254
6	·026	26	·124	46	·263
7	·031	27	·129	47	·273
8	·035	28	·135	48	·283
9	·040	29	·141	49	·293
10	·045	30	·147	50	·303
11	·049	31	·153	51	·314
12	·054	32	·159	52	·326
13	·059	33	·165	53	·338
14	·063	34	·171	54	·350
15	·068	35	·178	55	·363
16	·073	36	·185	56	·377
17	·078	37	·192	57	·392
18	·083	38	·199	58	·407
19	·088	39	·206	59	·424
20	·093	40	·213	60	·441

$\tan x° \sin 1'' \operatorname{cosec}^2 15'$ as far as $x = 60$. Thus in latitude $l°$ when a body (Sun or star) of declination $\delta°$ is at its maximum altitude, the sum or difference (according as l and δ are of different or of the same name) of the arguments corresponding to l and δ multiplied by w gives the hour-angle in minutes of time: the sum or difference multiplied by $\frac{w^2}{2}$ gives the reduction in seconds of arc. For the hour angle of the Moon the sum or difference must be multiplied by $1{\cdot}035w$, and for the reduction by $\frac{1}{2}(1{\cdot}035w)^2$.

Example.—D.R. latitude 48° N. Moon's declination 18° 48′ S. decreasing 120″ per 10m., ship steaming S. 20° E. 16 knots.

Remembering that when the ship is in N. latitude, and steaming towards south

$$w = -v \mp \dot{\delta},$$

we have

$$w = -27,$$

and

$$h = 27 \times 1{\cdot}035({\cdot}283 + {\cdot}087) = 10{\cdot}3\text{m}$$
$$x = 144''$$

If a ship whose maximum speed is 20 knots does not reach a higher latitude than 60, the greatest values that h and x can have, are for the Sun, 9m. 15s. and 1′ 37″; for the Moon, 17m. 20s. and 5′ 41″.

I will now investigate the nature of a diagram [1] from which the reduction in ordinary ex-meridian observations may be obtained, as well as the hour angle and reduction for maximum altitudes. It is found convenient for this purpose to express x in minutes of arc, when (1) becomes

$$h^2 = 2x(\tan l \mp \tan \delta) \sin 1' \operatorname{cosec}^2 15' \quad . \quad . \quad . \quad (7)$$

Now if a circle of radius a be referred to a point in its circumference as origin, its equation is

$$r^2 = 2ax,$$

r being the radius vector and x the abscissa measured along the diameter through the origin. Comparing this with (7) we see that if a system of circles be described passing through a common origin O, their centres being collinear and on the same side of O, the reduction x is the abscissa of the point whose radius vector is h on one of these circles: the particular circle on which the point lies being that whose radius is the sum or difference of the ordinates of the curve

$$y = \tan x \sin 1' \operatorname{cosec}^2 15'$$

corresponding to

$$x = l \text{ and } x = d.$$

[1] A diagram based on the properties of the parabola was given by Prof. Foscolo, of Venice, and published by the Hydrographic Office about 1870.

It will be noticed that when

$$h > 2(\tan l \pm \tan \delta) \sin 1' \operatorname{cosec}^2 15',$$

the above construction fails, and x may be then considered as twice the abscissa of the point on the circle whose radius is

$$2(\tan l \mp \tan \delta) \sin 1' \operatorname{cosec}^2 15',$$

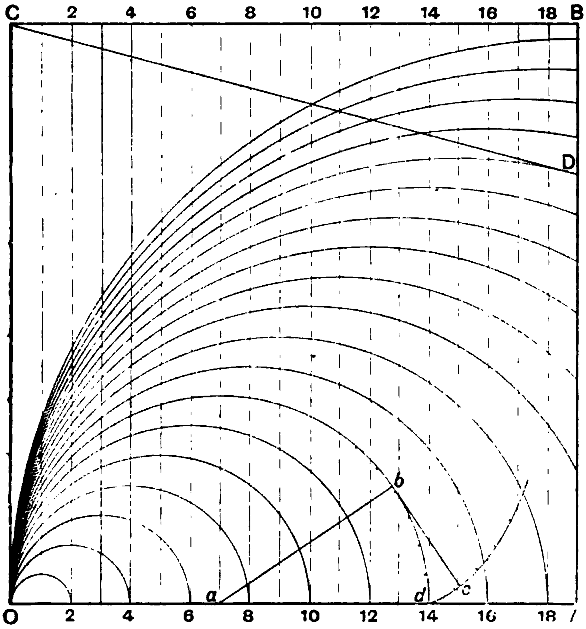
By making a diagram on ruled paper, the distance between the lines being taken as unit, the difficulty of measuring x and h is more or less overcome.

A portion of such a diagram is represented in the annexed figure, C D being a portion of the curve

$$y = \tan x \sin 1' \operatorname{cosec}^2 15'$$

described with C as origin, y being for convenience reckoned negatively.

As an example of its use, suppose it were required to find the reduction for latitude 17° N., declination 9° S., and hour-angle 12m. By using a pair of dividers the sum of the ordinates of the curve C D corresponding to 9 and 17 is found to be



7, and a radius vector of length 12 meets the circle of radius 7 at a point whose abscissa is 10. The required reduction is therefore 10′.

Again, x being now expressed in minutes of arc (5) and (6) may be written

$$h = -\frac{w}{60}(\tan l \mp \tan \delta) \sin 1' \operatorname{cosec}^2 15'$$

$$x = \left(\frac{w}{60}\right)^2(\tan l \mp \tan \delta) \sin 1' \operatorname{cosec}^2 15'.$$

So that h and x are the lengths of the arcs of a circle and its involute respectively, corresponding to the angle at the centre whose circular measure is $w/60$ in the case of the Sun, and $1·035w/60$ in the case of the Moon. Now for the former body w will not in general exceed 20, and for the latter 38, so that we may assume for graphical purposes that in the case of the Sun w is the number of degrees in an angle of circular measure $w/60$, and in the case of the Moon w is the number of degrees in an angle of circular measure $1·035w/60$.

Thus in both cases h is approximately the arc of a circle of radius

$$(\tan l \mp \tan \delta) \sin 1' \operatorname{cosec}^2 15'$$

intercepted between the diameter and the radius which makes an angle w degrees with it.

Having obtained h, x may be found as in the general case, or by drawing a tangent to meet the involute, as in the figure.

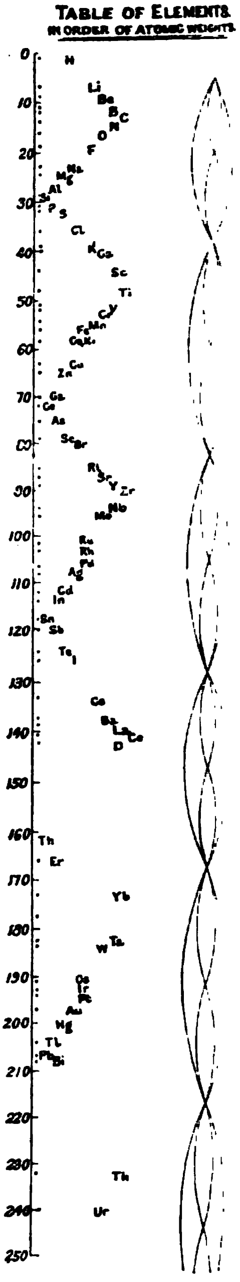
In the preceding example, suppose the ship to be steaming south 20 knots, the declination decreasing 160″ per 10m. Here $w = -36$. By laying off at an angle of 36°, the intercepted arc bd is found to be about 4·3, and by drawing the tangent at b the intercepted arc of the involute is about 1·3. The hour angle and reduction for the maximum altitude are therefore 4m.·3 and 1′·3 respectively.

The graphical method considered above will be found to give results which, although approximate, are sufficiently accurate for purposes of navigation; in fact, if the diagram be constructed on a large scale, the reduction may be easily obtained within fifteen seconds of the truth.

H.M.S. *Hawke*, Mediterranean. J. WHITE.

Argon and the Periodic System.

THE annexed engraving is a copy, on a small scale, of a large diagram which I have used with advantage for some years in dealing with the periodic classification of the elements. It may prove of some little interest to your readers who are actively discussing the probable position of "argon," on the assumption that this remarkable substance is an element.



To the left of the illustration is a scale of equal parts, and the dots indicate the atomic weights of the elements the symbols of which are placed farther to the right. The latter are arranged in zig-zag fashion so as to exhibit the periodic rise and fall in general properties, observed in each set of seven elements. A certain analogy may be traced between these periods and the loops into which a suspended cord of somewhat unequal weight can be thrown when set in vibration. Each small loop pictures for us a small period; and, just as the *alternate* loops are those which are in the same phase at any given moment, so the alternate periods of the elements are those between which the closest resemblances can be traced.

The members of Mendeléef's eighth group, or the "triplets," as they are sometimes called, viz. Fe, Ni, and Co, with atomic weights from 56 to 59: Ru, Rh and Pd, 102 to 106: Os, Ir and Pt, 191 to 195, seem to form another system of elements which—to pursue the analogy of the vibrating cord—is related to that of the other elements somewhat as a given note to its octave. On carrying the eye along the curves it will be seen that the atomic weights of triplets occur nearly opposite to the points of maximum displacement of three of the greater loops. We know very little as yet about the elements the atomic weights of which lie between 140 and 180, hence we cannot recognise the triplets the atomic weights of which should be near to 150; and a similar remark applies to the elements above 210. But the distribution of the triplets throughout the whole of the best-known elements is so nearly regular that it is difficult to avoid the inference that *three* elements should also be found in the symmetrical position between 19 and 23, *i.e.* between fluorine and sodium. And further, that these elements—of which "argon" may be one—should exhibit properties differing chiefly in degree from the alternate palladium and platinum triplets; while hydrogen would appear as the primary of both systems of elements.

Dr. Gladstone's letter, which appeared in your issue of February 21, admirably puts the reasons for preferring an atomic weight of about 20 for argon to the higher number which Lord Rayleigh and Prof. Ramsay are now disposed to assign to it; but Dr. Gladstone seems to think that there is room for only one element, whereas three are possible, as I pointed out at the Oxford meeting, for the reasons given in the foregoing.

It will be seen from the illustration that an element with an atomic weight between 36 and 39 would belong to a third system of elements. But the sole ground for concluding that the atomic weight of argon lies between these points, is the ratio of the specific heats as determined by Kundt and Warburg's method. Lord Rayleigh and Prof. Ramsay found this ratio to be nearly equal to that afforded by mercury gas, the molecule of which is monatomic and density only half its atomic weight; hence they conclude that the argon molecule is monatomic, and that its density of nearly 20 represents but half the atomic weight. Now, while any opinion on this point, coming from the distinguished discoverers of argon, is of the highest value, it seems possible to attach undue weight to the very slender evidence afforded by the specific heats, for mercury at present is the only one of the known cases of monatomic elementary molecules in which the ratio of the specific heats has been determined. But, even admitting that the energy of the mercury and the argon molecules is chiefly translational, it is still conceivable that the argon molecule includes two atomic vortices so closely interlinked as to have a common centre, and therefore to enable the molecule to simulate a monatomic character. Such a structure would be consistent with great stability and, consequently, with exceptional chemical indifference. J. EMERSON REYNOLDS.

Trinity College, Dublin, March 19.

Variation in *Caltha palustris*.

READING the notice of Mr. Burkill's paper on "Variations in Stamens and Carpels," in NATURE of February 7 (p. 359), I remembered the following notes on *Caltha palustris*, which my wife and I made at Corfe, Dorset, June 11, 1891.

C. palustris: heads in pairs on a dichotomously branching stalk; number of follicles in each head, counted in several specimens, as follows:—

7 follicles on one, 4 on the other, of a pair. 8—5, 5—7, 5—6, 6—6, 6—7, 7—5, 9—9, 10—8, 11—8, 9—6.

Thus there is great variation. One stalk is longer than the other, of a pair, and it is presumed that in every case the shorter one flowers first. It will be noticed that in the above eleven instances, only two had the same number of follicles on both stalks. Of the remaining nine, three had most follicles on the longer of the stalks, and six had most on the shorter. Those on the shorter stalk were larger than those on the longer, presumably because older.

A second memorandum gives the results of fifteen more counts, all taken at random, thus (L. = longer, S. = shorter stalk):—

L. with most follicles. L. S.		L. and S. equal. L. S.		S. with most follicles. L. S.
5—4	...	8—8	...	4—6
				4—8
9—8	...	5—5	...	6—7
9—7	...	10—10	...	8—10
		7—7	...	9—10
		10—10	...	7—8
				4—5

It accordingly appears that the later-flowering, longer-stalked head produced more follicles in just half the number of cases counted (13 out of 26), and the shorter-stalked head had a majority in only 5 cases, the remainder being equal.

In a *Bidens* found at Barbadoes (West Indies), on July 6 of the same year, there were similarly two heads, a long-stalked and a short-stalked, the latter flowering first. It would be interesting to get statistics of the numbers of akenes in the heads in this. The species was not certainly determined, but it is of the section of *B. bipinnata*. T. D. A. COCKERELL.

New Mexico (U.S.A.), February 24.

DR. M. FOSTER ON THE TEACHING OF PHYSIOLOGY IN SCHOOLS.[1]

THE teaching of science in schools has, it seems to me, two uses. The first is what I may call the "awakening" use. Many minds who feel no interest in the ordinary subjects of school learning, to whom the ordinary lessons appear as so much dull mechanical work, are at once stirred to intellectual activity when the teaching of this or of that science is presented to them. The second use is the more distinctly "educational," training use.

The minds of the young being, happily, differently constituted, one mind is especially "awakened" by one branch of knowledge, another by another. One boy or girl dates the beginning of his or her intellectual activity from the day on which he or she had a first lesson in chemistry. Another starts in the same way with botany. And the number of those to whom physiology thus serves as "awakening" knowledge, is, it seems to me, sufficiently great to render it desirable, by the introduction of the teaching of physiology into schools, to afford adequate opportunities for its exercising this benefical effect.

It follows that, taught from this point of view, physiology should be taught as a new independent subject, not demanding any previous knowledge; it should be presented as a wholly new field into which the natural mind may wander at will without any restrictions as to being qualified for entrance. It also follows that the teaching must be of a most elementary kind, that as much of chemistry or physics as is necessary for the comprehension of the physiological matters should be taught with the physiology, and, as it were, as a part of it, the pupil being led into chemistry and physics by his interest in physiology, and not being compelled to learn the one for which he or she perhaps does not, at present at least, care before beginning the other.

The instruction given, however elementary it may be, should consist in part of demonstrations and practical exercises. I need not enumerate these in detail, but they must necessarily be limited in scope; the dissection of a rabbit or some other animal to show structure, some little microscopic work, such as the microscopic study of the blood and of a few tissues, the examination of the structure and working of the heart, the mechanics and elementary chemistry of breathing, and the like. But all these demonstrations, like the rest of the teaching, I may repeat, should teach so much of chemistry, of mechanics, &c., as is needed, as a part of the physiological lesson.

As an "awakening" study, I am in favour of physiology being very widely taught; but, as almost necessarily follows from the view on which I have been dwelling, it ought not to be made a compulsory study. Made compulsory, it would as an awakening study lose much of its virtues. I do not hide from myself the fact that the present gross ignorance which prevails among most men and women as to the most elementary facts concerning their own bodies is most undesirable, especially perhaps as regards women; but I am most decidedly of opinion that it is better to meet this evil by encouraging the study of physiology than by making it compulsory.

Physiology, as a distinctly educational study, as a training for the mind, is a very different matter; and it is, in my opinion, in this aspect unsuitable for schools. The training for the mind which physiology affords is one, I venture to think, of no small value, but is one

[1] A short time ago, on my consulting him on behalf of a committee appointed by the Headmasters' Association, to draft regulations for major scholarships' examinations, Prof. Michael Foster was good enough to give me this statement of his opinion on the teaching of physiology in schools—a subject of great importance, but of great difficulty, regarding which much misconception prevails; it appears to me to be so valuable, that I have sought for and obtained his permission to publish it.—HENRY E. ARMSTRONG.

which, especially compared with that afforded by some other sciences, is relatively slight when the knowledge is elementary, increasing rapidly as the study becomes advanced. Further, while I have just urged that elementary physiology as an awakening study may be and indeed should be taught by itself, independent of other kinds of knowledge, I can now urge equally strongly that a study of physiology, beyond the mere elements, is impossible without a previous adequate knowledge of chemistry and physics. Again, while the practical teaching of the rudiments of physiology can be carried out anywhere and by any one, the further study of physiology demands no inconsiderable laboratory accommodation, complicated apparatus, and experiments on animals. Lastly, if the study of physiology is to be real, the whole body must be dealt with, no parts being excluded for special reasons; and this means that the real study cannot be taken up until after puberty. For these reasons it seems to be undesirable to press the introduction of physiology into schools as an educational subject; all the more so, since not only both chemistry and physics are admirably adapted for this purpose, but also a not inconsiderable knowledge of both these sciences is needed for the proper study of physiology; and I imagine that by the time a boy or girl is thus prepared to study physiology, it is time that he or she should leave school.

While I am thus opposed to physiology being placed in a false position in the school curriculum, I feel myself all the more free to urge the very general introduction of an elementary study of the subject on account of its awakening value. I cannot define the amount of physiology which should thus be introduced more closely than by saying that the ground covered should be about that covered by my Primer. I would add that so far as is possible the pupils should *see* for themselves everything which is talked about in the lesson.

As to "physiology being a proper subject to be included among subjects for scholarship examinations for young pupils," I am so impressed with the painful evils of the present scholarship system, that I am most loth to say anything that would in any way lead to an addition to that system. If the scholarship examination is to be a test of education, of intellectual training, it is obvious from what I have said above, that physiology cannot be put on the same level with chemistry and physics. At the same time, if such subjects as physiology or botany are excluded from scholarship examinations, no little injustice, it appears to me, is likely to be done in the following way. A lad, let us say, shows an early bent towards physiology, and acquires at school a very considerable knowledge of its rudiments. His future career depends on his gaining a certain scholarship. If in the examination for that scholarship his place depends solely on the way in which he has acquitted himself in chemistry and physics, in which his interest is of a secondary character—he regarding them merely as helps to physiology—the world may be robbed of an eminent physiologist. Hence I would say that if the evil of a scholarship examination must come, I would give an opportunity of an elementary knowledge of physiology being, in some way, rewarded.

NOTES.

PROF. RAMSAY has been good enough to forward to us the following translation of a passage in a letter he has recently received from Prof. Olszewski: "I have at last succeeded in determining the critical temperature and the boiling-point of hydrogen. I have found for the former $-233°$ and for the latter $-243°$. I have used the dynamical method, which I described in the *Philosophical Magazine*. A thermal couple proved of no use, and I was obliged to avail myself of a platinum-wire thermometer, measuring the temperatures by the alteration in resistance of the wire. I have obtained satisfactory results, and intend to publish an account of them in English."

MR. FREDERICK WEBB has presented the sum of £1000 to the Medical School of St. George's Hospital, to found an annual prize in bacteriology.

PROF. VICTOR HORSLEY, F.R.S., has been elected into the Athenæum Club, under the provisions of the rule which empowers the annual election by the committee of nine persons "of distinguished eminence in science, literature, the arts, or for public services."

WE are glad to learn that there is no foundation for the report of the death of Prof. H. Wild, of St. Petersburg, noted in these columns on February 28. The mistake arose owing to the announcement of the decease of a German investigator of the same name.

AT the meeting of the Royal Irish Academy, on March 16, the following were elected honorary members. In the section of Science: Dr. Karl Weierstrass and Prof. du Bois Reymond, and Prof. E. Suess. In the section of Polite Literature and Antiquities: Prof. A. Erman, Dr. E. Zeller, Lieut.-General H. L. F. Pitt-Rivers, and Mr. S. R. Gardiner.

AT the Paris Academy of Sciences last week, a bronze medal, engraved by Chaplain, was presented to M. Bertrand, in honour of his jubilee. The medal has on one side a likeness of M. Bertrand, and the reverse side bears the following sentiment: "To Joseph Bertrand, member of the French Academy, Perpetual Secretary of the Academy of Sciences, in honour of fifty years' devotion to science and education, from his pupils, admirers, and friends. March, 1844–1894."

THE Anniversary Dinner of the Fellows of the Chemical Society will be held at the Hôtel Métropole on Wednesday, March 27, when Dr. Henry E. Armstrong, President of the Society, will occupy the chair. The Right Hon. A. J. Balfour, M.P., James Bryce, M.P., the Presidents of some of the learned Societies, and several other distinguished guests have accepted invitations to the dinner.

A NUMBER of organisations for scientific research in the leading cities of the American sea-board, including Philadelphia, Princeton, New York, Brooklyn, and Boston, have combined to organise an expedition to the west coast of Greenland. The expedition will be fitted out at Newfoundland, and will sail next June. Elaborate preparations are under way to insure important results to science. Each of the Societies participating will send a representative, including several who went last year, such as Profs. Libley and Chamberlin. The Brooklyn Institute will send a representative, to be chosen hereafter.

THE death is announced of Mr. A. W. Beetham, at Dawlish, in his ninety-fifth year; he was elected a Fellow of the Royal Society in 1835. We also notice the death of Mr. J. C. Smith, president of the Institution of Civil Engineers of Ireland; of Dr. Hermann Grote, one of the most eminent experts in numismatics; of Mr. G. N. Lawrence, a leading American ornithologist; of General de Nansouty, founder and director of the Pic du Midi Observatory, which for twenty-one years has rendered great service to agriculturists in the French Pyrenees; and of Prof. Julien Brunhes, at Dijon.

THE Belgian Academy of Sciences offers a prize of 600 francs for the best essay on each of the following subjects:—(1) On the number of chromosomes before impregnation in an animal or a plant; (2) On the Quaternary Flora, especially that of peat-bogs; (3) Is there a nucleus in the Schizophyta? if so, what is its structure and its mode of division? The essay must contain a critical review of the publications existing on the subject. Each essay must be the result of original investigation.

THE Bologna Academy of Sciences offers a gold medal having the value of one thousand Italian lire (£40) as a prize to the author of a memoir which describes the best system or new apparatus for preventing or extinguishing fires, by chemical, physical or mechanical means. The competition is open to persons of all nationalities, and the memoirs must reach the Secretary of the Academy before the end of May, 1896. The descriptions should be written in Italian, Latin, or French, but memoirs will be permitted to compete if written in any other language, provided a translation in Italian accompanies them.

THE *Times* correspondent at Cairo reports that the Council of Ministers has approved Mr. Garstin's proposal for clearing Philæ of débris, in order to make a thorough examination of the bases of the temples, and explore the subterranean passages which intersect the island. This work, which is of high importance to the scientific world, will be done by the Public Works Department, an official from the Antiquities Department attending to insure that all objects of interest are preserved. The Ministry of War will be asked to lend Captain Lyons, R.E., to superintend the work.

THE United States Government is (we learn from the *British Medical Journal*) about to undertake an investigation of the climates of the country in connection with the indigenous diseases. The investigation will be conducted by the Weather Bureau of the Department of Agriculture, the Chief of which, Mr. Mark W. Harrington, has on many previous occasions given proof of an active interest in sanitary climatology. The precise manner in which the results of the investigation will be made public has not yet been decided upon, but it is hoped soon to publish a periodical devoted to climatology, and its relations to health and disease.

BY the consent of her Majesty the Queen, a piece of ground —the Palace Meadow—about four and a half acres in extent, has been ceded to the Royal Gardens at Kew, for the use of the public. The concession is a great convenience, for the removal of the fences will allow visitors to make a direct, instead of a circuitous, access to the finest part of the Arboretum. The Gardens are 251 acres in extent. It is not generally understood (says the *Kew Bulletin*) that they were originally the private property of the Crown, and not acquired out of public funds. The building used for the Herbarium and Library was sold to the nation by George IV. Access to the remainder has been step by step conceded to the public by the liberality of her Majesty the Queen.

The annual general meeting of the Italian Botanical Society will be held this year in Palermo, from April 16 to 23. The opportunity will be taken of celebrating the hundredth anniversary of the foundation of the Botanic Garden at Palermo.

ON Thursday next, March 28, Dr. E. B. Tylor, F.R.S., will deliver the first of a course of two lectures at the Royal Institution, on "Animism as shown in the Religions of the Lower Races." The Friday evening discourse, on March 29, will be delivered by Dr. H. E. Armstrong, F.R.S. His subject will be "The Structure of the Sugars and their Artificial Production."

THE Zoological Society of France held its second annual reunion on February 28, under the presidency of Prof. Léon Vaillant. The meeting was a marked success, a number of zoologists from all parts of France favouring the Society with original communications. It has been decided to make these annual conferences, to which all naturalists are cordially welcomed, a permanent feature, and to arrange in future for microscopical and other demonstrations, as well as numerous social gatherings.

WHEN the Council of the Zoological Society of France voted to support the movement for the establishment of an international bibliographical bureau, it charged one of its members, Prof. E. L. Bouvier, to present a report at the annual reunion of the Society. Basing its decisions upon this report, the Society has nominated a central Committee of Management, composed of the following titular members:—Dr. Raph. Blanchard, Prince Roland Bonaparte, Prof. Ives Delage, Prof. Henri Filhol, Prof. Albert Gaudry, Baron Jules de Guerne, Prof. A. Milne-Edwards, and Prof. A. Raillet. Twenty zoologists, residing in various parts of France, have been nominated as associate members. To complete the organisation, eleven special correspondents have been appointed, whose duty will consist in reporting to the Bureau such works as are inaccessible to it. A preliminary inquiry among the various scientific societies and the leading publishers has shown, however, that nearly all the zoological publications of France will be sent gratuitously to the Central Bureau. Not a single failure to accept this invitation to co-operate has thus far been reported.

THE annual meeting of the German Zoological Society will be held this year at Strassburg, on Tuesday, Wednesday, and Thursday, June 4 to 6. A preliminary general programme of the meeting has already been issued, and in the list of papers promised for the occasion we notice one by Prof. Goette, "On the Ancestry of the Vertebrata," and another by Dr. Bürger, "On Nemertines." The mornings will be devoted to general business and the reading of scientific communications and reports, and the afternoons will be reserved for demonstrations and the inspection of the laboratories. The meeting should possess considerable interest, and many will probably be glad to avail themselves of the cordial invitation which the Society extends to zoologists of other nationalities to attend the meeting as guests, and to take part in the proceedings of the Society.

THE Paris Geographical Society has awarded its prizes for 1895, as follows:—Gold medals, to Lieut. L. Mizon, for his explorations in West Africa; E Gautier, for his explorations in Madagascar; F. Foureau, for his explorations in the Sahara; E. Ponel, for his explorations in the region of the French Congo; Th. Moureaux, for his magnetic map of France; Father Colin, for his observations and triangulations in Madagascar; A. Courtry, for the production of a map of the Congo; V. de la Blache, for his general atlas; and Dr. Thoroddsen, for his explorations in Iceland. Silver medals have been conferred upon E. D. Poncins, for his journey from Turkestan to Kashmir by the Pamirs; J. Gaultier, for his works on the production of plans by photography; B. d'Attanoux, for his exploration in the Sahara; and J. Forest, for his studies on the breeding and habits of the ostrich in the Sahara. The Jomard prize has been awarded to L. A. Rainaud, for his memoir entitled "Le Continent austral: hypothèse et découverte."

SINCE the decision in the case of the Leeds Sunday Lecture Society, when it was held that the delivery of a lecture on a Sunday came within the meaning of the "Act for Preventing certain Abuses and Profanations on the Lord's Day, called Sunday," if the public were not admitted free, the Sunday Society has been exerting itself to procure an amendment of the vexatious Law as it now stands. Lord Hobhouse, who presided at a conference of Sunday Societies held last month, has introduced a Bill into the House of Lords for amending the Act in accordance with a resolution passed on that occasion. The Bill aims at securing that in future—"No action for the recovery of any penalty shall be commenced against any person in respect of the opening of any Museum, Art Gallery, Science or Art Exhibition, Garden or Library, as such, or the delivery of any lecture on science, literature, art, or kindred subject, or any recitation, or the giving of any performance of music, either vocal or instrumental, on Sunday, provided that the same take place under the management and control of a Society, Committee, or other body of persons, for the public advantage and not for pecuniary profit."

It is proposed to hold an International Exhibition at Atlanta, Georgia, U.S.A., from September 18 next, to December 31. The classification includes the usual departments of International Exhibitions, the following being the divisions:—Minerals and Forestry; Agriculture, Food and its accessories, Machinery and Appliances; Horticulture, Viticulture, Pomology, Floriculture, &c.; Machinery; Manufactures; Electricity and electrical appliances; Fine Arts, Painting, Sculpture, and Decoration; Liberal Arts, Education, Literature, Music, and the Drama; Live Stock, Domestic and Wild Animals, Fish, Fisheries, and Fish Culture; Transportation. The United States Government have given permission for exhibits to be brought in free of Customs' duties, unless the goods are entered for consumption in the States. Exhibits are invited from foreign countries on the usual conditions. Further information may be obtained from the Director-General, Mr. C. A. Collier, Piedmont Park, Atlanta, Georgia, U.S.A. Copies of the classification and general regulations have been sent to the Secretary of the Society of Arts, and can be seen at the Society's offices by any persons interested.

At a recent meeting of the Oriental Club of Philadelphia (Dr. D. G. Brinton writes in *Science*), Dr. J. P. Peters, whose researches among the ruins of the valley of the Euphrates are well known, mentioned his observations on the deposition of alluvium by the river as a chronometer for measuring the antiquity of some ruin-mounds. The deposits from the known date of Alexander's conquests display marked uniformity; and taking the depths of these as a standard, the foundations of Ur (the "Ur of the Chaldees" of Genesis, the modern Muchair) and of Eridu (the modern Abu-Shahrein) must have been laid about seven thousand years B.C.

A substitute for wood is badly wanted in the construction of warships. In the recent actions between the Chinese and Japanese fleets, several ships were disabled by serious fires on board, and this has caused much attention to be given to the invention of artificial wood, both at home and abroad. A Board of experts, says the *Journal* of the Franklin Institute for March, was lately convened by direction of the Secretary of the U.S. Navy to consider the subject of dispensing with wood in the construction of the naval ships now building, and also for the purpose of finding some suitable substitute for wood where it is impracticable to use metal. The Board has decided that a substitute for wood should be light, or not heavier than wood, non-conducting, non-combustible, and, when struck by shot, should not fly into splinters. Wood has the very objectionable property of splintering from the effect of shot; and the fact is well known that, in wooden ships, frequently as many persons are wounded by splinters as by shot.

A solution of the problem of finding a substitute for wood, seems, in the opinion of the Board, to lie in the following direction:—Select something in the nature of cheap wood or vegetable fibre and fine sawdust; treat them chemically with some insoluble fire-proof substance, not too heavy; then press and roll into boards, more or less dense, according to the use for which the material is desired. Such a material will be non-inflammable all through, will not splinter, will not be heavy, and will be a non-conductor. Possibly this artificial board can be strengthened by enclosing within it a tough, fine wire netting. If sawdust, or other fine cellulose material, after being rendered non-inflammable, can, by mixing with other materials not too heavy—or, if heavy, in small quantities—be applied to metal in a plastic state, so as to harden into a compact mass impervious to water, then it will be of great value. In other words, if a light, non-conducting, non-inflammable, insoluble cement can be discovered, it will be of great use in ship construction.

Numerous objects made of wood and covered with copper have been found during the exploration of mounds in Ohio. Prof. F. W. Putnam has described specimens of this kind, and copper objects sheathed with silver. The examples found are quite sufficient to show that the American aborigines in the Mississippi valley and in South America had the art of cold-hammering copper, of heating it to overlie and fit upon a warped or curved surface, and of turning the edges under. This process must not be confounded with the mere hammering-out of implements, nor with the process of making a sheet of copper as thin and uniform as a ship's sheathing, and then producing figures by rubbing or pressure. A note by Prof. O. T. Mason, in the *Proceedings* of the U.S. National Museum (vol. xvii. No. 1015), shows that the Haida Indians, who occupy the Queen Charlotte Islands, and are famous for their carved work, also cover wood and bone with copper. He describes two figures of humming-birds carved in wood, and having their wings and tails overlaid with a covering of sheet copper. The surfaces are neatly engraved with the conventional wing and eye signs of the Haidas. These specimens, and those from the mounds of Ohio, throw some light upon the processes employed by the aboriginal metallurgists of America.

It will be remembered that in June last, Prof. C. V. Riley resigned his position as Chief of the Division of Entomology of the United States Department of Agriculture, and was succeeded by Mr. L. P. Howard. Owing to these changes, the publication of *Insect Life*—the premier of entomological bulletins—appears to have ceased for a time. The periodical has, however, been revived, and three numbers of a new volume (vol. vii.), edited by Mr. Howard, have come to us, together with the last number of vol. vi., published under the joint editorship of Prof. Riley and Mr. Howard. Each of the numbers contains a store of information, in the form of articles or notes, on the life-habits of insects, especially in relation to agriculture. In one (vol. vi. No. 5) we notice an address on "Bees," by Prof. Riley, and in another (vol. vii. No. 1) we have an illustrated description of the senses of insects, by the same writer. The second number of the new volume is devoted to the proceedings of the sixth annual meeting of the Association of Economic Entomologists, held in August 1894. The presidential address delivered by Mr. Howard on that occasion, dealing with the rise and present condition of official economic entomology, shows what official encouragement is given to the investigation of insect problems in all parts of the world.

Most of the great advances in entomology have come from America, but, as Mr. Howard points out in the address referred to above, this progress would not have been possible without legislative encouragement. At the present time the amount of money expended for work in economic entomology is far greater in the United States than in any other country. There the regular annual expenditure in the support of entomological offices amounts to about one hundred thousand dollars. Probably the total sum expended annually in experiments and publications exceeds the entire amount expended in the same direction by the remainder of the world. No wonder, then, that the whole world looks to America for instruction in economic entomology. And the results obtained justify the money expenditure. Not a year passes, Mr. Howard remarks, in which the sum saved to agriculture and horticulture, as the direct result of the investigations of entomologists, does not amount to many times that which the United States Government grants. The results have thus added greatly to the productive wealth of the world, and this fact alone should be sufficient to lead our own Government to a more generous recognition of work in economic entomology.

SEVERAL German periodicals have published an account of a remarkable balloon ascent made in the "Phœnix" by Dr. A. Berson, on December 4 last. The balloon was inflated with 70,600 feet of hydrogen, and ascended from Stassfurt (Prussia) in the morning, taking a north-westerly direction, the weather at the time being somewhat misty. The temperature at first increased up to a considerable height; at 4900 feet the thermometer stood at 41°, and at 16,400 feet it read 0°, with a very dry air. At noon, an hour and half after starting, a height of 22,150 feet was reached, and the thermometer fell to −20°. At this time Dr. Berson began the artificial inhalation of oxygen, with excellent results. At about 29,500 feet the balloon passed through a veil-like stratum of cirrus clouds; these did not consist of ice crystals, but of perfectly formed flakes of snow. About two and a half hours after starting, a height of about 31,500 feet had been reached, the thermometer dropped to −54°, and indicated only −11° in the sun's rays; at this height Dr. Berson, being alone, thought it prudent to commence the descent. At 4600 feet the highest temperature was recorded, viz. 43°, and between this point and the earth it dropped to about 34°. The ascent occupied 3 hours, and the descent 2h. 20m., the balloon having travelled 186 miles, notwithstanding that the wind was almost calm on the surface of the earth. Dr. Berson obtained observations at a greater altitude than they had before been made; in Mr. Glaisher's celebrated ascent of September 5, 1862, the last actual observation was at 29,000 feet, although it is supposed that the balloon rose at least 7000 feet higher. The above particulars are taken from an account given in the *American Engineer* for this month.

ABOUT three years ago, the Botanic Garden at Cape Town was transformed into a town garden supported by municipal rates. A similar change has lately taken place at King William's Town, in the eastern province of the colony. The *Kew Bulletin* for March rightly condemns these changes, and the perfunctory manner in which botanic gardens in South Africa have generally been treated. It points out that, at the present moment, Cape Colony is the only important British possession which does not possess a fully-equipped botanical institution. It is true it possesses a fine colonial herbarium, under the competent charge of Prof. MacOwan, and an agricultural department which he efficiently advises on botanical subjects. But beyond this it has no central authority dealing with the practical aspects of the science of botany, and no gardens under technical control where careful experimental cultivation could be carried on, or where special seeds and plants could be obtained for starting new industries. This condition of affairs, the *Bulletin* holds, is scarcely credible to a large and wealthy community like that at the Cape. Something more than an ornamental garden, dotted here and there, is required in South Africa. A central establishment in the neighbourhood of Cape Town, devoted to the scientific study and experimental cultivation of plants, fully equipped to discharge its studies as a national institution on the lines of Kew, would alone be worthy of the future of South Africa. The flora of this part of the world is one of extreme interest. It deserves to be carefully and exhaustively studied, and numerous plants, now in danger of becoming extinct, should be preserved in some central spot for the observation of students. Of the economic influences of such a central institution it is needless to enlarge. There are hundreds of problems connected with the cultivation of industrial plants in South Africa awaiting solution, and these could only be dealt with at an institution specially devoted to scientific research, where careful trials could be conducted extending over many years.

IN a recent publication by Dr. L. A. Bauer, entitled "Beitraege zur Kenntniss des Wesens der Saecular Variation des Erdmagnetismus" (Inaug. Diss., University of Berlin), some interesting and important contributions to our knowledge of that enigmatical phenomenon of terrestrial magnetism—the secular variation—have been made. The author has constructed the actual curve described in the course of centuries by the north end of a "free magnetic needle" at various stations (24) distributed over the globe. The result has been the establishment of a law governing the *direction* of the curve, which the author claims is the first law that has been established thus far with regard to the secular variation as applying to the whole earth. This law may be expressed as follows:—The north end of a freely suspended magnetic needle, as viewed from the point of suspension of the needle, moves, in consequence of the secular variation of terrestrial magnetism on the entire earth, in the direction of the hands of a watch. With regard to the period, Dr. Bauer believes that it has not yet been proved that the earth actually possesses a common secular variation period. The only way he thinks it possible to deduce a common period is by the supposition that the curve described by the magnetic needle is not a single closed one, but consists of loops. Indications of such loops, he says, make themselves apparent at various stations. A comparison is also drawn between the secular variation and the momentary distribution of terrestrial magnetism. A secular wave is followed around the earth with the aid of the projected curves. It would appear as though a continuation of the secular curve is obtained by going around the earth eastwardly. The fact thus revealed, the author says, would have, as a direct consequence, that if a survey be made along a parallel of latitude in an easterly direction, a similar motion of the magnetic needle would be encountered as in the case of the secular variation. Dr. Bauer has carried out this idea for three epochs, viz. 1780, 1829, and 1885, and along several parallels of latitude. The curves described by the needle are projected and given on a special plate. It has been found that in every case the north end of the needle, as observed from the centre of the needle, moves clockwise. Furthermore, by a comparison of both sets of curves—the secular and the momentary—it would appear as though they are subject to similar laws.

THE method adopted in the Physikalisch-Technische Reichsanstalt for turning true spheres is described by Herr von Liechtenstein in the *Zeitschrift für Instrumentenkunde*. Three grinding cylinders, the diameter of which is less than that of the sphere, are mounted in a lathe, two of them being carried by one head and one by the other. They are disposed at angles of 120° to each other in a horizontal plane, and grasp the sphere between them. Their rotation produces a perfectly irregular motion of the sphere, and between the three cylinders it is ground to an extraordinary truth of figure. Iron and steel spheres of 25 mm. diameter thus produced showed errors of diameter not exceeding 0·0015 mm.

IN the yearly report of the Russian Geographical Society, we notice that M. Roborovsky, chief of the Tibet expedition, has made a careful survey of the Lukchun depression, the level of which, as is known, lies below the level of the ocean. It appears that the depression has a length of nearly 100 miles, and an average width of 50 miles, and that its level is from 100 to 150 metres below the level of the sea. The desert which is situated in the south of it was crossed in several directions, and M. Roborovsky succeeded in obtaining no less than six specimens of the wild camel. After having reached Sa-chou, the expedition made extensive surveys in the Nan-shan highlands, and then it went out for the exploration of the country in the east of Lake Kukunor.

WITH reference to Mr. Culverwell's recent criticism of the astronomical theory of the Ice age, the Rev. O. Fisher (*Geol. Mag.* for March) quotes the opinion of the late Prof. Adams, expressed to him in a letter dated February 28, 1866. He says: "I do not myself believe in the change of eccentricity of the earth's orbit being a cause of climatal changes on the earth. The effect, if any, would depend only on the *square* of the eccentricity; and this always remains so very small, that I believe the effect on the earth's mean temperature would be almost insensible. Depend upon it, geologists who look in this direction for the cause of glacial epochs are entirely on the wrong track. It seems to me much more likely that the actual act of emission of heat from the sun is variable, than that the change of eccentricity of the orbit should have any sensible effect."

PROF. F. BRIOSCHI read before the Accademia dei Lincei, on March 3, a very full account of the life and works of the late Prof. Cayley, who was a Foreign Associate of the Academy.

A WORK almost entirely concerned with Insurance sta tistics is "Bourne's Handy Assurance Directory," now carried on by Mr. W. Schooling. Every one interested in statistical information relating to human life will find the volume useful.

IN the "Handbook of Jamaica" (Stanford) for 1895, compiled by Mr. S. P. Musson and Mr. T. L. Roxburgh, short biographical descriptions are given of the men of science who have been associated with the island, in addition to the historical, statistical, and general information concerning it.

THE number of the *Bulletin* of the Botanical Department, Jamaica, for January 1895, edited by the Director, Mr. W. Fawcett, is largely occupied with the insect enemies of the cocoa (*Theobroma*) and pine plantations, and some of the Coccidæ or scale-insects. It also contains a very interesting report on the services rendered in the island by the Botanical Department of Jamaica.

WITH the March number, *Science Progress* commences its third volume. Dr. E. Klein, F.R.S., contributes to the number an article on antitoxin, and Mr. J. E. Marr, F.R.S., summarises recent literature concerned with foreign work among the Precambrian and Palæozoic rocks. The subjects of the remaining articles are:—"Insular Floras," by Mr. W. B. Hemsley, F.R.S.; "Peptone," by Dr. W. D. Halliburton, F.R.S.; "Budding in Tunicata," by Mr. W. Garstang; and "The Reserve Materials of Plants," by Prof. J. R. Green.

THE first part of Mr. C. B. Moore's valuable report of his excavations in the prehistoric sand mounds of the St. John's River, Florida, was noticed in these columns last November (vol. li. p. 27). The second part, which has now reached us, contains the results of seven months' continuous work upon all the remains that could be found, and the complete report practically exhausts the study of the mounds on the banks of the St. John's River; for the river has been explored from the source to its outlet. The mounds described in the part of the report before us are, perhaps, not quite so interesting as those of which an account was given in the former part, but this does not diminish their value to archæologists. Future workers among the mounds will find that all the objects found are recorded, instead of merely the rare ones, and those of unusual workmanship. The flint implements, curious types of earthenware, and human remains described, and finely illustrated, furnish material for much scientific study. The Philadelphia Academy of Sciences, in the *Journal* of which (vol. x.) Mr. Moore's report appears, deserves much credit for the admirable illustrations.

METEOROLOGISTS and physicists have reason to be grateful to Mr. S. P. Langley for the valuable series of numerical tables which he has projected, to take the place of a series of meteorological tables compiled by Dr. Arnold Guyot, and published by the Smithsonian Institution in 1852. Dr. Guyot's tables were widely used and appreciated, but the new series will be of even greater service. The work will be completed in three parts: Meteorological Tables, Geographical Tables, and Physical Tables. The first of these volumes appeared in 1893; the second (Smithsonian Miscellaneous Collections, No. 854) lies before us. This has been prepared by Prof. R. S. Woodward, whose experience in geodetic work particularly qualifies him for the task. The introductory part of the volume is divided into seven sections, under the heads: useful formulæ, mensuration, units, geodesy, astronomy, theory of errors, and explanation and use of tables. This section takes up a hundred pages, after which come tables running into one hundred and eighty pages. Every effort appears to have been made to avoid errors, and Prof. Woodward has made a judicious selection of matter from a vast amount of available material. It requires no great prophetic instinct to say that his compendium will be prized by geographer and meteorologist, as a standard work of reference.

THE Meteorological Society of Berlin has published its Report for the year 1895; the Society holds monthly meetings between October and May, and a summary of the papers read is regularly printed in our columns. Prof. Hellmann, the President, appends to the Report a discussion of the wind velocity at Berlin from ten years anemometrical observations. The principal maximum, in the yearly period, falls in March, and the minimum in September; in the daily period, the maximum throughout nearly the whole year occurs between 1h. and 2h. p.m., with a tendency to a second maximum during the night in the cold season. The greatest hourly velocity recorded was fifty miles an hour, which is about half the rate that has been registered in the greatest storms on our own coasts.

WE have received from Dr. Henry Bovey a paper of high technical value, containing the results of numerous experiments which have been carried out in the testing laboratories of the McGill University, on the strength of Canadian Douglas fir, red pine, white pine, and spruce. The tables given tend to prove that timber, unlike iron and steel, may be strained to a point near the breaking-point without being seriously injured. In almost all cases the increments of deflection and extension, almost up to the point of fracture, are very nearly proportional to the increments of load, thus showing that it is difficult to define a limit of elasticity for timber. This, Dr. Bovey thinks, probably accounts for the continued existence of many timber structures of wood in which the timbers have been, and are still, continually subjected to excessive stresses, the factor of safety being often less than one and a half. Whether it is advisable so to strain timber is another question, and experiments are still required to show how wood is affected by frequently repeated strains.

A FURTHER memoir concerning the interesting sodium derivative of nitro-ethane, and the sodium compounds of nitro-paraffins generally, is contributed by Prof. Victor Meyer to the *Berichte* of the German Chemical Society. The nature of these unstable compounds has not hitherto been satisfactorily determined, for in a communication to the *Annalen der Chemie*, J. U. Nef, some time ago, stated that they do not partake of the nature of true derivatives of nitro-paraffins, but contain an altogether differently constituted organic residue. The experimental evidence adduced in support of this view consisted chiefly of the observation which he made that the parent nitro-paraffin was not, or only to a slight extent, regenerated upon treating the sodium compound with dilute sulphuric acid, the compound being decomposed with evolution of nitrous oxide and formation of an aldehyde or ketone. Prof. Meyer has made further experiments in this direction, and their results definitely fix the nature of these sodium compounds, proving that they are indeed true sodium derivatives of the nitro-paraffins, being formed by the replacement of one of the hydrogen atoms of the alkyl radicle by sodium. It is a fact that when sodium nitro-ethane, $C_2H_4NaNO_2$, is dissolved in excess of dilute sulphuric acid at the ordinary temperature, a somewhat vigorous evolution of nitrous oxide occurs. But if the most elementary precautions are taken to prevent the decomposition of so unstable a substance by the thermal change involved in so energetic a reaction, the decomposition proceeds quite differently. If the sodium compound is first dissolved in a little water well cooled by ice, and then an equivalent added of dilute sulphuric acid similarly cooled to near 0°, only a very few bubbles of gas escape, and barely a trace of the odour of aldehyde is perceptible, while a layer of oil, consisting of nitro-ethane, separates out. Even after the operations of purification, which involve some loss owing to the volatility of nitro-ethane, over 60 per cent. of the theoretical quantity of the pure nitro-paraffin was isolated. Moreover, the small quantity of decomposition indicated by the few bubbles of nitrous oxide can be entirely avoided by employing acetic instead of sulphuric acid; the reaction is then less vigorous, and consequently produces at temperatures not far above 0° no dissociation of the nitro-paraffin. The observation of Nef, that the sodium derivatives of the nitro-paraffins are decomposed at the ordinary temperature by the stronger acids, even when diluted, into nitrous oxide and an aldehyde or ketone, is an interesting one; but Prof. Meyer's work now shows that this is due merely to the fact that the nitro-paraffin first regenerated is decomposed in all probability by the heat of the reaction between the sodium and acid, and that when the precaution is taken to prevent this rise of temperature by reacting with ice-cold solutions, the regenerated nitro-paraffin remains intact. Hence it must be concluded that the sodium compounds are true derivatives of the nitro-paraffins which can thus be regenerated from them.

The additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*, ♀) from South Africa, presented by Captain Scarlett Vale; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Miss K. Fleming; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. Richmond Allen; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mrs. Lewis; fifteen —— Rats (*Mus*, sp. inc.) from Sunday Island, Kermadec Group, presented by the Countess of Glasgow; a Hooded Finch (*Spermestes cucullata*) from West Africa, a Chestnut-eared Finch (*Amadina castanotis*) from Australia, presented by Mr. C. H. Hastings; a Woodcock (*Scolopax rusticula*), British, presented by Mr. Charles Smoothy; a Long-necked Chelodine (*Chelodina longicollis*) from Australia, deposited; four Marbled Newts (*Molge marmorata*), European, purchased.

OUR ASTRONOMICAL COLUMN.

PARTIAL ECLIPSE OF THE SUN, MARCH 26.—On March 26 a small partial eclipse of the sun will, if the weather be favourable, be seen from all parts of the British Isles, with the probable exception of places which are to the east of a line joining Lowestoft and Hastings. At Greenwich the magnitude of the eclipse, sun's diameter = 1, will be 0·013, and the first contact will occur at 9.56 a.m., with a duration of only 27 minutes. At Oxford the magnitude will be 0·03, and the duration 40 minutes. At Dublin the magnitude will be 0·09, with a duration of 67 minutes, and at Edinburgh 0·08, with a duration of 62 minutes. The eclipsed part will be a maximum (0·36) as seen from the north-east of North America.

In the *Nautical Almanac* for the current year the eclipse is said to be *invisible* at Greenwich, but the error was corrected in the *Almanac* for 1897. The mistake, however, has not been corrected in many of the almanacs in common use.

DISTRIBUTION OF MINOR PLANETS.—An interesting diagram has been constructed by General Parmentier, to show the distribution of the minor planets at present known between the orbits of Mars and Jupiter (*Bulletin Soc. Ast. de France*, March). Of the 390 planets for which sufficient data are available, 93 have a mean distance between 2·16 and 2·48; 152 between 2·52 and 2·82; 128 between 2·85 and 3·25; and 10 between 3·38 and 3·48. The interval between Brucia (at 2·16) and Mars, is occupied by a single asteroid, comparatively recently discovered, with a mean distance of 2·09. On the outer side of the dense swarm, there are only six minor planets in a zone very nearly as wide as that occupied by the group of 383, and extending to a mean distance 4·68. The region of greatest density of the asteroids so far discovered is at a mean distance from the sun very nearly equal to that indicated by Bode's law (2·80); Ceres, Pallas, and Juno fall a little short of this distance.

At the present rapid rate of discovery of minor planets by the photographic method, data will no doubt soon be available to determine if the outer zone between Camilla and Jupiter is really an almost deserted region.

THE ROYAL OBSERVATORY, EDINBURGH.—We are glad to hear that the new National Observatory for Scotland is making rapid progress towards completion. The buildings are quite finished so far as the outside is concerned, and it is hoped that the two equatorials and the transit instrument will be erected in the early summer. The library will be ready to receive the magnificent collection of twenty thousand volumes as soon as the heating arrangements are completed.

PHYSICAL WORK OF HERMANN VON HELMHOLTZ.[1]

II.

KÖNIG has shown that in many cases, when two notes are sounded simultaneously, beats are heard, as though the most prominent phenomenon was the production of beats not between the two fundamental notes, but between the upper of these, and the nearest partial of the lower note. Inasmuch as these beats are heard when the lower note (as far as can be tested) is free from upper partials, this rule is not the explanation of the phenomenon, but it is a convenient way of expressing the results. In the experiment just described, the frequencies of the two notes were in the ratio 12 to 15. The first partial of the lower note (12) is therefore the nearest to the higher tone; that is to say, König's beat tone and the first difference tone are identical.

It is easy to arrange an experiment in which these conditions are not fulfilled. Thus let the notes be in the ratio 9 : 15. The second partial of the lower note is 18, which is nearer to 15 than to 9; hence the König beat-tone would have a relative frequency of $18 - 15 = 3$. If the siren rotates 10·6 times per second, the frequencies of the two fundamental notes are $9 \times 10·6 = 96$ and $15 \times 10·6 = 160$ respectively. As before, the difference tone is 64.

In this case we can use another method of determining the speed of the siren. In 1880 Lord Rayleigh constructed an instrument in which the mass of air enclosed in a tube is excited by resonance, and the fact of the excitation is indicated by a light mirror, which is set where the motion is greatest, inclined at 45° to the direction of the air-currents. In accordance with the general law that a lamina tends to place itself perpendicular to the direction of a stream, the mirror moves when the air vibrates. In the original apparatus the amount of the movement was controlled by magnets. Since that date Prof. Boys has modified the instrument by substituting a quartz thread suspension for a silk fibre, and using the

[1] A discourse delivered at the Royal Institution, by Prof. A. W. Rücker, F.R.S., on Friday, March 8. (Continued from page 475.)

torsion of the thread instead of the directing force of the magnets. In a lecture delivered before the British Association, in Leeds, he exhibited the apparatus, which is sometimes called a mirror resonator. Prof. Boys has been good enough to make two of these instruments for me, and for reasons, which I will not at the moment enter into, we decided that one of them should respond to 161 vibrations per second. It so happens that this coincides almost exactly with the frequency of one of the notes in the experiment under discussion (160). It is thus possible to use the mirror resonator as an auxiliary instrument to test the speed of the siren. When the proper note is reached the spot of light will move, and if the difference tone is objective the interference bands ought to disappear simultaneously. We tried this experiment several times. An observer, so placed that he could not see the interference bands, lifted his hand when the spot of light moved. It was quite extraordinary to note the absolute agreement between his movements and the behaviour of the bands.

By throwing the spot of light and the bands near together on the screen, the coincidences can be watched by a number of persons. We have tried whether the difference tone is objective in four cases, and in all have detected it by the disappearance of the interference bands. The details of the experiments are collected in the following table. In the first two experiments the first difference tone is, and in the last two it is not, coincident with König's lower beat note.

Difference Tones.

Number of holes in siren.	Interval.	Frequencies.		Difference—and König's beat-tones.	
15 and 12	Major third	320	256	64	64
16 ,, 12	Fourth	256	192	64	64
15 ,, 9	Major sixth	160	96	64	32
18 ,, 8	An octave and a major tone	115·2	51·2	64	12·8

Of course the question at once arises, whether, when it can be distinguished separately, König's beat tone is also objective. I do not wish to express a final opinion on this point, but I may say that when the rows of eight and eighteen holes were opened the speed of the siren was increased till the notes corresponding to 256 and 576 vibrations were produced. König's note would in that case have a frequency of $576 - 2 \times 256 = 64$. We tried twice to obtain this. On the second occasion, especially, all the conditions were favourable, and the experiment was carried on for a long time. On neither occasion did we obtain the smallest sign of an effect on the fork and interference bands.

We must next turn to the summation tone which Helmholtz discovered. It has been almost universally denied that this note is objective. Without going into details, it is only necessary to remark that the late Mr. Ellis, the translator of the "Tonempfindungen," who took a dispassionate view of the controversy, thought that the position assumed by Helmholtz had been disproved. To the statement of Helmholtz that "it was formerly believed that the combinational tones were purely subjective and were produced in the ear itself," Ellis appended the note: "the result of Mr. Bosanquet's and Prof. Preyer's quite recent experiments is to show that they are so."

In an experiment on the summation tone, as the total number of vibrations must not exceed 64, the notes will be too low to be well heard. I shall therefore use a third method of determining the rate of speed of the siren. A mirror attached to the lower plate of the instrument rotates with it. Concentric with, and lying on this, is a circle of paper with eighteen cogs. Light reflected from the mirror passes through holes in two pieces of tinfoil attached to the prongs of a tuning-fork. When the fork is at rest, these holes are superposed; but when the fork vibrates, they move apart, are closed by the tinfoil, and only cross each other twice in each complete vibration. The tuning-fork makes 27·2 vibrations per second, and thus allows the light to pass 54·4 times per second. But when the siren makes 3·048 revolutions per second, the rows of nine and twelve holes give a summation tone of 64 vibrations, and each cog moves over $18 \times 3·048 = 54·9$, or say 55 times the distance between two consecutive cogs. If the wheel were viewed 55 times a second, the cogs would appear stationary, as in that interval each would be replaced by the next. As they are really seen about 54·4 times a second, they appear to move slowly forwards at the rate of about one inter space in two seconds. When this speed is attained the bands disappear, thus proving the objective existence of the summation tone.

We have repeated this observation in various ways, and always with success. The results are summed up in the table.

Summation Tones.

Numbers of holes in siren.	Interval.	Frequencies.		Sum.
10 and 8	Major third	35·5	28·4	64
12 ,, 9	Fourth	36·57	27·43	64
16 ,, 9	Minor seventh	40·96	23·04	64

It is, perhaps, a drawback that all the notes in these experiments are very low. In order to remedy this, and also to put the matter to the test by means of another instrument, we have employed a mirror resonator, which responds to 576 vibrations per second.

The rows of 15 and 12 holes being opened, notes of 320 and 256 vibrations were produced. When they were sounded separately, the noise seemed just to make the resonator move. When they were sounded together, the spot of light was driven off the scale, when the upper note coincided with that of a 320-vibration fork, but immediately returned when this pitch was lost.

The summation tone of 576 vibrations was also obtained by two other combinations of holes. The 320-fork was used, and the disturbance occurred in the one case when the pitch of the upper note given by the siren was nearly the same as before, and in the other case when it was about a tone higher.

The results are summed up in the table.

Summation Tones.

Numbers of holes in siren.	Interval.	Frequencies.		Sum.
15 and 12	Major third	320	256	576
16 ,, 12	Fourth	329·15	246·85	576
16 ,, 9	Major sixth	360	216	576

I venture to think that these experiments prove the accuracy of von Helmholtz. They show that the siren, at all events, does produce objective tones, the frequencies of which coincide with those of the first difference and summation tones, and that this statement is valid as regards the difference tone, whether it is or is not coincident with König's beat-tone.

I have now in one single case tried to convey to you some idea of the complexity of the problems with which von Helmholtz dealt. He was the first man who detected a relation between the surging mass of partials and combination tones and our sensations of concord and discord. The main facts of his theory are, I believe, generally accepted. On some points modern opinion has tended to stray from his views; one of these we have studied afresh this evening.

It was the fact that I had to deliver this discourse which led me to investigate the question anew, and therefore I felt bound to tell you the results we have at present attained. Had it not been for this, I should not have published them as yet. We have several improvements of the apparatus in view. We do not pretend to have covered the field. I do not, therefore, wish to generalise. My object has been to refute hasty generalisations. I am content if I have convinced you, as I have convinced myself, that Helmholtz was correct in stating that the siren produces objective tones, whose frequencies are equal to the sum and difference of their primaries, and that the methods we have employed have brought to light no facts opposed to his view that these notes cannot be explained as secondary effects of partials, but as phenomena of the first order—in other words, as real combination tones.

But brief space now remains to discuss the vast remainder of his work, and as I have already published an appreciation of that (*Fortnightly Review*, November 1894). I must content myself with trying to give you, in a few sentences, some idea of the range of his intellect.

His investigations on optics were not less important than those on sound. He invented the ophthalmoscope, by which the oculist can study the inmost recesses of the eye. The theory of colour vision, the theory of binocular vision, the curious subjective effects which are produced when we deliberately deceive our own senses by the stereoscope; these subjects he made especially his own.

In the field of mathematics he was the first to define the peculiar rotatory motion of a liquid known as vortex-motion. Great men had laid the foundations of hydrodynamics before him, but all had overlooked the importance and laws of the vortex. Since the memoir of Helmholtz was published the subject has been widely studied. Lord Kelvin has originated the famous vortex-ring theory of matter; Prof. Fitzgerald has suggested that the ether may be a complex of vortices, or, as it has been called, a vortex-sponge.

On electricity he wrote much—on the theory of the galvanic cell, on electrolysis, on electromagnetism.

In England, at all events, we give the preference, as regards the last subject, to the theory and writings of our own Maxwell.

A lecture, or rather many lectures, might be delivered on each of these topics, but I prefer to devote the few minutes that remain to other subjects.

As I have already said, von Helmholtz, in an age of specialists, was a universal genius. His intellect could light on nothing which it did not illuminate. Hence his opinions on side issues are of more than ordinary importance, his "obiter dicta" are worth attention, his popular lectures acquire a special interest. Let us for a few moments turn to these.

The watchword of Helmholtz in dealing with educational problems is "freedom." Freedom for the student, freedom for the teacher.

In England we are fond of insisting that there are certain things which everybody who aspires to academic rank must know; of hedging in our students by prescribed courses of study. We make them feel that general culture is an iron-bound safe, which they must wrench open before they can attain the gem of real knowledge, rather than a setting, without which the most profound acquirements seem unattractive and dull. Yet von Helmholtz, one of the most highly educated men, one of the most comprehensive geniuses of the latter end of the century, will have no set courses, except as a preparation for a definite profession, is proved that Germany has "retained the old conception of students, as that of young men responsible to themselves, striving after science of their own free will, to whom it is left to arrange their own plan of studies as they think best." Not content with having made the attainment of this ideal almost impossible for English students, doctrinaire educationalists are now beginning to throw their net around the teacher. It is claimed that as the student must go through a prescribed course of study in order to learn, so the teacher must be drilled and examined before he is allowed to teach. Whatever can be said for this plan as regards the less advanced class of teachers, who are to devote themselves to the instruction of children—and in this case I believe there is something to be said for it—it is quite opposed to von Helmholtz's view of what is best when the teaching is of university rank, and the students are men and women. Make it easy for whoever has given some proof of knowledge, and wants to teach, to try his hand; make it easy for the student to go to the teacher from whom he gains the most. Look for the best educational results, not necessarily from the best lecturer, but from the man who is in closest contact with his subject. Do not force your teacher on his audience, but do all you can to establish a bond of sympathy between them. Trust, in a word, to the free play of living forces, and not to the hampering restrictions of "necessary subjects" and "compulsory lectures." This is a paraphrase of the views which Helmholtz held, and he illustrated them by the history of this Institution itself.

"I have often," he said, "wondered that the Royal Institution of London, a private society, which provides for its members and others short courses of lectures on the progress of natural science, should have been able to retain permanently the services of men of such scientific importance as Humphry Davy and Faraday. It was no question of great emoluments; these men were manifestly attracted by a select public, consisting of men and women of independent mental culture." And then he goes on to show that in a German university the teacher is attracted to his work, because he has to deal with a body of students, who are capable of forming opinions, and of judging what is best for themselves.

And this leads us to another point. Von Helmholtz insisted that it is useless and dangerous to crowd the universities with students, who are not capable of taking advantage of the opportunities they offer. "The majority of students," he says, "must come to us with a sufficiently logically trained judgment, with a sufficient habit of mental exertion, with a taste sufficiently developed on the best models to be able to discriminate truth from the bubbling appearance of truth. . . . It would be very dangerous for the universities if large numbers of students frequented them, who were less developed in [these] respects. The general self-respect of the students must not be allowed to sink. If that were the case, the dangers of academic freedom would choke its blessings. It must, therefore, not be looked upon as pedantry, or arrogance, if the universities are scrupulous in the admission of students of a different style of education. It would be still more dangerous if, for any extraneous reasons, teachers were introduced into the faculty, who have not the complete qualifications of an independent academical teacher." ("Popular Lectures," vol. ii. 1881, p. 264-5.)

It would be out of place on this occasion to attempt to apply these views to existing circumstances in London; but with the knowledge that the final constitution of a Teaching University for the metropolis may be decided within the next few months, I cannot but feel that London will be happy if it escapes from the fetters which some of its so-called friends are forging for learning; and if, on the other hand, the wise determination of the Gresham Commissioners to include in the university only institutions of university rank, can be maintained against the attacks which will be made upon it.

Lastly, I wish to defend the memory of von Helmholtz from a possible misconception. Those who cultivate art may perhaps look upon him as the poet or the master of style look upon the grammarian, as a mere gerund-grinder, occupied with the study of the dead materials which they alone can use. Of course Helmholtz was not a great artist in the sense that he was a great scientific man, but it would be most unfair to picture him as interested only in the study of laws, and as insensitive to beauty, as occupied with sound and light, but careless as to music and painting. I could quote passage after passage from his works to prove his keen sense of the loveliness as well as of the order of nature, to show the homage that he paid, and the freedom he accorded to art. His object was not to lead art captive to science; but rather to unite them in an alliance of mutual confidence and support.

"The horizons of physics, philosophy, and art have," he said, "been too widely separated, and, as a consequence, the language, the methods, and the aims of any one of these studies presents a certain amount of difficulty for the student of any other of them." To smooth away these difficulties, to bridge over the separating gulf, to supply the common language, were the objects of the life-work of von Helmholtz. It was a noble ideal, nobly pursued, and crowned with as much success as could reward the efforts of one man. It is an ideal akin to that which dominates this Institution, where science, literature, and art are all heard in turns.

If it is possible to sum up in a sentence the teaching of von Helmholtz, and the work of his life, it is that, in spite of the apparent diversities between science and science, between science, philosophy, and art, there is a fundamental unity, and that the future is for those who detect, amid the seeming discords of the schools, the true harmony which underlies and dominates them all.

ELECTRIFICATION OF AIR AND OTHER GASES.[1]

§ 1. AT the meeting of the British Association in Oxford in August 1894, a communication was given to Section A, entitled "Preliminary Experiments to find if Subtraction of Water from Air Electrifies it." These experiments were performed during July of 1894, and were a continuation of experiments which were commenced in the Physical Laboratory of the University of Glasgow in December of 1868 with the same object, but which were then, for various reasons, discontinued before any decisive result had been obtained.

1 A Paper by Lord Kelvin, P.R.S., Magnus Maclean, and Alexander Galt, read at the Royal Society on February 21.

§ 2. A glass U-tube with vertical branches (Fig. 1), each 18 inches long and about 1-inch bore, with the upper 8 inches of one of the branches carefully coated outside and inside with clean shellac varnish, was held fixed by an uninsulated support attached to the upper end of this branch. The other branch was filled with little fragments of pumice soaked in strong sulphuric acid or in water, and a fine platinum wire, with one end touching the pumice, connected it to the insulated electrode of a quadrant electrometer. A metal can, M, large enough to surround both branches of the U-tube without touching either, was placed so as to guard the tube from electric influences of surrounding bodies, the most disturbing of which is liable to be the woollen cloth sleeves of the experimenters or observers moving in the neighbourhood. This metal can was kept in metallic connection with the outside metal case of the

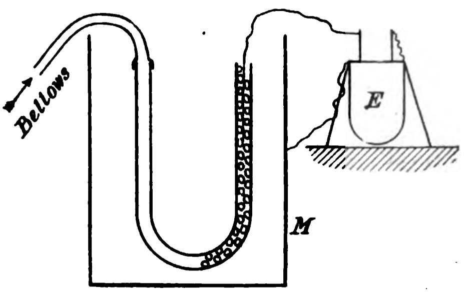


FIG. 1.

quadrant electrometer. The length of the exposed platinum wire between the U-tube and the electrometer was so short that it did not need a metal screen to guard it against irregular influences. An india-rubber tube from an ordinary blow-pipe bellows was connected to the uninsulated end of the U-tube. Air was blown through it steadily for nearly an hour. With the pumice soaked in strong sulphuric acid in the other branch, the electrometer reading rose in the course of three-quarters of an hour to about 9 volts positive. *When the pumice was moistened with water, instead of sulphuric acid, no such effect was observed.* The result of the first experiment proves decisively that the passage of the air through the U-tube gave positive electricity to the sulphuric acid, and therefore sent away the dried air with negative electricity. A corresponding experiment with fragments of pure chloride of calcium instead of pumice in sulphuric acid, gave a similar result. In repetition

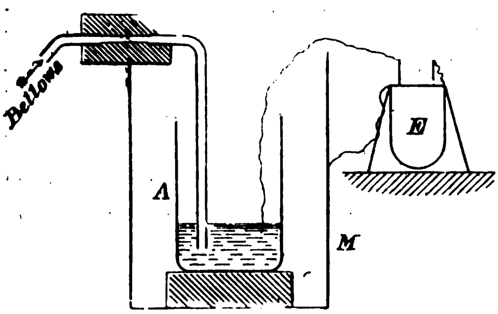

FIG. 2.

of the experiments, however, it was noticed that the strong positive electrification of the U-tube seemed to commence somewhat suddenly when a gurgling sound—due to the bubbling of air through free liquid, whether sulphuric acid or chloride of calcium solution in the bend of the U-tube—began to be heard. It has since been ascertained that it was because no liquid accumulated in the bottom of the U-tube that no electric effect was found when the pumice was moistened with pure water.

§ 3. Arrangements were made to prevent any bubbling of the air through liquid, by using a straight tube instead of a U-tube. In a large number of experiments with pumice, moistened with pure sulphuric acid in the straight tube, and air blown through for about half an hour, no definite electrification was obtained. In this straight tube, as formerly with the U-tube, pumice moistened with pure water gave no electrification. Chloride of calcium in lumps, not specially dried, gave no effect in the straight tube; but if previously heated to 180° or 200° and put into the straight tube when still hot, it gave an enormous positive electrification immediately on the commencement of blowing. Strong positive electrification was obtained a second time, by discharging the electrometer to zero, re-insulating, and re-commencing the blowing. But after discharging a second time, re-insulating, and re-commencing the blowing, no further electrification was found.

§ 4. In continuation of these experiments on September 25, the arrangement represented in Fig. 2 was set up. The outer metallic guard-vessel, M, was kept connected by a wire to the case, and to one pair of quadrants of a quadrant electrometer, E. The water in the inner glass jar, A, was connected by a platinum wire to the other pair of quadrants of the electrometer.

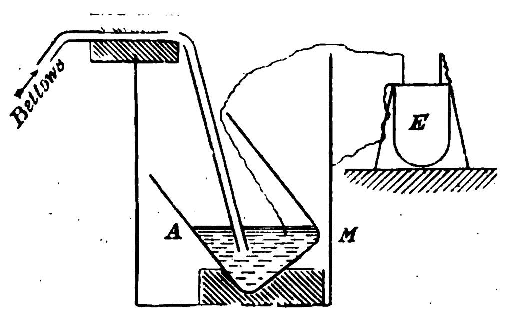

FIG. 3.

To have this inner jar well insulated, it was supported on a block of paraffin; and the other end of the glass tube dipping into the water was fitted into one end of a tube of paraffin, to the other end of which was fitted a tube for ingress of air, from bellows, as shown in the figure. The insulation of this arrangement was found to be good. When air was blown through the water it was found that the jar containing the water became positively electrified.

§ 5. To prevent splashing of water out of the jar, a paper cover was put on its mouth, or the jar was tilted, as shown in Fig. 3, so that the bubbles broke against the inside of the jar. In three experiments thus made, the same electrification was still found, amounting to about 6 volts positive in a quarter of an hour.

§ 6. As the jar was in every experiment positively electrified,

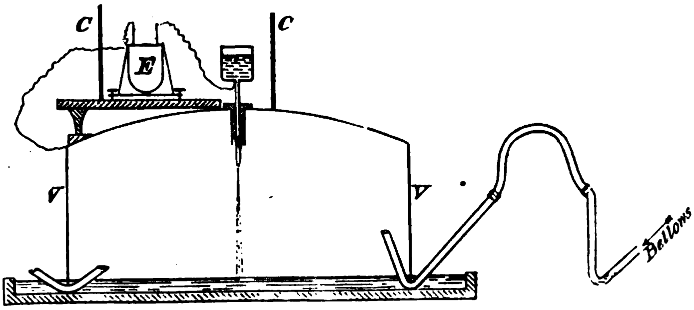

FIG. 4.

the air, if unelectrified[1] when entering it, must have been negatively electrified when leaving it.

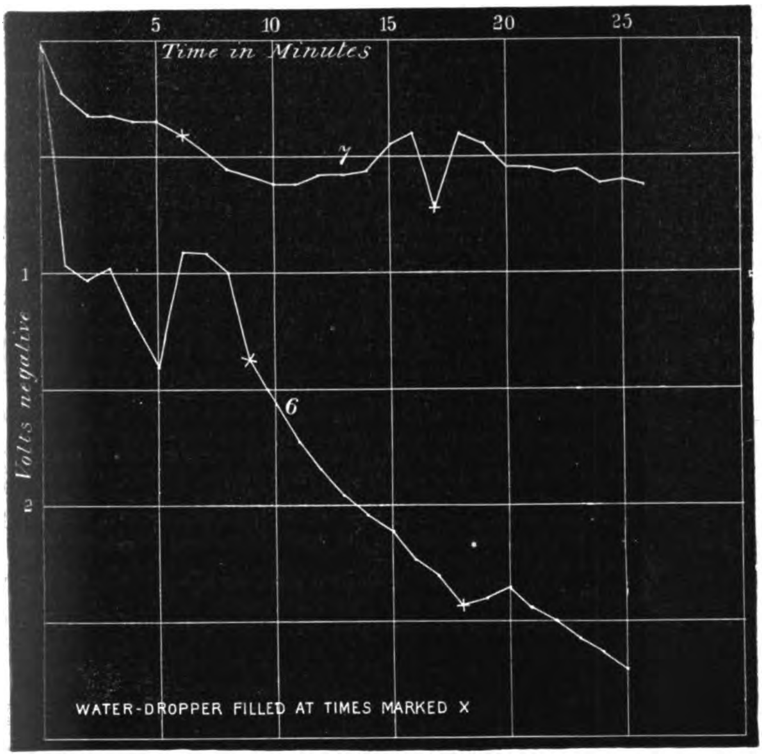
§ 7. To test if the air was negatively electrified after bubbling, on October 11 the apparatus[2] shown in Fig. 4 was set up. The apparatus consists of a large sheet iron vat, V V, 123 cm. in diameter and 70 cm. in height, inverted on a large wooden tray lined with lead, and supported by three blocks of wood. By filling the tray with water the air is confined in the vat.

C C is a metal screen kept metallically connected with the

[1] Air was similarly blown from bellows into the vat (see § 7) without any bubbling, and no electrification was observed.

[2] The vat, the water-dropper, and the electrometer are the same as in the apparatus described in the *Proceedings* of the Royal Society, vol. 56, year 1894, "Electrification of Air," by Lord Kelvin and Magnus Maclean.

case of the electrometer, and with the vat. It surrounds both the electrometer and the water-dropper, to prevent any external



CURVES 6 AND 7.

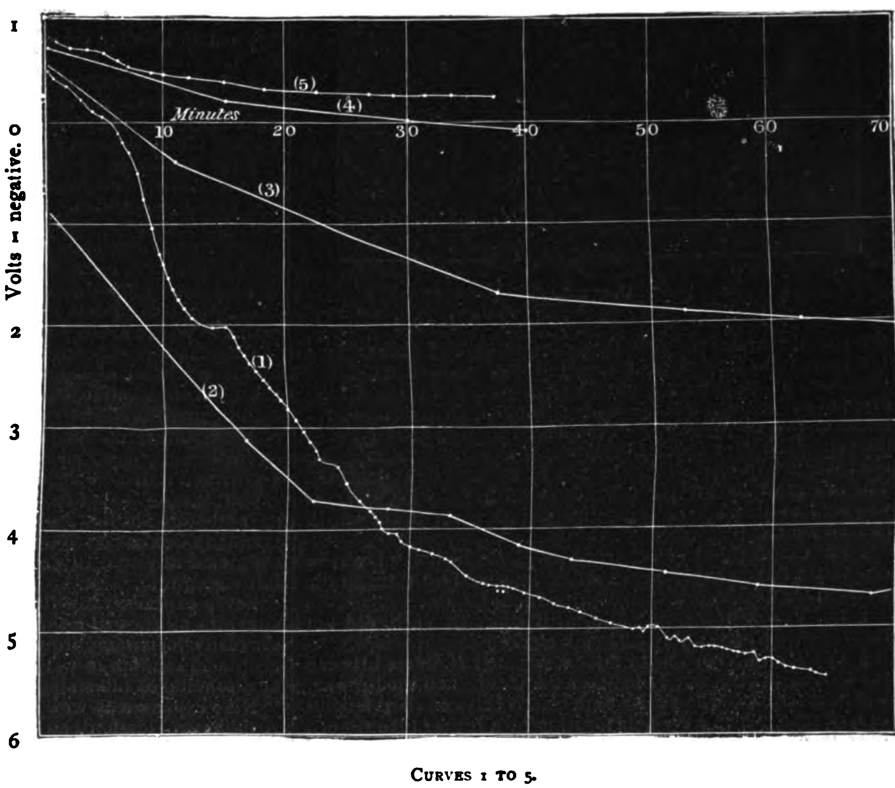
varying electrifications from vitiating the proper results of our experiments.

This screening of the electrometer is absolutely necessary when it is used with high sensibility (70 scale divisions per volt in our experiments) in a laboratory or other place where various other electric experiments may be simultaneously going on. Four years ago the electrometer, the vat, and the water-dropper, were set up on the class-room table *without a metal screen.* When the deflection indicated about 4 volts negative (see § 8), the negative lead of Lord Kelvin's house electric-light circuit, which passes through the class-room, was joined to earth. This changed the deflection of the electrometer suddenly by 1 volt in the positive direction. When the positive lead was "earthed," the deflection was changed suddenly by 6 volts in the negative direction. Putting on sixteen 8 c.p. electric lamps, eight on each side of the class-room, changed the deflection by two-thirds of a volt in the negative direction.

§ 8. In experimenting with the same apparatus[1] in 1890, it was found that the water jet gave negative electricity to the ordinary air of the laboratory enclosed in the vat. The present experiments fully confirm this result, showing a gradual negative electrification of the enclosed mass of air rising to about 5 volts in an hour, once every day for the first few days. For twenty-eight days after the vat was set up, in October 1894, fifteen observations of an hour each were taken to find the effect of the water-dropper, with no other disturbing influence on the unchanged volume of air inside the vat. These experiments verify the conclusion (*Phil. Mag.*, August 1890) that the more the air inside the vat became free of dust, the less became the rate at which the air was negatively electrified by the water-dropper.

§ 9. On October 15 last the vat was lifted from the tray to remove some obstruction in the nozzle of the water-dropper, which was not then flowing freely. Curve (6) was obtained that afternoon. The air in the vat was the ordinary air of the laboratory, and the curve shows the effect of the water-dropper alone in electrifying the air negatively. For the next two days the water-dropper was kept running continuously for about eight hours each day, to wash the dust out of the air, and on October 18 curve (7) was obtained. It shows a much less rate of negative electrification than curve (6). In the experiments of summer 1890 an aspirator was used to draw the air from the vat, and a tube full of cotton-wool was used to filter the air drawn into the vat.

Curves (1) to (5) are reproduced from the *Philosophical Magazine*, and they show that the more the air becomes free from dust the less is the rate at which the



CURVES 1 TO 5.

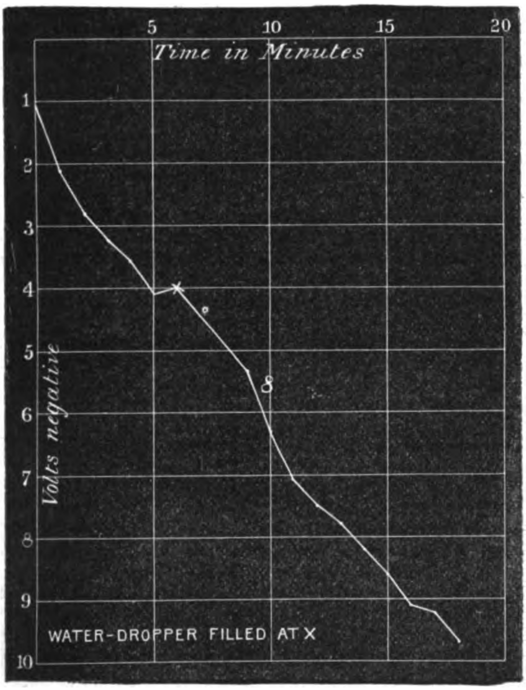
[1] *Phil. Mag.* August, 1890, "Electrification of Air by a Water Jet," by Maclean and Goto.

water-dropper electrifies. Thus curve (1) was obtained from the ordinary air of the laboratory in the vat, and curve (2) after the aspirator was working for some time. In this curve the water-dropper itself was running for some time before the first observation was taken. The other curves were obtained after further continuous working of the aspirator.

After curve (4) was obtained the aspirator was worked continuously for twenty-five hours, and then curve (5) was obtained.

§ 10. At the end of twenty-three days of October and November 1894 (§§ 8, 9, above), when the air inside the vat must have been fairly free from dust, and when the water-dropper of itself was giving little negative electrification, we bubbled air into it by a forked tube, one end of which was connected to a bellows, and three other open ends were below the water inside the vat. In five experiments thus made—two on November 7, two on November 8, and one on December 17, an average negative electrification of 5 volts in twelve minutes was obtained.

§ 11. We now arranged a U-tube with pure water in it (Fig. 4) outside the vat. Air from the bellows bubbled



CURVE 8.

through the water in this U, and was carried thence by a block-tin pipe into the vat without any further bubbling. Observations by the quadrant electrometer, while the water-dropper was running and the bellows worked, gave us measurements of the varying state of the electrification of the air in the vat. The average of fifteen experiments gave a negative electrification of the air in the vat of 8½ volts in 25 minutes. The rate at which the air was blown in in these experiments was such as to displace the entire volume of air in the vat in half an hour.

§ 12. Curve (8) shows the rate of electrification of air, in one of the fifteen experiments, when thus bubbled through the water in the U-tube and then admitted into the vat.

§ 13. Two U-tubes, in series, with water in each, did not seem to give a perceptibly cumulative effect.

§ 14. The effect of one or more wire gauze strainers between the U-tube and the vat, or between the U-tube and the bellows, was next tested. The gauzes were placed between short lengths of lead tube, which were held together by a rubber tube slipped over them. The arrangement is shown by longitudinal and cross sections in Fig. 5. Twelve wire gauzes, with or without cotton-wool between them, placed between the bellows and the U-tube, did not prevent the subsequent electrification by bubbling of the air thus filtered. But when placed between the U-tube and the vat they almost entirely diselectrified the air, even without the cotton-wool, and still more decidedly when cotton-wool was loosely packed between the wire gauzes. A single wire-gauze strainer produced but little of dis-electrifying effect.

§ 15. The interpretation of these experiments is complicated, and the time required for each is lengthened, on account of the large mass of air in the vat to start with, whether uncharged or retaining electricity from previous experiments, and also on account of the effect of the water-dropper itself. Hence, in our later experiments, we fell back on the arrangement shown in Fig. 2, by which we test the electrification of the liquid, and not directly that of the gas blown through it.

§ 16. In our first experiment with this apparatus the amount of the electrification did not seem much affected when a paper cover was put on the beaker, or when we tilted the beaker as shown in Fig. 3. We now made a large number of tests with different covers and screens (chiefly of sheet copper or sheet zinc, or brass wire gauze) at different heights above the liquids, and we concluded that, if the screens are not within a centimetre and a half of the liquid surface, they do not directly affect the magnitude of the electrification obtained. In nearly all of the subsequent experiments a horizontal circular screen of thin sheet copper, leaving an air space of about 3 mm. all round between its edge and the inner surface of the jar, about 3 cm. above the liquid surface, was used to prevent spherules of the liquid from being tossed out of the jar by the bubbling.

§ 17. In the following short summary of our results the duration of each experiment was ten minutes. The effect of blowing air through water and other liquids is summarised in §§ 18 to 27, and of blowing other gases than air through water in §§ 28 to 31.

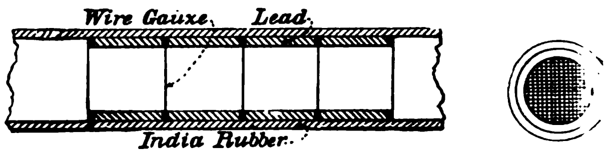


FIG. 5.

§ 18. The jar contained 200 c.c. of the Glasgow town-supply water (from Loch Katrine). A mean of seventeen experiments showed an electrification of the jar to four volts positive when air was blown through it for ten minutes.

§ 19. A solution of zinc sulphate of different strengths was now used instead of the pure water. Three experiments, with 150 c.c. of water containing one drop of a saturated solution of the zinc sulphate, gave half the positive electrification that would, under similar circumstances, have been obtained from water only. With five drops no definite electrification was obtained. With greater proportions of the zinc sulphate solution up to saturation (twenty-four experiments altogether) the electrification was on the average slightly negative.

§ 20. Twelve experiments were then made to test the effect of adding a solution of ammonia to the water. One drop reduced the electrification to one-half; two drops brought it down to one-quarter. With larger proportions of ammonia than this, up to a saturated solution, we found a very slight positive electrification, never amounting to more than a small fraction of a volt, and therefore negligible in the circumstances.

§ 21. Seven experiments with sulphuric acid of different strengths all showed small *positive* electrification, the amount gradually decreasing from ¼ volt, in ten minutes, with 0·5 per cent. acid in water to $\frac{1}{16}$ volt, in the same time, with acid of full strength.

Seven experiments with hydrochloric acid solution of different strengths all showed a small *negative* electrification, the amount gradually increasing from ½ volt, in ten minutes, with ⅓ per cent. acid solution in water to 1¼ volts, in the same time, with acid solution of full strength.

Nine experiments with calcium chloride solution were made. A saturated solution and a solution diluted to 75 per cent. of full strength gave no result; but solutions of gradually diminished strength, from 50 per cent. down to $\frac{1}{10}$ per cent., showed a negative electrification from fully ½ volt, in ten minutes, down to $\frac{1}{15}$ volt.

Additions of very small quantities of washing soda to water greatly reduce the positive electrification obtained.

Loch Katrine water, supersaturated with carbonic acid, and placed in the insulated jar, showed, when air was bubbled through it for ten minutes, a negative electrification of ¼ volt.

§ 22. Ten drops of paraffin oil added to water reduced the electrification to about half of that obtained from water only. Thirty drops reduced it to about a tenth, which, as it amounted to only 0·4 volt during the time of the experiment is negligible.

§ 23. Ten drops of benzene reduced the electrification to half, and thirty drops to about a third of that taken by pure water.

§ 24. A saturated solution of granulated phenol (carbolic acid) was made, and small portions of it added to the water in the jar. Several experiments showed no diminution in the electrification as long as the quantity of the phenol solution present in the water was under 10 per cent. With 25 per cent. the electrification was reduced to a third. With strengths greater than this up to saturation the electrification was reduced to one-sixth.

§ 25. A saturated solution of common salt was prepared. Blowing air through 200 c.c. of water containing the quantities of the salt solution mentioned, gave us in ten minutes the following electrifications:—

Per cent. of saturated solution of salt in water.	Volts positive.
(*a*) 0·004	2·4
(*b*) 0·02	1·2
(*c*) 0·1	0·6
(*d*) 0·5	0·4
(*e*) 2·0	0·15
(*f*) 4·0	0·0

§ 26. Several experiments showed that with 200 c.c. of water containing not more than ten drops of absolute alcohol, practically the same amount of positive electrification (4 volts in ten minutes) is obtained as if pure water were used. With fifty drops less than 2 volts were got, and with 100 drops less than 1 volt. 25 and 50 per cent. alcohol in the water gave very small and hence negligible positive electrification.

§ 27. One drop of saturated solution of copper sulphate in 200 c.c. of water showed one volt positive in ten minutes. With ½ per cent. of it in the water, the electrification was reduced to a fraction of a volt positive. With greater proportions of copper sulphate present, up to saturation, slightly negative electrifications were obtained, but never amounting to more than about one-tenth of a volt, and hence negligible.

§ 28. On blowing carbonic acid gas from a cylinder obtained from the Scotch and Irish Oxygen Company, through pure water in the glass jar, the water became electrified to 8¾ volts positive in ten minutes. Blowing the breath through water gave an electrification of 3 volts positive in the same time: this diminished result is doubtless due chiefly to the diminished rate of bubbling.

§ 29. The blowing of oxygen from a cylinder, obtained from the Oxygen Company, through water, gave as a mean of four experiments a positive electrification to the water of half a volt in ten minutes. When continued for fifty-five minutes, it gave the very decided result of 5 volts positive.

§ 30. Hydrogen prepared from zinc and dilute sulphuric acid was passed into a large metal gas-holder; and was passed on from this to bubble through the water in the insulated jar. In two experiments this was done immediately after the preparation of the hydrogen; in another it was done after the hydrogen had remained eighteen hours in the gas-holder. In each of the three experiments the water was electrified to 2 volts positive in ten minutes.

When the hydrogen was allowed to pass direct through a tube from the Wolffe's bottle where it was generated, to bubble in the insulated jar, the magnitude of the effect obtained was very much larger. In one case a mixture of muriatic acid and sulphuric acid and water was used, and the reading went off the scale positive in thirty seconds (more than 10 volts). In other two experiments with dilute sulphuric acid and zinc in the Wolffe's bottle, the electrifications obtained were 6 volts positive in seven minutes, and 7·3 volts positive in thirteen minutes, in the last of which the hydrogen was allowed to bubble through caustic potash contained in a small bottle between the Wolffe's bottle and the insulated jar.

The hydrogen was next generated in the insulated jar itself, the tube for ingress of air used in the ordinary experiments being taken away. 200 c.c. of pure water, along with some granulated zinc, was put into the jar. Then some pure sulphuric acid was added, and electrometer readings were taken. In two experiments with no screen in the jar (§ 16) the reading went off the scale *negative* (1) in two minutes and (2) in four minutes (more than 9 volts in each case). In another experiment in other respects the same, but with a copper screen 7 cm. above the surface of the liquid, the electrification showed 2 volts *negative* in two minutes, then came back to zero in five minutes, and in the next six minutes went 4 volts *positive*. The jar and pair of quadrants connected with it were then metallically connected with the outer case of the electrometer for a few seconds, and reinsulated; in five minutes the reading went up to 2 volts *positive*. A little more sulphuric acid was added to the jar, which was disinsulated for a short time and reinsulated; the reading went up to 7 volts *positive* in four minutes. The jar was again disinsulated for a few seconds and reinsulated; the reading went up in four and a half minutes to 6½ volts *positive*.

§ 31. Coal-gas, bubbled through water in the insulated jar, gave 1·4 volts positive in ten minutes.

§ 32. In the ordinary experiment of bubbling air through a small quantity of water in the bottom of the jar it was noticed that the electrification did not commence to be perceptible generally till about the end of the first minute; and that it went on augmenting perceptibly for a minute or more after the bubbling was stopped. The following experiment was therefore tried several times. One of us stood leaning over the jar, with the head about 10 inches above it, and the mouth so partly closed that breathing was effected sideways; another blew the bellows, and another took the readings of the electrometer. After bubbling had been going on for some minutes, and the readings were rising gradually (4 volts per ten minutes, as in § 18), blowing was stopped. As soon as the bubbling ceased, the first-mentioned observer, without moving his head or his body (see § 7, regarding the necessity to have the electrometer screened from outside influences), blew into the jar to displace the negatively electrified air in it. In every case the electrometer reading showed instantly a small rise in the positive direction.

In the carrying out of these experiments we have received much valuable help from Mr. Walter Stewart and Mr. Patrick Hamilton.

§ 33. The very interesting experiments described by Lenard, in his paper on the Electricity of Waterfalls (*Wiedemann's Annalen*, 1892, vol. 46, pp. 584–636), and by Prof. J. J. Thomson, on the Electricity of Drops (*Phil. Mag.* April 1894, vol. 37, pp. 341–358), show phenomena depending, no doubt, on the properties of matter, to which we must look for explanation of the electrical effects of bubbling described in our present communication, and of the electrification of air by drops of water falling through it, to which we have referred as having been found in previous experiments which were commenced in 1890 for the investigation of the passage of electrified air through tubes.[1]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Isaac Newton Studentship in Astronomy has been awarded to Mr. S. S. Hough, Scholar of St. John's College, Third Wrangler in 1892, and Smith's Prizeman in 1894.

Mr. C. T. Heycock, Lecturer in Chemistry at King's College, First Class in the Natural Sciences Tripos 1889 has been elected to a Fellowship.

The discussion by the Senate of the proposals for the encouragement of Advanced Study and Research, by the admission under special conditions of Graduates of other Universities, was on the whole favourable to the scheme. There seems little doubt that the preliminary resolutions on the subject will be passed early next term.

Mr. Arthur R. Hinks, of Trinity College, has been appointed Second Assistant at the Observatory for five years, from July 1, 1895.

[1] "Electrification of Air by a Water Jet." By Magnus Maclean and Makita Goto, *Phil Mag.* August 1890, vol. 30, pp. 148–152.

SIR JOHN LUBBOCK has been elected President of the London Society for the Extension of University Teaching, in succession to Mr. Goschen, M.P., resigned.

MR. GILBERT R. REDGRAVE has been appointed Chief Senior Inspector of Schools and Classes under the Science and Art Department, and Mr. T. B. Shaw, Inspector of the North-Western District, has been promoted to a Senior Inspectorship.

SCIENTIFIC SERIALS.

WE have received two recently issued parts of the *Journal of the Asiatic Society of Bengal* (vol. lxiii. part ii. Nos. 1 and 3) containing, *inter alia*, an important paper by Mr. Lionel de Nicéville (the author of the admirable book on the butterflies of India, Ceylon, and Burma, now approaching completion), on new and little-known butterflies from the Indo-Malayan region, illustrated by five excellent coloured plates, representing species belonging to most of the principal families represented in the district. Among the species figured is a handsome new species of *Stichophthalma* (*S. sparta*) from Manipur, allied to the well-known Chinese *S. howqua*, of Westwood, belonging to a genus allied to the great blue Morphos of South America, and not inferior to some of them in size; a gynandomorphous specimen of the common, but very remarkable, Indian Fritillary, *Argynnis niphe*, L., the female of which mimics the abundant, highly-protected, and much-imitated *Danaus chrysippus*, L.; several species of *Laxita*, Butler, a beautiful genus allied to our Duke of Burgundy Fritillary, but much larger, and with rounded brown wings, generally suffused with crimson on the fore wings, and marked with metallic blue spots beneath; three species of *Papilio*, two of which mimic species of the widely-removed sub-family *Euplœinæ*; and many other interesting species. Several genera, as well as a large number of species, are described as new, and much fresh information is given relative to species already known. Several very useful lists and tables are also included in the paper, relative to the species of *Daphla*, allied to *D. teuta*, Doubleday and Hewitson, and those of the genera *Gerydus*, Boisduval, *Logania*, Distant, &c. When we look at the number of important books and papers that are now constantly issuing from the press on the butterflies of various parts of the British East Indies, it seems strange to remember that thirty years ago almost nothing had been published specially on the subject, except Horsfield and Moore's Catalogue of the Lepidoptera in the East India Company's Museum, and Westwood's "Cabinet of Oriental Entomology."

Memoirs (*Trudy*) *of the St. Petersburg Society of Naturalists*, vol. xxiv. part 1, Zoology and Physiology.—Notes on birds found in the Mediobor Mountains of Podolia, by I. D. Mikhalovsky. Seventy-two species are mentioned.—On the structures and reactions of the cells of the digestive tube of the pupæ of *Musca Cæsaris vomitoriæ*, by N. Kholin, with one plate.—The Natural History Museum of Great Britain, and other zoological institutions of West Europe, by A. Yaschenko.—Report on the cruise of the *Nayezdnik* in the Arctic Ocean in 1893, by N. Knipovitch. Leaving Reval, the cruiser visited the Murman coast, the Dvina and Onega bays of the White Sea, and the west coast of Novaya Zemlya, entering the Matochkin Strait and the Yugorskiy Shar. No less than eighty successful dredgings, down to depths of 190 fathoms, as well as measurements of temperature, were made. The author's remarks on the differences of colour and density of the blue Gulf Stream water, which is easily traced along the Murman coast, and the more so along the coast of Novaya Zemlya, are especially interesting. The colour and the density better delineate the south-east limits of the Gulf Stream current than the differences of temperature which are affected in both the Gulf Stream and the cold current by various local causes. In the bays of the White Sea, M. Knipovitch found in the bottom mud, which has temperatures of one or two degrees below zero, the *Yoldia arctica*, characteristic, as is known, of the Glacial period deposits and the Arctic Seas; while the same has never been found in the Arctic Ocean off the Murman coast, nor in the eastern parts of the Barents's Sea.—Report on the zoological institutions of West Europe, by Prof. K. Sainte Hilaire.—In the *Proceedings* we notice a very interesting report, by A. A. Birulia, on the part played by the phagocytes in the sexual processes with the *Galeodes*, and A. K. Trotsin's report on his zoological journey to the Transcaspian region and Russian Turkestan.

THE *Meteorologische Zeitschrift* for January contains a careful discussion of the rainfall of the Sandwich Islands, by Dr. J. Hann, based chiefly on observations supplied by the Director of the Weather Service at Honolulu. The amount of the rainfall is subject to great fluctuations. At Hilea, Kau (on the south side of Hawaii), 44·5 inches fell in 1886, and of this amount 51 per cent. fell in November. In 1889 the annual fall was only 13·9 much as, or about half as much as in November 1886. At Honolulu the average annual fall is 40 inches. The heaviest falls occur on the windward side of the largest of the islands, that is, on the north-east of Hawaii, and the smallest falls occur on the southern part of Oahu, and the south-west of Maui. The wettest period in almost all the islands is from November to March. The principal exception to this is on the leeward side of the mountains of Hawaii, where more rain falls in summer than in winter.

SOCIETIES AND ACADEMIES.

LONDON

Physical Society, March 8.—Mr. Walter Baily, Vice-President, in the chair.—Mr. Naber exhibited, and shortly described, a new form of gas voltameter. The chief advantages claimed for this instrument are that either the oxygen or the hydrogen can be collected separately, and that the level of the liquid inside and outside the burette can be made the same; thus no correction has to be applied to the volume of the gas on this account. Variations in the temperature and barometric pressure are allowed for by reading an air thermometer which is fixed alongside the burette. The inventor considers that this instrument will compare favourably in accuracy with the copper and silver voltameters now in general use. Prof. S. P. Thompson considered that now so much care had been bestowed on the design of a gas voltameter, this instrument might come into more general use than heretofore.—Dr. Johnstone Stoney, F.R.S., exhibited (1) the local heliostat, (2) an improvement in siderostats. By a local heliostat the author means one which can only be used in places the latitudes of which differ slightly from that of the place for which the instrument was specially constructed. The limits within which the instrument works with sufficient accuracy for ordinary spectroscopic work, are such that one instrument can be used in any place in the British Isles. The heliostat exhibited was a modification of one previously described by the author, which is now in very general use, and it is capable of sending a reflected ray in any direction in, or nearly in, a horizontal plane. In the new instrument the pendulum clock previously used to supply the motive power, is replaced by a balance-wheel clock; this change decreases the cost of the instrument, while it adds to its portability. A tangent screw, worked by a long rod, supplies a slow motion for adjusting the position of the reflected beam, and is of use when examining the spectra of the solar prominences, &c. The instrument is adjusted in the meridian by means of a gnomon and horizontal divided circle which form a sun-dial. This divided circle is so arranged that it is always horizontal when the polar axis is in adjustment, and can therefore be used whatever the latitude of the station at which the observations are being made. In connection with the use of a heliostat in conjunction with a spectroscope, the author recommends, when using a grating, the introduction of a large glass prism between the heliostat and the slit of the spectrometer. An impure spectrum is thus formed on the slit, and by moving the slit to the part of this spectrum corresponding to light of the wavelength under observation, the difficulties due to the overlapping of the spectra may in a great measure be overcome. After mentioning that the great difficulty in designing a siderostat which should work with "astronomical accuracy," is to get a form of sliding motion quite free from back-lash, and which will move perfectly regularly, Dr. Stoney exhibited a model of a form of mechanism for obtaining such a motion which he had devised. The principle on which the instrument depends is that, if you have a point fixed to a circle which rolls on the inside of another circle of double the diameter, this point will describe a straight line. The smaller disc does not, in the model exhibited, roll directly on the larger disc, but an idle wheel is introduced which rolls on the *outside* of both the discs. Slip is avoided by placing steel bands between the idle wheel and the discs, one end of each of the two bands being fixed to the circumference of the idle wheel, while the other ends are fixed, one to the circumference of each of the discs. Back-lash is prevented by means of a spiral spring attached to a point on the smaller disc; this point being so chosen that it moves nearly perpendicular to the direction in which the spring acts. Hence the spring is always stretched to nearly the same amount, and no extra strain is brought to bear on the driving-clock in different positions of the instrument. Prof. S. P. Thompson considered that the best method to employ when using sunlight was to incline the telescope, &c., parallel to the polar axis, under which circumstance the mirror of the heliostat need only rotate about a vertical axis.—A paper, on a simple form of harmonic analyser, was read by Mr. G. U. Yule. At a former meeting of the Society, Prof. Henrici showed a form of analyser in which the paper on which the curve is traced was given a to-and-fro movement, a planimeter being used as an integrator. The author being struck with the advantages of the use of a planimeter, both as regards cheapness and simplicity, has devised another form of analyser in which a planimeter is used. The principle on which this instrument works is as follows:—Suppose we have a straight line (X X) which can move parallel to the base line of the given curve, so that every point in this line describes a perpendicular to the base; further, suppose that a disc, the circumference of which is some aliquot part of the base of the curve, say $2l/n$ where $2l$ is the base length, is capable of rolling on the line (X X) without slip. If the centre of the disc is brought over the initial point of the curve, and any point (D) at a distance r from the centre on a horizontal diameter is marked, then if the centre of the disc is made to describe the curve which is to be analysed, the area of the curve described by the point D is given by the equation

$$R_1 = a + \cos n\pi \frac{rn\pi}{l}\int_{-l}^{+l} y \sin n\theta \, dx,$$

where a is the area of the curve to be analysed. Similarly, if the point D is taken originally on a vertical diameter, the area of the curve traced out is

$$R_2 = a + \cos n\pi \frac{rn\pi}{l}\int_{-l}^{+l} y \cos n\theta \, dx.$$

In any practical case it is convenient to take r some multiple of a/π units of length, say 10, then the above equations become

$$R_1 = a + \cos n\pi . 10n. B_n$$

and

$$R_2 = a + \cos n\pi . 10n. A_n$$

where B_n and A_n are the coefficients of sin $n\theta$ and cos $n\theta$ in the Fourier series expressing the equation to the curve. The areas of the curves traced out by the point D (R_1 and R_2) are obtained by allowing the tracing-point on an Amsler planimeter to rest in a small conical hole at D. The line X X is the edge of a rolling parallel ruler which has a rack cut along it. A series of toothed wheels give the coefficients of the different terms in the series. In the instrument exhibited there were wheels to give the first four terms, but the author said it was possible to work with wheels which gave the sixth term. The above analyser was the outcome of a simple step-by-step integrator which the author had devised. In this case the base line of the curve having been divided into a number of equal parts, then, by means of a scale of sines attached to the instrument, the tracing-point of a planimeter is set at a point whose abscissa is sin $n\theta$, while it is moved parallel to the axis of y through a distance δy corresponding to one of the elements into which the base was divided. Prof. Henrici said he had at one time considered the question of constructing an analyser which should employ a planimeter as the integrator, and he was particularly pleased with the instruments exhibited. Since the area required was the difference between the area of the original curve, which is traced out by the centre of the disc (K), and the curve traced out by the point D, and since this area is really the area swept out by the straight line K D, if we attach an integrating wheel to the disc, with its axle parallel to K D, the required area can be directly obtained from the reading on this wheel. In addition, if a second integrating wheel were fixed to the disc, with its axle perpendicular to K D, the coefficients of cos $n\theta$ and sin $n\theta$ could both be obtained by going round the curve once. The instrument devised by Mr. Yule was practically the inverse of one the (Prof. Henrici) had invented. Dr. Burton pointed out some incorrect signs in the proof given; these, however, do not affect the final expressions obtained. Mr. Inwards suggested that errors due to back-lash might be avoided by using either a double wheel or a double rack, so that by means of a spring each side of the teeth which were engaged might be in contact at the same time.—Prof. Minchin gave a short account of a paper by Mr. H. N. Allen, entitled "The Energy Movements in the Medium Separating Electrified or Gravitating Particles." The object of the paper is to trace out the equipotential surfaces and lines of flow for two electrified points or gravitating particles, and then to consider the paths along which the "energy cells" move when the charged points or gravitating particles either move towards or away from one another. By energy cell the author understands the small volume of the dielectric bounded by the walls of a tube of force, and by two neighbouring equipotential surfaces, which can be looked upon as containing a certain definite amount of energy. The author gives two figures showing the paths of the energy cells: (1) when the charged particles come together and meet; (2) when they separate and move off to infinity in opposite directions. Using Maxwell's expression for the pressure along the lines of force, and the equal tension at right angles required by his theory to account for the attraction exerted by the sun on the earth, the author has calculated the energy density in the medium at the surface of the sun. The value obtained is 16-horse power-hours per c.c. Hence he concludes that, at a distance from all gravitating bodies, a c.c. of ether contains at least this amount of energy. Prof. Minchin showed how, by the use of polar coordinates the expressions given by the author could be simplified. He also gave a graphical method of obtaining the equipotential surfaces for any configuration having given those for any other configuration. He pointed out that by a similar line of reasoning to that used by the author, the energy per c.c. of the medium at the surface of Arcturus must be 8100 times as great as at the surface of the sun, so that the minor limit given above by the author must be multiplied by 8100 at least.

Entomological Society, March 6. — Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. B. G. Nevinson exhibited a long series of *Heliothis peltigera*. He stated that the specimens were bred from larvæ found on the Dorsetshire coast during July 1894, feeding on the flowers of *Ononis arvensis*, which were extremely luxuriant. A few also were taken on *Hyoscyamus niger*. He added, that all the larvæ went down by the end of July. The first emergence took place on August 20, and they continued coming out at the rate of about five a day, through the rest of that month and September; only five emerged in October, and the last one appeared on November 11. Mr. G. T. Bethune-Baker, Mr. Eustace Bankes, Mr. B. A. Bower, the Rev. Seymour St. John, and Mr. H. Goss made remarks on the habits and distribution of the species in England.—Mr. Bower exhibited a variable series of *Scoparia basistrigalis*, Knaggs, showing light, intermediate and dark forms, taken at Bexley, Kent, from June 12 to July 7, 1891–94. He said the species appeared to be poorly represented in collections, and when present was almost invariably misnamed. Mr. Bankes commented on the rarity of the species, and said the specimens exhibited formed the most interesting collection of it and its varieties which he had ever seen.—Lord Walsingham, F.R.S., exhibited larvæ of *Pronuba yuccasella*, which he received more than four years ago from Colorado, and which were still living. One specimen of the moth had emerged two years ago.—Mr. Goss exhibited, for Mr. G. C. Bignell, a pupa of a Tortrix, with the larval legs, and also a specimen of a Sawfly, *Emphytus cinctus*, L., with eight legs. Mr. G. H. Verrall and Mr. McLachlan made some remarks on the latter species, and as to the insertion of the fourth pair of legs.—Prof. Meldola exhibited a wooden bowl from West Africa, from which, after arrival in this country, a number of beetles (*Dermestes vulpinus*) had emerged. Specimens of the latter were also exhibited. It was not clear to the exhibitor whether the larvæ had fed upon the wood, or had simply excavated the cavities which were apparent in the interior of the bowl for the purpose of pupating. Mr. McLachlan, Mr. J. J. Walker, Herr Jacoby, and Lord Walsingham made some remarks on the habits of Dermestes.—Mr. Champion read a paper entitled "On the Heteromerous Coleoptera collected in Australia and Tasmania by Mr. J. J. Walker, R.N., during the voyage of H.M.S. *Penguin*, with descriptions of new genera and species.

Part ii." Mr. Walker and Mr. Gahan made some observations on the distribution of certain of the species described.—Mr. Roland Trimen, F.R.S., contributed a paper entitled "On some new species of butterflies from tropical and extra-tropical South Africa."—Mr. G. A. James Rothney contributed a paper entitled "Notes on Indian Ants," and sent for exhibition a number of specimens in illustration of the paper, together with nests of certain species.

Geological Society, February 20.—Dr. Henry Woodward, F.R.S., President, in the chair.—The President announced to the Fellows the grievous loss which the Society had suffered in the decease of its Foreign Secretary, Mr. J. W. Hulke, F.R.S., President of the Royal College of Surgeons. He dwelt on the great value of Mr. Hulke's work in vertebrate palæontology, on his long services as a member of Council and an officer of the Society, and on his amiable personal qualities, which had endeared him to a wide circle of friends. He read the following resolution which the Council had that afternoon unanimously voted, and communicated to Mrs. Hulke with the expression of their heartfelt sympathy: "That this Council most deeply deplore the sad loss that the Society and all those interested in palæontology have sustained by the untimely decease of our Foreign Secretary, Mr. J. W. Hulke, F.R.S., whose investigations in various branches of science have led to such valuable results."—Contributions to the palæontology and physical geology of the West Indies, by Dr. J. W. Gregory. The earlier part of the paper was largely concerned with the corals of the raised reefs of Barbados, and, on account of the confusion in the synonymy of the West Indian corals, the synonymy of the species was given in some detail. A list of the mollusca of the low-level reefs followed. In discussing the age of the Barbados rocks, the author stated that the following was the sequence (in descending order):—

Raised coral reefs	Low level: Pleistocene. High level: Pliocene.	
Oceanic series ...	*Archæopneustes-abruptus*-limestone. Thalassic marls.	Miocene (and possibly partly Pliocene) and partly Oligocene.
Scotland beds ...	Oligocene (probably Lower).	

—The Whitehaven sandstone series, by J. D. Kendall. The Whitehaven sandstone, with its associated shales, is a purple-grey deposit sometimes having a thickness of 500 or 600 feet. The author gave details of a large number of sections of the series, which also contains thin coal-seams and occasionally *Spirorbis*-limestone.—Notes on the genus *Murchisonia* and its allies, with a revision of the British carboniferous species, and descriptions of some new forms, by Miss J. Donald.

Zoological Society, March 5.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of February, and called special attention to a fine female giraffe recently arrived from South Africa. This was believed to be the first example of the large, dark-blotched race ever seen alive in Europe, the giraffes previously exhibited having belonged to the smaller and paler form found in Northern Tropical Africa. The Society has also purchased a pair of Sable Antelopes (*Hippotragus niger*) and a pair of Brindled Gnus (*Connochætes taurina*), all in excellent condition.—Dr. St. George Mivart, F.R.S., read a paper on some distinctive structural characters in the hyoid bone in certain parrots.—Mr. A. D. Michael read a paper on a new Freshwater Mite found in Cornwall, and belonging to the genus *Thyas*, of which only two species were previously known. It is proposed to call it *Thyas petrophilus*.—Mr. G. A. Boulenger, F.R.S., read a paper "on the nursing-habits of two South-American Frogs," and exhibited a specimen of *Hyla goeldii* with eggs on the back. He also made remarks on a male specimen of *Phyllobates trinitatis* from Venezuela, carrying its tadpoles on its back, in the same way as had previously been observed in frogs of the genus *Dendrobates* from Surinam and Brazil.

Royal Meteorological Society, February 20.—Mr. R. Inwards, President, in the chair.—Mr. W. Marriott gave an account of the thunderstorm and squall which burst over London so suddenly on the morning of January 23. It appears that this storm passed across England in a south-south-easterly direction at the rate of about forty-seven miles an hour, being over Northumberland at 4 a.m., and reaching the English Channel by 11 a.m. Thunder was first heard in the vicinity of Leeds, and accompanied the storm in its progress across the country. One of the most remarkable features of the storm was the sudden increase in the force of the wind, for in London it rose almost at one bound from nearly a calm to a velocity of thirty-six miles an hour. This sudden increase of wind caused considerable damage, and at Bramley, near Guildford, twenty-eight trees were blown down along a track 1860 yards in length.—Mr. E. Mawley presented his report on the phenological observations for 1894. Between the third week in March and the third week in May plants generally came into blossom in advance of their usual time, and towards the end of April the dates of first flowering differed but little from those recorded at the same period in the very forward spring of 1893. The cuckoo made its appearance even earlier than in the previous year. The year 1894 was a very productive one, and both the hay and corn crops proved unusually heavy, but much of the latter was harvested under very trying conditions as regards weather. The frosts of May 21 and 22 entirely destroyed the previous prospect of a glorious fruit season. Indeed, the only really good crop was that of pears, which were singularly abundant throughout nearly the whole of England.—Mr. A. B. MacDowall read a paper on some gradual weather changes in certain months at Greenwich and Geneva.

Dublin.

Royal Dublin Society, November 21, 1894.—Prof. W. J. Sollas, F.R.S., in the chair.—The following papers were read: On the occurrence of seiches in Lake Derravaragh, co. Westmeath, by Staff-Commander J. R. H. MacFarlane, R.N. This paper (communicated by Prof. D. J. Cunningham, F.R.S.) is interesting as being the first record of observations, from the United Kingdom, of these phenomenal changes of the level of the water in lakes. These singular rhythmic movements, somewhat resembling tidal ebb and flow, were found occurring in the Swiss lakes towards the close of the last, and beginning of the present, century, and many skilful observers devoted considerable time in the endeavour to elucidate the cause or causes; but, as yet, no distinct explanation has been given, although it would appear to have been generally noticed that they are accompanied by a low barometer. It also appears that the characteristics of the land, surrounding the observation spot, influence the time occupied by a complete rise and fall of the water, which has been termed the *duration of the seiche*; and, further, that it is probable such durations are constant for each observation spot, but the *amplitude*, or amount of rise above, and fall below the level, will depend on the amount of influence exercised in causing the seiche; this influence being at present unknown. The observations made at Lake Derravaragh were necessarily confined to one spot, no other observers being available for synchronous observations at different stations. The maximum amplitude recorded was 5·8 inches, and the duration of seiche, fairly constant, about 39 minutes.—A paper was communicated by Sir Charles Cameron, on the effect of poisons and antiseptics on germination, by Mr. F. H. Perry Coste.—The Rev. R. Budkin described an "automatic image-finder," the object of which is (1) to show where the image of any object placed before any lens must be formed; (2) to prove that the image is found there; (3) to help to explain the construction of the various optical instruments in use such as the microscope, telescope, camera, and projection lamp.

December 19.—Sir Howard Grubb, F.R.S., Vice-President, in the chair.—The following papers were read: Mr. John R. Wigham described and demonstrated a method of increasing the power of continuous lighthouse lights.—Prof. W. J. Sollas, F.R.S., gave a description of a new fossil, resembling annelid tubes, from the Cambrian of Puck's Rocks, Howth, near Dublin. Upon this fossil the author has bestowed the name *Pucksia MacHenryi*.

Paris.

Academy of Sciences, March 11.—M. Marey in the chair.—On argon, by M. Berthelot. The author announces the combination of the new element with benzene vapour under the influence of the electric discharge, and promises details to follow.—Remarks on the curves defined by a differential equation of the first order, by M. Émile Picard.—On the total eclipse of the moon of March 11, by M. J. Janssen. The importance of observations of lunar eclipses by photographic photometry in connection with the constitution of the higher regions of our atmosphere is emphasised.—On the losses of nitrogen carried off by infiltrated water, by M. Schlœsing. The loss of nitrogen by soils in the basin of the Seine through the elimination of nitric acid in drainage waters is discussed. In conclusion the author believes such losses not to be very important; they are roughly proportional to the richness of the soil in organic matter, and do not much impoverish already poor soils.—Analysis of oyster-shells, by MM. A. Chatin and A. Muntz.—Demonstration of a theorem of whole numbers, by M. de Jonquières. If $a_1, a_2, a_3, \ldots, a_n$ are n different whole numbers, the product $\Pi(a)$ of all these numbers, multiplied by the product $\Pi(a_i - a_j)$ of their differences by twos, is a multiple λ of the product of n first numbers $1, 2, 3, \ldots, n$, multiplied by the product of their differences by twos, that is to say, is equal to $\lambda(1^n . 2^{n-1} . 3^{n-2} \ldots \overline{n-2}^3 . \overline{n-1}^2 . n)$.—Observations of Wolf's planet BP (23 February, 1895) made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet and L. Picart, noted by M. G. Rayet.—Volumes of salts in their aqueous solutions, by M. Lecoq de Boisbaudran.—On M. Darboux' method for the integration of equations to the derived partials of the second order, by M. E. Goursat.—On certain algebraical groups, by M. E. Cartan.—On "fonctions entières," by M. H. Desaint. The "fonctions entières" of the type 0, 1 or 2, of which the exponential multiplier of the infinite product of primary factors of M. Weierstrass is of the form $Ae^{\alpha x^2+\beta x+\gamma}$, where A is a constant, α and β real and α positive, possess the property that, if their zeros are real, the zeros of their derivatives are also zeal.—On the direct measurement of the mean spherical luminous intensity of sources of light, by M. A. Blondel. A description of the instrument termed a *lumen-mètre* and its use.—On the analysis of silicon, by M. Vigouroux.—Action of formaldehyde on ammoniacal salts, by MM. A. Brochet and R. Cambier. The first action of ammonium chloride on formaldehyde may be admitted to be the production of $(CH_2 : NH.HCl)_3$. This reacts on heating as follows: $2(CH_2 : NH.HCl)_3 + 3CH_2O + 3H_2O = 6(CH_3.NH_2.HCl) + 3CO_2$, giving a theoretical yield.—On acid chlorides and aldehyde chlorides, by M. Paul Rivals. The thermal data are given for monochloracetic chloride and trichloracetic chloride, and are shown to vary in the same way as with the corresponding acids.—Optical resolution of α-oxybutyric acid, by MM. Ph. A. Guye and Ch. Jordan. The synthetical α oxybutyric acid is a racemic form. The authors have successfully separated the lævorotatory form from the dextrotatory form by means of their brucine salts.—On daturic acid, by M. E. Gérard. The acid is shown to have a real existence, and forms definite metallic salts. It does not consist of a mixture of stearic and palmitic acids.—Glycogen in the blood in normal and in diabetic animals, by M. M. Kaufmann. Glycogenic matter is a constituent of normal blood. The blood of animals rendered diabetic by extirpation of the pancreas contains much more glycogen than that of healthy animals.—On the signification of the disengagement of carbonic acid by the isolated muscles of the body, compared to that of the absorption of oxygen, by M. J. Tissot. The total quantity of carbonic acid disengaged by a muscle placed in the air has no relation with the phenomena of physiological activity, of which the isolated muscle is yet the seat. The absorption of oxygen is alone related to the manifestation of physiological activity, the absorption being at the maximum when the muscular activity is greatest, and at the minimum when it is diminished or on the point of disappearing.—On the structure and affinities of *Microsporon*, by M. Paul Vuillemin. The author includes *Microsporon vulgare* among the Phycomycetes, and not among the Saccharomycetes. It is not a necessary parasite, is found on healthy skin, but is adapted for parasitism, and is most abundantly found in the epidermis of new-forming spots of simple pityriasis.—On the embryonic development of the Dromiacean genus *Dicranodromia*, by M. Eug. Caustier.—On a new combination of forms on quartz crystals, by M Fred. Wallerant.—On an approximate estimate of the frequency of earthquakes on the surface of the globe, by M. F. de Montessus de Ballore.

BERLIN.

Physiological Society, February 1.—Prof. du Bois Reymond, President, in the chair.—After a discussion on Dr. Cohnstein's communication on "intravenous infusion of sodium chloride," Prof. G. Fritsch discussed the simple principles on which he had for many years obtained stereoscopic photographs on an enlarged scale. He exhibited a series of these photographs, among which those of the inner ear excited particular interest.

February 15.—Prof. du Bois Reymond, President, in the chair Prof. Zuntz gave an account of experiments, made in conjunction with Staff-Surgeon Dr. Schumburg, on the effect of load on the metabolism and body-functions of soldiers on the march. Two students, feeding uniformly on a somewhat complicated but accurately analysed diet, made on alternate days marches up to 45 kilometres with a load increasing to 31 kilograms. Taking first the nitrogenous metabolism, it was found that the excretion of nitrogen through the urine and sweat was but slightly increased by even the most severe exertion. The slight loss of proteid thus noticed was made good in the subsequent period of rest. At the end of each experiment the consumption of oxygen was found to be greater than at the beginning. When the marches were made on three consecutive days with an increasing load, it was found that the consumption of oxygen was increased even at the beginning of the third day's march, and was still further increased at its end. The body-temperature rose to 38°·5 C., and in some cases to 40° C. The heat production was three times as great as during rest, and the regulation of temperature to compensate for this was almost entirely brought about by the evaporation of sweat. The concentration of the blood was found to be but very slightly increased by exhausting marches; the red blood-corpuscles were scarcely more numerous than normally, whereas the white were markedly increased in number. The movements of the heart at the end of the experiments showed a lengthening of the systole and distension of the right ventricle, whose dull area on percussion, as also that of the liver, was extended during severe exertion. The respiratory activity was at first, and with light loads, improved, but later on difficulties of breathing made their appearance. The psychic condition, as measured by the reaction-time to simple stimuli, was not depressed by heavy marches; but when fatigued the patients reacted more slowly to complicated stimuli. Muscles not used in marching, were as readily excitable at the end of the most severe march as during complete rest. A high external temperature was found to exert the same influence with a light load, as the heaviest load did at more moderate temperatures, and some details of the experiments were found to depend on individual peculiarities.

Meteorological Society, February 5.—Prof. Hellmann, President, in the chair.—Prof. von Bezold spoke on the unstable equilibrium of the atmosphere which precedes a thunderstorm. The fact that in the interior most thunderstorms occur in the afternoon and during the summer, whereas near the coast they are most frequent at night and in the winter, shows that there must be different causes for the instability. As a matter of fact the speaker showed that not only over-heating of the lower layers of air, but also excessive cooling of the upper layers, must lead to unstable equilibrium and a correspondingly powerful upward current of air. A similarly unstable state is brought about by the sudden solidification of strongly cooled water-drops, or the condensation of air highly supersaturated with moisture. The conditions for the realising of the above states are different in the interior and at the coast or over the sea, and the mode of formation of a thunderstorm is also correspondingly different. He considered it very desirable that further observations of thunderstorms at sea should be collected.—Mr. Archenhold exhibited water-colour drawings, made by Captain Henning in 1884, of the unusual twilights then occurring, he being at the time ignorant of the abnormality as observed by others. One of the most remarkable features in the drawings were the sharp and straight lines of demarcation in the colours of the sky. The speaker further exhibited a photograph of a halo he had observed by moonlight.

Physical Society, February 8.—Prof. Schwalbe, President, in the chair.—Dr. Neuhaus exhibited a series of colour photographs taken by Lippmann's method with prolonged exposure. Spectra show, if the exposure is sufficiently long, a greenish band in the infra-red as well as in the ultra violet, in addition to the ordinary colours. The coloured band was very markedly displaced by both over- and under-exposure. The photographs of objects with mixed colours, such as fruits, flowers, butterflies, &c., were also good; but their production was extremely difficult, and only one plate in twenty-five was, on an average, successful. It was found more easy to photograph naturally mixed than artificially mixed colours. When describing his methods, it was pointed out that some substance such as eosin or cyanin must be added to the films to make them more sensitive to red rays, and less sensitive to blue. When dealing with the theory of colour photography, which was expounded by Dr. Zenker as early as 1868, the speaker referred to a number of difficulties which had not yet been solved. Thus, in the first place, nobody has as yet demonstrated the existence of the superimposed silver films in the gelatine, although they should be visible under the microscopic powers now available. In the next place, the presence in the gelatine film of granules whose diameter is equal to several half-wave-lengths is not reconcilable with the usual theory of colour photography; so that, on the whole, a comprehensive theory of the phenomena has still to be established.—Mr. Archenhold gave some additional details as to the mechanical parts of the great telescope he had described in the previous meeting of the Society.

February 22.—Prof. von Bezold, President, in the chair.—Prof. Lummer spoke on the necessary corrections of dioptric systems, and developed theoretically the possibility of the law of points holding good for certain relations between focal length and aperture. Prof. Raoul Pictet spoke on the "critical point," and explained his own views, according to which substances must still be in the fluid state at the critical point. This follows from the fact that the amount of heat which must be put into the substance, as reckoned from absolute zero, is less than the latent heat of the liquid, and the fact that solid bodies do not separate out from solution at the critical temperature. They must be still in solution in the fluid, since they separate out in the crystalline form by a further rise of temperature, and go into solution again as the temperature falls to the critical point. This last fact was demonstrated by the speaker on a solution of iodide of potassium.

AMSTERDAM.

Royal Academy of Sciences, January 26.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Franchimont communicated a paper on a new class of urea-derivatives, viz. the urea-alcohols or ureols, one of which, ureo æthanol, has been prepared by the author and Mr. Van Breukeleveen. This body, obtained from amino aethanol through Wöhler's synthesis of urea, forms colourless crystals, which fuse at 95°, and dissolve readily in water, methyl-alcohol and ethyl-alcohol, but very sparingly or not at all in most organic solvents. It appears to possess properties both of urea and of an alcohol. With nitric acid it forms a compound, which is decomposed by so-called real nitric acid at the ordinary temperature, with the formation of carbonic acid and nitrous oxide. With benzoyl chloride it yields a benzoate, which fuses at 129°, and is decomposed by nitric acid in the manner described above. With acetic anhydride and sodium acetate, a diacetyl derivative is obtained, which fuses at 102°.—Mr. Hoogewerff directed attention to an apparatus, devised last summer by Mr. J. Boot. The object of the apparatus is to easily and quickly graduate retorts, pipettes, and burettes, especially such as are intended for techno-chemical researches. The firm of Kobb at Stützerbach in Thüringen has been commissioned to make the apparatus. Mr. Van der Waals showed that the condition for the equilibrium between coexistent phases, viz. the equality of the thermodynamic potential, may be deduced from the kinetic theory by assuming that the two phases interchange an equal number of particles, and may be regarded as a particular instance of the more general law by which the kinetic theory expresses the density in different parts of a space, wherein the moving molecules are subjected to the action of forces.—Prof. Kamerlingh Onnes communicated the results of investigations in the Leiden laboratory by: (1) Dr. L. H. Siertsema on the magnetic rotational dispersion of oxygen and nitrogen at a pressure of 100 atm., giving the following relation between the rotation w and the wave-length λ: oxygen $w = C. \frac{868 \cdot 03}{\lambda}\left(1 + \frac{0 \cdot 07202}{\lambda^2}\right)$, nitrogen $w = C. \frac{560 \cdot 41}{\lambda}\left(1 + \frac{0 \cdot 32424}{\lambda^2}\right)$ and proving again the superiority of Maskart's formula (see p. 470). (2) Dr. P. Zeeman on the Kerr effect in polar reflection on iron and cobalt at normal incidence, tending to the conclusion that none of the proposed theories completely explains Sissingh's phase-difference. (3) Dr. P. Zeeman on the optic constants of magnetite, determined with regard to the relation between Sissingh's phase in the Kerr phenomenon and the maximum of magnetisation. (4) Mr. A. Lebret on the variation of the Hall effect in bismuth with temperature, it being found to be nearly linear between – 38° and 239°.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

BOOKS.—The Pygmies: A. de Quatrefages, translated by F. Starr (Macmillan).—The German Universities, their Character and Historical Development: Prof. F. Paulsen, translated by Prof. E. D. Perry (Macmillan).—A Treatise on Bessel Functions and their Applications to Physics: Profs. Gray and Mathews (Macmillan).—Meteorology, Weather, and Methods of Forecasting, &c.: T. Russell (Macmillan).—Diary of a Journey through Mongolia and Tibet in 1891 and 1892: W. W. Rockhill (Washington).—Bourne's Handy Assurance Directory, 1895 (Schooling).—An Elementary Text-Book of Hydrostatics; W. Briggs and G. H. Bryan (Clive).—The Telegraphist's Guide to the New Examinations in Technical Telegraphy: J. Bell (*Electricity* Office).—The Source and Mode of Solar Energy throughout the Universe: Dr. I. W. Heysinger (Lippincott).—Handbook of Jamaica, 1895 (Stanford).—Im Reiche des Lichtes: H. Gruson (Braunschweig, Westermann).—Honest Money: A. T. Fonda (Macmillan).—Collected Papers on some Controverted Questions of Geology: Dr. J. Prestwich (Macmillan).

PAMPHLETS.—N.S.W. Government Railways and Tramways—Annual Report of the Railway Commissioners for the Year ending June 30, 1894; Do., Supplement to the Railway Commissioners' Annual Report.—Die Reisen des *Jason* und der *Hertha* in das Antarktische Meer 1893–94: Dr. J. Petersen (Hamburg, Friederichsen).

SERIALS.—Science Progress, March (Scientific Press, Ltd.).—Medical Magazine. March (Strand).—Proceedings of the Physical Society of London, Vol. xiii. THURSDAY, MARCH 28, 1895.

ORB-WEAVING SPIDERS OF THE UNITED STATES.

American Spiders and their Spinning Work; a Natural History of the Orb-weaving Spiders of the United States, with Special Regard to their Industry and Habits. By Henry C. McCook, D.D. Vol. iii., with descriptions of orb-weaving species and plates (pp. 1–284, pl. 1–30). (Published by the Author, Academy of Natural Sciences of Philadelphia, A.D. 1893.)

VOLS. i. and ii. of this work have been already noticed in these columns. (See NATURE, vol. xlii., p. 244, 1890; *Ibid.* xliii., p. 74, 1890.) The volume before us completes the work, and bears date 1893; but it was only issued to the public at the end of 1894. To the general reader this is a matter of little consequence, but to the specialist it is often important, for it frequently happens, as in this instance, that new genera and species are characterised and described; it then often becomes necessary to decide, on the questions of priority that may arise, as exactly as possible when such descriptions were made, and the date inscribed on the work, it is manifest, cannot be implicitly relied upon.

In the preface to the present volume, it is stated that the work has engaged the author's thoughts for more than twenty years, and to this the amount of research and observation testified to in three large volumes amply bears witness. The first six chapters of vol. iii. (pp. 1–131), being part i., are a kind of supplement to vols. i. and ii., and are "on various natural habits and physiological problems" of spiders. Part ii. (pp. 132–277) carries out the prospectus of the work at first issued, viz. *descriptions* of the American "orb-weavers," illustrated by thirty coloured plates of great beauty and accuracy, especially in regard to the anatomical details; two, however, of these plates are of spiders of various groups and species alluded to in the foregoing part of the work, though without special description. The author speaks of this portion of his task (part ii.) as in many respects its most difficult part; but this may be taken as tolerably certain, that though vols. i. and ii. and the first half of vol. iii. will always be the most popular part, the latter portion of vol. iii. will prove of most value to the scientific world. The observation and detailing of habits, manners, and general economy, whether of spiders or any other group in the natural world, afford unlimited scope for imagination, sentiment, as well as popular and picturesque description, all of which the true scientific worker has resolutely and wholly to shun, or, at any rate, to repress with a strong hand. It seems almost a pity that these two distinct portions of Dr. McCook's work had not been issued separately, as the total cost of the whole—50 dollars—is a heavy sum to pay for the 136 pages and thirty plates, which will alone be indispensable to the systematic working araneologist. Nor will it be possible (we are told in this vol.) to obtain vol. iii. apart from the other two.

All that was said in the notices, above alluded to, of vols. i. and ii. can be again here repeated in praise of the execution of the work in this third volume. Chap. i. is "on toilet, drinking, and social habits"; chap. ii. on "memory, mimicry, and parasitism"; chap. iii., "biological miscellany"; chap. iv. "on weather prognostications, sundry superstitions, and the commercial value of spiders' silk"; chap. v., "on moulting habits of spiders"; chap. vi., "regeneration of lost organs, and anatomical nomenclature." On all these subjects there are many most interesting and useful observations.

In chapter i., p. 1, speaking of spiders' habits of cleansing themselves of objectionable matters by their having a spiny armature of the legs and mandibles (*falces*), so evidently well adapted for the purpose, it is asked, "Did the habit of cleanliness arise from the possession of these implements, or were the implements developed out of the vital necessity for a cleanly person?" In the first place, it suggests itself as hardly tenable to assume, *à priori*, such a vital necessity in respect to spiders, any more than with regard to some Acarids, or the larvæ of certain insects, whose habit it seems to be not only to need no cleansing, but to encourage the accumulation upon their bodies of various kinds of adventitious and, at times, of even excrementitious matter; but not to dwell on this view of it, the case of the spiders might perhaps be simply presented in this way. The accumulation of dust, or soil, or what not about them, arises mainly from their having clothing and spinous armature, in which those substances become entangled and retained, while at the same time those very causes of the inconvenience become the means of obviating it; for we may take it that the first efforts of a sentient being are to rid itself of whatever may adhere to it, to its hindrance or annoyance; in this process, whatever existing portion of structure came handiest would necessarily be the first used, whether, as in the case of cows and other horned cattle, the lashing of its sides by a heavily-tipped tail, or the muscular movements of the ears, or the action of the hinder hoofs; but it would scarcely be argued, either, that the ears, tails or hoofs of cows were developed just for the purpose of ridding them of insect or other inconveniences, or that the habit of so using them arose out of the animals' possession of ears, tails, and hoofs. Nor can we, it is conceived, argue either that spiders' habits of using hairs and spines in cleansing themselves arose from the possession of such implements, nor that these implements were developed from those habits. All that we can say with any certainty, seems to be that while hairs and spines, &c., were developed by various means and for various ends, the more perfect adaptation of some of them for special functions would no doubt be effected by natural selection; such, for instance, as the development of the calamistrum on the metatarsi of the fourth pair of legs in numerous widely separated genera, and even families of spiders, for the utilisation of the silk-matter of the supernumerary spinners, which last are always found correlated with the calamistrum. Under the heading of "Burrowing Spiders," pp. 31-35, we have a very interesting and important account of trap-door nests made by Lycosid spiders; those hitherto known as "trap-door spiders" having been exclusively of the family Theraphosidæ. A remarkable account of a spider apparently voluntarily changing its

Z

colour, is given at p. 51. This account, it seems, is taken from NATURE, April 13, 1893, p. 558; but it appears to need corroboration.

Among other points in respect to spiders' spinning work, the use and commerical value of the product is naturally referred to (pp. 83-89), and the various experiments (already published from 1709 to the present time) made to ascertain their use and value are noted; but the subject does not seem to have attracted much attention since Prof. Wilder's experiments in 1865-1869. Some subsequent researches made by a Mr. Stillbers, an Englishman (quoted in a paper by M. Guatier), appear to need more circumstantial reference and explanation. It may, however, be mentioned here, that in 1884 a small mass of spider's silk was received, through Prof. Thiselton-Dyer, by the present writer, from Almora, Saharunpur, India. This was mixed up with the débris of dead insects and spiders, as well as with portions of the plants among which the silken webs were spun. Some of this mass was examined by Mr. Thomas Wardle, who reported upon it in the *Journal* of the Society of Arts, May 1885 (pp. 679-680). In an exhaustive paper in that journal, on "Researches on Silk Fibre," Mr. Wardle says, in the course of his report:—

"I believe, if it can be obtained in quantity, it might be packed in bales and sent to England, where it would readily find a market for being carded and spun into silk threads for sewing or weaving purposes. It is difficult to estimate its market value. I dare say it would, at any rate, realise one shilling to two shillings per lb. It is rather dirty, and this would to some extent detract from its value as compared with silk waste."

The spider to which this silken mass was referable is *Nephilengys* (*Epeira*) *Malabarensis*, Walck., a species of very wide tropical distribution, and apparently in great abundance where it occurs. There seems to be no reason why almost any amount of this silk should not be obtainable from the low plants and scrub on which the spiders spin their snares, and, with a little care in gathering, much less intermixed with dirt and other adventitious matter than the sample above alluded to. In fact, we may easily conceive that it would be possible, with a little trouble, to form a kind of spider-farm for the purpose of producing this silk in the greatest possible perfection and abundance. From Mr. Wardle's analysis and treatment of this silk, it may be seen that it possesses some very valuable and curious characters.

The chapter on "Moulting Habits" is full of exceedingly interesting details, both from published works and the author's own observations. Moulting is a critical operation in spider-life, and is usually attended with a great demand on the vital powers of the spider; and though spiders probably seldom succumb when in a state of nature, moulting, when in confinement, frequently proves fatal, especially when the spider is advanced in age. A large Theraphosid, for eighteen months kept in confinement in the gardens of the Zoological Society of London some few years ago, died at length in its last moulting process. After the last moult, which completes the structural development of the spider, it seems that no further ecdysis takes place, whatever age the spider may attain. The number of moults appears to vary, not only with the species, but with individuals of the same species; food, temperature, and other conditions no doubt affecting it. Chapter vi., on "Regeneration of Lost Organs," is based chiefly on the researches of Voldemar Wagner ("La régeneration des organes perdus chez les Araignées," *Bull. Soc. Imp. Moscow*, 1887, No. 4) and the observations of H. Heineken (*Zool. Journ.* iv. 1828–29). Papers on the subject by the late Mr. Blackwall are also noted.

Part ii. consists of "Descriptions of Genera and Species." In his introductory remarks to this part, Dr. McCook defines the extent of the group comprised in his "Orb-weaving Spiders." This is coextensive with the "Orbitelariæ" of Dr. Thorell, and includes *Uloborus*, which is far removed structurally from the *Epeiridæ*, as well as *Pachygnatha*, which, so far as known, spins no snare at all. The difficulty of drawing any decidedly marked line between the *Retitelariæ*, and *Orbitelariæ* is no doubt great. Witness the results arrived at by M. Eugène Simon in his work now in progress—"Histoire des Araignées," second edition, 1893–4—in which these two enormous groups are fused, and again subdivided; the materials being recast in a way which upsets all the previously conceived ideas of araneologists. However, until these new views are better understood and generally adopted, the old division into geometric web weavers and those whose snares are not geometric, but net-like, with exceptions such as the *Uloboridæ* and *Pachygnatha*, are sufficient for popular as well as faunistic purposes.

At pp. 8 and 133, reference is made to drawings of American spiders made by John Abbott early in the present century, and the descriptions of which are contained in Baron Walckenaer's Ins. Apt., A.D. 1837. It appears from Dr. McCook's remarks that he was under the impression that some drawings which he saw in the British Museum in 1887 were the original drawings of John Abbott's spiders. This, however, is not so. The British Museum set of drawings are either a copy of those of Abbott, or, may be, a duplicate set done by Abbott himself. The originals (or, at any rate, those from which Walckenaer drew up his descriptions of the spiders) are in the possession of the authorities at the Jardin des Plantes, Paris. Many years ago it was proposed to the present writer by the late Dr. John Gray, of the British Museum, to prepare and publish descriptions of the spiders from the British Museum copy, along with plates engraved some years previously from that copy, under Dr. Gray's orders. Such descriptions, however, it is quite obvious, could not possibly be done satisfactorily from the drawings alone—witness Baron Walckenaer's efforts—though no doubt numbers of the spiders delineated can, with more or less certainty, be specifically determined from them. The result of an inquiry made at that time, was that the French nation has Abbott's original drawings, which were presented, directly or indirectly, to Baron Walckenaer by Abbott himself; but what the British Museum set was, or how it was acquired, seemed to be very doubtful.[1]

In a general notice like the present, part. ii. of the vol.

[1] Dr. McCook evidently was not aware that the present writer, in a review of N. M. Hentz's "North American Spiders" in 1876 (NATURE, vol. xiii. p. 282), mentions these facts and considerations respecting John Abbott's drawings.

under consideration needs but little remark. The descriptions are full and accurate, and the figures are nearly all engraved from drawings beautifully executed by Miss Elizabeth F. Bonsall, and leave but little to be desired. Three, however, of the plates—Nos. 2, 10, and 15—are from the author's own drawings, and are fully equal, if not superior, to the rest. 123 species of spiders of the orb-weaving group are described, and, of these, twenty-four are considered to be new to science. Four new genera are also characterised. In every way, part ii. will be of great use and importance to systematic araneologists. A portrait of Nicolas Marcellus Hentz (justly called the father of American araneology) forms a most appropriate frontispiece. O. P. CAMBRIDGE.

THE SEA AND ITS COASTS.

Sea and Land, Features of Coasts and Oceans, with special reference to the Life of Man. By N. S. Shaler, Professor of Geology in Harvard University. Illustrated. (London: Smith, Elder, and Co., 1895.)

IN more than one sense this book is a thinner one than "Aspects of the Earth." Of the seven essays which it contains—in the main republications—the first four deal with familiar subjects—the work of the sea, its beaches, its depths, and icebergs; the last three treat of harbours, and introduce some questions which are less hackneyed and more interesting. Prof. Shaler writes pleasantly, and his sentences flow easily, but it is sometimes possible to read through several paragraphs without much progress in knowledge, or to find a rather large number of well-turned phrases expended in stating what amounts to a truism. But as the preface informs us that the object of the book is "to introduce unprofessional students of nature to certain interesting phenomena of the sea-shore and of the depths of the ocean," it is very possible that babes in science will find well-sweetened pap more digestible than strong meat. We must, however, protest against the liberties which Prof. Shaler takes occasionally with our mother-tongue. He is too fond of "telephonese" or "telegraphese," as it might be called This tongue may be good American, but it is not good English. We do not mean to assert that no improvements could be made in the latter, or to pose as prudes of etymological purity, but we object to the coinage of new words, or, rather, the misuse of old words, where grammatical expressions already exist, longer only by a few more letters or, at most, syllables. Brevity may be the soul of wit, but it is not always an adornment in speech. Is there any real gain (to take a few examples) in such an adjective as "pivotal," such participles as "fiorded," "forested," "peninsulated," "well-harboured" (*i.e.* with many harbours), and such a verb as to "raft off" in the sense of transport or carry off like a raft.

Prof. Shaler is a picturesque writer, and his descriptions usually are clear and vivid; but dangers lurk in the attempt to be graphic when a locality is known only at second-hand. Of this the book before us affords an amusing instance. Speaking of the advance of dunes, he quotes the well-known case of Eccles (Norfolk), saying: "Thus in Britain one of these dunes in the last century invaded the village of Eccles, and buried the dwellings and the parish church, so that even the top of the spire was hidden. After a number of years the summit of the church began to reappear on the leeward [? windward] side of the hill, and in time the remote descendants of the dispossessed people may be restored to their heritage." But the dwellings had practically disappeared before the dunes rolled over them: the church had been a ruin for at least two centuries; of its body only the foundations remained; there was no spire, and apparently never had been one; and the octagonal lantern of the tower was never wholly buried, unless the well-known engraving in "Lyell's Principles of Geology" represents an exceptional condition of the sandhills. So if the descendants of the original villagers do return to their ancestral domiciles, they will find themselves "Lords of the sands, an heritage of waves." Indeed, since Prof. Shaler wrote, even the old tower has tumbled down, destroyed by the waves during a gale last January.

We venture also to think that Prof. Shaler takes rather too much for granted in assuming, without a hint that this has been disputed, that great rock basins have been excavated by glaciers. Moreover, he is hardly correct in saying that fjords are restricted to ice-worn regions, for Cornwall can show more than one very respectable imitation of such an inlet, and on the Dalmatian coast they are not rare; yet we can hardly suppose that even in the coldest part of the Great Ice Age, precipitate glaciers descended from the Montenegrin Highlands to scoop out the Bocche di Cattaro. But perhaps an inlet of the sea only becomes a fjord when it shallows towards its mouth; if so, that should have been clearly stated. Doubtless these basin-like fjords are difficult to explain; but as Prof. Shaler admits the existence of submerged moraines, no excavation need be required. At any rate it would be well, as a preliminary step, to prove that glaciers are agents of excavation to any important extent, for this has been denied by many geologists, who vainly ask to be shown any proofs of such effects in the subaërial part of their course.

But we must not dwell too much on blemishes, which after all are light. Even the four earlier essays, already mentioned, exhibit a certain freshness, for Prof. Shaler, as an American, selects the majority of his examples from the other side of the Atlantic, instead of using those which have become the stock-in-trade of every European geologist. By this means more than one point is brought out more clearly than is usual in English books, because illustrations are difficult to obtain from our own islands, or any readily accessible part of the neighbouring continent. For instance, his remarks on the action of vegetation in a shallow estuary or bay, and particularly on the growth of "mangrove swamps" are valuable. He describes how the large tapering cylindrical seed of the mangrove, floats in a vertical position, settles down and becomes entangled on the bottom by means of the numerous hooklets which arm its lower extremity, then sends a shoot up above the surface of the water, from which come wide-spreading, low-growing branches. From these long runner-like processes are thrown off, which at last curve sharply downwards through the water till they strike root at the bottom, and then support new crowns, each having its own trunks and branches. "Thus a single tree may rapidly march away from the original planting-point until its outer verge may be an indefinite distance from its place of origin." This method of growth enables the grove to resist even fairly strong waves, and facilitates the accumulation of organic débris and inorganic sediment.

Again, there are some striking remarks on the accumulation of molluscs, especially bivalves. Prof. A. Agassiz has already called attention to this process on the great Florida plateau, and Prof. Shaler particularly mentions the special importance of the oyster as a rock builder along the whole coast from New York southwards.

"In its maximum development" he says, "the larger part of the shallow bottom inside the ocean beach is occupied by beds of these shells. So crowded are these forms, that they push their growth above the level of low-tide mark, and in the region where the mangroves abound they cluster on the roots of the trees to such numbers as often to hide them from view. . . . Between Charleston, South Carolina, and Biscayne Bay, Florida, there is an aggregate area of nearly a thousand square miles which, when the shore assumed its present elevation, was occupied by tolerably deep water that has now become filled to near the level of high water, by sediments composed in large part of oyster-shells."

In fine, these three essays contain not a few interesting and suggestive passages. The illustrations often are very good.

THE CHEMISTRY OF COD-LIVER OIL.

Cod-liver Oil and Chemistry. By F. Peckel Möller, Ph.D. (London: Peter Möller, 43 Snow Hill, E.C., and at Christiania, Norway, 1895.)

THIS book is divided into two parts—the title of part i. is "Cod-liver Oil"; the title of part ii. is "The Law of Atomic Linking, diagrammatically illustrated," and the heading of the first chapter of the second part is "Chemistry." There is a separate preface to each part, and, though bound together in one volume, each forms an independent treatise, and is separately paged. One hundred and eleven pages are devoted to "cod-liver oil," and rather more than five hundred to "chemistry."

In the preface to the first part the author gives two reasons for the publication of the work: (1) to deal with all matters connected with cod-liver oil, and especially with those likely to be of interest to members of the medical profession; and (2) to give the results of the investigations lately undertaken by Mr. Heyerdahl, which "throw the first and only true light on that mystery, the real nature of the oil."

The first and second chapters give an interesting account of Norway, which is styled "the land of the midnight sun and cod-liver oil"; its people, past and present; its social customs; the Gothenburg system in every town; its land question; its fisheries, fishermen, and fishing boats, their tackle and bait; its tourist visitors, and its "oldest established visitor," the cod-fish.

The next chapter is on "cod-liver oil,' and the reader is instructed, as pleasantly as in the preceding chapters, in the ancient and modern methods of preparing the oil for use. The older method, it appears, was in use until so late as the year 1853, when a great improvement was effected by the introduction of the steam process of extraction, by which means the pure oil only is obtained from the livers, instead of oil mixed with a great number of decomposition products. This steam process was a great advance. The resulting oil had lost much of its objectionable taste and smell, but it still retained one very bad characteristic—it was still very apt to give rise to nauseous eructations. Unwelcome flavours continued to assert themselves after a dose of such oil, not once only but again and again, till, as the author says, the unhappy recipient was tempted to say, "life is not worth living if it is to be only at the cost of taking cod-liver oil." Hence the host of attempts that have been from time to time made to treat the oil so as to abolish these disagreeable properties. These are dealt with in the chapter called "Pharmaceutical Annotations," and some forty different ways of disguising or improving the oil are described in detail—the ingredients for mixing with the nauseous article including such diverse things as beer, iron-water, peppermint oil, coffee, eucalyptus oil, wood-tar, ammonia, ketchup, celery-seed infusion, vinegar, iodoform, saccharin, acetic ether, &c.; and, besides all these, every conceivable form of emulsion seems to have been tried. It will be welcome news to many that, in Dr. Möller's opinion, all these elaborate preparations are now quite uncalled for, and that Heyerdahl's investigations have at length led to the possibility of an oil being produced more curative than the old oil, and quite free from nauseating powers. These researches are fully described in a separate chapter, and are considered to have revealed the presence in the oil of two hitherto unknown glycerides, which have been named, respectively, *therapin* and *jecolein*. They are both exceedingly unstable compounds, and easily become oxidised, and these oxidation products are believed to be the real cause of the too well-known unpleasant after-effects of the drug. As a result of these discoveries an apparatus has now been devised by which cod-liver oil can be produced on a large scale without even the slightest oxidation taking place. Air is excluded from the beginning to the end of the operation, the process being conducted in a current of carbonic acid from the moment the livers enter the apparatus until the oil obtained from them is safe within the bottles.

The chapter giving a synopsis of the chief researches on the oil since 1822 is very complete, and will no doubt prove of great interest to medical men and pharmacists.

The conclusion arrived at as to the therapeutic agent in cod-liver oil is that "it is the oil itself," and that its remarkable power as a nutritive food is the cause of its medicinal efficacy, and not any special active principle contained in it. This opinion is in agreement with that of the late Prof. J. Hughes Bennett, of Edinburgh, who published, in 1841, a pamphlet on cod-liver oil, which had much to do with the general introduction of the oil as a medicine into this country. It is one of the omissions in the present volume that no reference is made to the work of Dr. Bennett in this direction.

The object of the second part of this work, as set forth in the preface, is mainly to bring the facts of organic chemistry, freed from unnecessary difficulties, within the grasp of busy medical practitioners. With this object graphic formulæ are profusely employed, so that "a glance will lay bare to the eye of the novice the whole details of the constitution of the most complicated compounds," and the practical preparation of the compounds has been generally omitted "because the much tried patience of medical men need not be burdened with things chiefly of interest to the chemist." With these exceptions a large proportion of organic chemistry is very fully treated, and a careful reading of the work in leisure moments would doubtless give any one, who had some previous knowledge of the science and some liking for it, a fair grasp of somewhat more than the outlines of this vast and ever-increasing field. Especially interesting, though demanding more than cursory reading, is the concluding chapter on atoms, linkage, and stereo-chemistry. In our earlier days chemists did not so much concern themselves with these things. The determination of mere composition and formulæ furnished enough occupation. But with advance of knowledge it has been found necessary to study what has been called the "atomic architecture of molecules." In the concluding pages this subject is very ably and lucidly discussed. A new hypothesis is suggested, to which the name of the "screw theory" is given, which, it is pointed out, may satisfactorily explain those cases of optical activity which are met with in certain bodies, *e.g.* some terpenes and glycerides, where there is no asymmetrical carbon-atom, and which are consequently not clearly met by van't Hoff's ingenious theory.

The volume is one in the production of which great labour and care must have been expended, and both parts are worthy of commendation. Possibly, however, it would have been advantageous to both, if they had been published separately. JAS. CAMERON.

OUR BOOK SHELF.

Astronomische Chronologie. By Walter F. Wislicenus. (Leipzig: B. G. Teubner, 1895.)

HISTORIANS, archæologists, and astronomers will hail with delight this work, as it fills a gap which for some time past has been very apparent. At the present day, to take one case only, archæologists are busy in Egypt deciphering and unravelling the legion of myths which are there recorded in the many forms and ways peculiar to that country. Many of these myths are, as has been recently more clearly pointed out, purely astronomical in their nature; and this is perfectly natural when one considers that the Egyptians, or, at any rate, the priests, for these were the chief writers, were astronomers. Archæologists in fathoming these depths are perfectly at home when archæology is in question, but as soon as the astronomical boundary is reached, and astronomy pure has to be attacked, then perfectly different problems are met with. In like manner, the astronomer himself, going from the astronomical to the archæological side, is also nonplussed, unless he wishes to enter somewhat generally into the study of Egyptology. In the book which we have before us, Dr. Wislicenus gives the historians and archæologists a helping hand, and presents them with the necessary means and ways of solving some of the problems which are generally encountered.

Without entering too minutely into the contents of these 150 odd pages, a general survey of the text will best give the reader an idea of their character.

The two parts, into which the book is divided, deal respectively with the fundamenta of astronomy, and the different methods of computation.

The former part is concise and brief, and the author in forty-four pages presents the reader with a general summary of the different systems of coordinates used, the different kinds of years, the course of the moon, eclipses, daily and yearly rising and setting of the heavenly bodies.

The methods of computation in the second part are so arranged that they follow, in the same order, the text in the first. At the commencement of this part Dr. Wislicenus brings together a list of the numerous tables which are used for the solution of chronological problems. These are here given with their full titles, and are explained further on. The remainder of the book is devoted to the solutions themselves, and these are arranged as follows: First, the known and the unknown quantities are separated, then the tables to be used in the problem in question are explained; following these, typical examples are taken and worked out by the use of the different tables.

A very full index makes reference easy, and completes what will prove a very useful book. W. J. S. L.

Die ältesten Karten der Isogonen, Isoclinen, Isodynamen By Prof. Dr. G. Hellmann. (Berlin: A. Asher and Co., 1895.)

THIS is the fourth of the elegant series of reprints devoted to classical contributions to meteorology and terrestrial magnetism. It contains seven maps, all excellently reproduced, and representing old standard charts of isogonic, isoclinic, and isodynamic lines. The maps portrayed are Halley's Declination Chart of the World, published in 1701; Whiston's two maps (1721), showing lines of equal magnetic Dip in the South of England; J. C. Wilcke's Isoclinic Chart of the World in 1768; a chart by Humboldt, published in 1804, showing Isodynamic lines over part of South America; and Hansteen's Isodynamic Charts (1825–26) of North-West Europe and of the world.

Halley's description of his "New and Correct Sea-Chart of the Whole World, ſhewing the Variations of the Compass," is reprinted, and brief descriptions are given of the other maps.

Whiston, it may be remembered, suggested that longitude might be determined from magnetic inclination, this element being preferred to declination for reasons which he stated as follows: "When, therefore, I considered that the Lines of equal Dip could hardly be more irregular than those of the Variation; I well knew that Mutation was a great deal slower; and that these might probably be useful over all the World; I conceived great hopes that this way of Application of the Power before us might very probably discover the Longitude."

Prof. Hellmann contributes a number of bibliographical notes, and these, with the maps, make the reprint a compact and useful work of reference.

An Elementary Text-book of Hydrostatics. By W. Briggs, M.A., and G. H. Bryan, M.A. Pp. 208. (London: W. B. Clive, 1895.)

THE portions of hydrostatics and pneumatics usually taught to beginners, and required for the matriculation examination of the London University, are concisely and clearly treated in this book. Though evidently constructed for examinational purposes, the book contains a number of good points. The mathematical formulæ are deduced from first principles instead of being stated dogmatically; so the student is led to rely more upon his real knowledge, and less upon mere memory. This and other commendable features distinguish the volume from ordinary text-books of hydrostatics, while the numerous problems, covering a wide field, furnish clear evidence of originality.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Statistical Investigation of Evolution.

MR. THISELTON-DYER states that Prof. Weldon has shown that "selective destruction" takes place in early life amongst individuals which deviate from the "mean specific form." He further says that the actual statistical demonstration of the fact that "minimum destruction is in position coincident with the mean of the whole system," deserves to rank amongst the most remarkable achievements in connection with the theory of evolution. But, to judge from the paper by Prof. Weldon, printed in NATURE of March 7, he does not claim to have made this remarkable achievement. He says that, according to the results of the statistical investigation, in two dimensions of the shore crab, the frequency of deviations increased during an early period of growth, and that in *one* case the increase was followed by a decrease; in the other case it was not. Prof. Weldon states that if a certain law of growth can be shown to be true by experimental tests, *then* the result implies a selective destruction in the one case and *not* in the other. So that all we have is the possibility in the future of a statistical demonstration of selective destruction in the case of one particular dimensional character, and the rigid proof in the present that in the case of the other dimensional character selective destruction does not take place. Surely every man of science must admit that Prof. Weldon's results, on his own showing, have done more against selective destruction than for it.

Prof. Weldon says that if we know that a given deviation from the mean is associated with a greater or less percentage of death-rate, we do not require to know how the increase or decrease of death-rate is brought about, and all ideas of functional adaptation become unnecessary. This may be his own state of mind on the subject, but I venture to state that it is not Darwinism, and that he cannot shut out others from the most interesting and most important fields of biology in this way. Darwinism states that selective destruction is caused by the struggle for existence, and that a selected character confers an advantage in the competition to get food and beget offspring. If a certain deviation is shown to be associated with an increased or decreased chance of life, we want to know how it acts, and no statistical Gallio can prevent us trying to find out.

It does not require much search to find deviations which are associated with an increased death-rate. In the human subject cyanosis, due to the retention of the fœtal communication between the two sides of the heart, is a well-known abnormality or deviation in the infant; but I believe few, if any, children born in that condition reach the age of 20. Here we have no difficulty in understanding the reason: the deviation necessarily leads to death. But now, in comparison, take the case of a child born blind, or deaf and dumb. Here there is no intrinsic reason why life should be shortened; but in a severe competition, if the individual depended entirely on his own exertions, he might be, probably would be, starved or trampled to death before he had lived very long. I think it is of some interest and importance to know of any given character or deviation, whether it is intrinsically harmful or beneficial, extrinsically so (*i.e.* in the struggle for existence and reproduction), or quite indifferent.

Prof. Weldon is silent, to some extent, about the cases which tell against the idea of selective destruction. He found that deviations in Aurelia were as numerous in the adult as in the Ephyræ. He told me in conversation, and did not say it was in confidence, that he abandoned some experiments on the selection of Daphnia, because he found that the mere fact of keeping a large number in the same water caused a progressive disappearance of a certain conspicuous spine. His investigations also entirely ignore the diagnostic value of the characters he deals with. It seems to me that a more valuable result would be gained if a parallel investigation were made of two characters—one obviously diagnostic, the other obviously adaptive. Such characters could be found in a swimming crab.

But above all, what we want is a comparative investigation of the results of selection without change of conditions, and of change of conditions without selection. I began, not long ago, to try to inaugurate a society for carrying on a thorough investigation of this kind, but have not at present received enough support to carry out the scheme. The method of the investigation is fairly obvious and not difficult, but the difficulty is to get the money and the time to carry it out. I differ from Prof. Weldon in thinking that the questions raised by the Darwinian hypothesis are not purely statistical, but experimental, and I agree with Mr. Thiselton-Dyer—that to talk of experimentally checking the hypothesis by the statistical method is a contradiction in terms.

Cleethorpes, March 15.

A True Spectrum Top and a Complementary One.

To make a true spectrum top—which is not copyright, so far as I know—take a disc of white paper, and one of black, of equal size. Spin the white one on a disc of cardboard mounted on a nail, and while it is spinning draw a small brush well charged with lamp-black water-colour paint, steadily and not too slowly from centre to circumference of the disc, thus describing a spiral line. Make a radial cut in each of the discs, and after interlocking them as in the well-known colour discs, place them on the top. We thus obtain a top in which the lines are spiral, and the relative sizes of black and of white areas are easily regulated by turning one disc to right or left, while the other is held still. If the lines be not too thin or too thick, and not too near together, and if the relative areas of black and white be adjusted suitably to the light, the top exhibits, when spun, broad bands of colour, each band containing all the colours of the spectrum in their natural order. The spaces between the lines should be not less than five times as broad as the lines themselves. The brightest effects are produced in my own case, by lamplight, with the areas of light and dark almost equal; by daylight, with the dark area about three times as great as the light. Other proportions, however, seem to give better results with other people.

A "complementary top," yielding colours complementary to those of the spectrum (*i.e.* the colours of mother-of-pearl) in a continuous band ranging from lemon-yellow, through puce to electric-blue-green, is made in the same way, except that the spiral line is to be drawn in white on the black disc.

In both cases the colours are somewhat dilute, but the proper regulation of the relative areas of black and white reduces this defect very considerably, and I have obtained bands on my spectrum top brighter and purer than any which I could get by painting a spectrum with colours on paper.

I communicate this description before my experiments are complete, in order to prevent anyone who may make the same discovery, from obtaining a copyright for the design of either these tops or of earlier ones which I made, in which one half the disc was black and the other white, with a white spiral on the black, or a black spiral on the white, or with both at different distances from the centre on the same top. Anyone who wishes to do so may make as many tops or lantern-discs as he chooses from the above description, provided he does not attempt to hinder anybody else from making or selling similar ones.

C. HERBERT HURST.

Owens College, Manchester, March 24.

A Foucault Pendulum at Dublin.

IT may perhaps interest some of your readers to learn that Foucault's pendulum experiment has recently been performed in Trinity College, Dublin, with complete success.

Immediately under one of the glass domes, by means of which the hall of the New Building is lit, a cast-iron bar was securely bolted, which terminates in a cylindrically-shaped piece of metal the axis of which is vertical. Into this cylinder a steel plug was inserted, which was drilled to receive the upper end of the wire supporting the bob, which was fitted with a screw. By placing the upper end of the wire in this position, Prof. FitzGerald and I secured a length of 45 feet for our pendulum; but, under the circumstances, we were unable to use the same weight as that adopted by Sir R. Ball when making the experiment, viz. 300 lbs., and were obliged to content ourselves with a bob weighing 16 lbs., which, however, answered admirably.

The experiment is made in the following manner:—About two feet behind the position of equilibrium of the bob, we place the electric lamp, and at a suitable distance in front a lens, so arranged that when the bob is swinging, and in the position of maximum amplitude nearest the lens, the shadow of a portion of the wire immediately above the bob, thrown on a screen some 32 feet distant, is clear and distinct, and coincides with a vertical black line thrown on the white screen.

The bob is drawn back towards the lamp about eight inches, by a loop of thread, and when we wish to experiment the thread is then burned in the usual manner.

When the pendulum completes its first oscillation, the shadow falls exactly on the black line traced on the screen. In about *five* minutes the shadow has moved to the left of the line, and in ten minutes conspicuously so. In this time the maximum amplitude has decreased so little that the image on the screen is still distinct and clear when the pendulum is in a position nearest the lens. W. R. WESTROPP ROBERTS.

Trinity College, Dublin.

Snake Cannibalism.

I HAVE read with interest the numerous accounts of snake cannibalism which have lately appeared in NATURE. During my residence in South Africa, I have come across several instances of a similar nature. A few weeks ago I received a large ronghals (*Sepedon hæmachate*) which had swallowed another one of the same kind and of nearly its own length. As the swallowed individual was too long to disappear completely before the front portion of its body was digested, its tail was sticking out of the mouth of the swallower by about six inches. I have dissected two yellow cobras (*Naja haji*), each of which had swallowed a puff adder (*Vipera arietans*) more than three feet long. This case is very interesting, as the puff adder has much larger fangs than the yellow cobra, and in a fight the latter would probably succumb. To mention only one more case, I received, some years ago, the skins of a cross-marked schaapsticker (*Psammophis crucifer*) and a spotted schaapsticker (*Psammophylax rhombeatus*), the former of which had swallowed the latter. In all cases which have come under my personal observation the swallowed snakes had entered head first, and thus probably they were simply drawn in after having caught hold of the same prey as the swallowers. In conclusion, I may mention that cases similar to the above are frequently described in the South African newspapers. J. SCHÖNLAND.

Grahamstown, South Africa, March 1.

American Fresh-water Sponges in Ireland.

A SHORT time ago, Dr. R. F. Scharff, Dublin, sent me a small collection of Irish Spongillidæ. The examination of the material resulted in the discovery of two or three American species, obtained from the West of Ireland, viz. *Heteromeyenia ryderi*, Potts, *Tubella pennsylvanica*, Potts, and (?) *Ephydatia crateriformis*, Potts, the first of these three species having been identified by Dr. W. Weltner, Berlin. All these species are new to Europe, and as they were found in a small collection taken more or less at random, it is probable that if the fresh-water fauna of the West of Ireland were thoroughly investigated, a great many more American species would be discovered.

Details will be published in the May number of the *Irish Naturalist*. R. HANITSCH.

University College, Liverpool, March 13.

Peripatus in the West Indian Islands.

WEST INDIAN records show that occasionally single specimens of various species of Peripatus have been found in the different islands. During the past week, Mr. Lunt, my assistant, found a single specimen, and a further search being organised, resulted in the capture, by two collectors, of fifty specimens. These, it is believed, belong to two different species, and a goodly number of the specimens have been sent for determination to the British Museum.

Either the animals are more numerous than usual, or the previous search for them has not been a very careful one, as the whole of our specimens were found within the precincts of the Gardens. J. H. HART.

Royal Botanic Gardens, Trinidad, March 6.

Planetary Photography.

I UNDERSTAND that in photographing a planet, such as Mars, only a short exposure can be allowed, because there is no way of compensating the planet's *axial* rotation.. But, while following the planet with the equatorial, would it not be possible to compensate this axial movement by slowly sliding the plate, so that certain features of the planet should fall always on the same parts of the plate? If this is so, an exposure of some length might be available for the more central portions of the disc, those portions for which, during the interval, no serious alteration due to foreshortening comes into play.

Cardiff, March 23. C. T. WHITMELL.

Cleaning Tobacco Pipes.

I HAVE discovered a new method for cleaning pipes which have become foul. A shallow cork, through which a hole is bored large enough to enable it to fit tightly on to the nozzle of a soda-water syphon, is fitted into the bowl. The nozzle is inserted, the mouth-piece directed into a vessel, about a wine-glassful of soda-water forced through, and the pipe is clean!

This is not a scientific discovery, but it may be of use to those scientific men who are smokers. Rubber stoppers answer better than corks. CECIL CARUS-WILSON.

THE HABITS OF LIMPETS.

SOME observations made by the present writer at the Scottish Marine Station during July 1884, were published in NATURE for January 1, 1885. These observations confirmed the statements previously made by various naturalists, from Aristotle onwards, that the common limpet (*Patella vulgata*) settles down on some eligible spot (its "scar") between tide-marks, and makes a home, to which it returns after having been out to feed. The conclusion was drawn from various data that this "locality sense" is independent of smell, sight, and touch so far as the head-tentacles are concerned. Prof. Lloyd Morgan, in a letter to NATURE ("Homing of Limpets," December 6, 1894), has shown that the limpet possesses an even greater power of "homing" than previous observers have suspected, and he believes that the head-tentacles are the sense-organs concerned.

Since 1884, I have made further notes, and aided by a grant from the Research Grants Committee of the Royal Society, to whom my best thanks are due, have pursued the subject with some care during the past year. The results, apart from those connected with histology, here follow.

The limpets observed live on a reef, which extends several hundred yards seawards (practically west) from the front of Aberystwyth College. The rocks are Silurian grits and imperfect slates, alternating in a very regular way, striking north and south, and tilted at high angles. At low tide the *Laminaria* zone is well exposed, and for some yards above this the rocks are somewhat bare, except that they are thickly encrusted with small *balani*. Nearer the land various brown seaweeds (mostly *Fucus serratus*, *F. vesiculosus*, and *Ozothallia nodosa*) thickly cover the reef, except towards high-water-mark, where they become scanty. Throughout this area limpets of all sizes abound, being specially numerous, however, on the barnacle-encrusted rocks above mentioned. Groups of them were here marked with enamel paint, and watched. A number of observations were also made on the small limpet, which lives on *Laminaria*, and has its shell marked by three diverging blue streaks (*Helcion pellucidum* = *Patella pellucida*).

Food and Feeding.—As before, the chief food noticed consisted of the minute algæ coating the *balani* and rock-surfaces. Specimens were also found feeding on the calcareous seaweeds *Corallina* and *Melobesia*, on *Fucus*, and on *Laminaria*. It was suggested in the previous notes that the great length of the radula is perhaps correlated with the large amount of wear and tear entailed by the constant "scraping" of barnacles, &c. This appears to be confirmed by comparison with *Helcion*, in which *Laminaria* constitutes the chief, if not the only, food, and in which the radula is relatively somewhat shorter.

At Granton, in July, the larger limpets appeared to feed most frequently; but at Aberystwyth, during the colder months, the small individuals are far more active. Sheltered corners and warm days afford the best chance of watching the movements. Though limpets undoubtedly regain their scars, or secure places, as the tide advances, I am inclined to think they must also often feed when covered by the water, for (1) the finest specimens are found low down, and their time for feeding when uncovered is limited; (2) I have seen a small limpet feed on *Corallina* in a tide-pool.

The scraping sound heard on the rocks during warm weather is not entirely due to feeding limpets. *Purpura lapillus* is also busy at work "sawing out" *balani* from their shells.

Locality-Sense.—I still think, *pace* Prof. Lloyd Morgan, that the head-tentacles are not indispensable to homing, though it must be admitted that they may commonly help in the process. One limpet observed homing by me, certainly seemed to be "feeling" its way along by means of these organs, which were extended and waved about and applied to the rock from time to time, not by the extreme tip only, but also laterally for about $\frac{1}{16}$ of an inch from this. This individual was No. 2 of a small group living among the barnacles, and kept under observation from November 26 till the present time. The dimensions of these limpets are as follows:—No. 1, $\frac{3}{4}'' \times \frac{5}{8}''$; No. 2, ditto; No, 3, $\frac{4}{5}'' \times \frac{2}{3}''$; No. 4, $\frac{7}{10}'' \times \frac{3}{5}''$; No. 5, $\frac{17}{30}'' \times \frac{7}{15}''$. On November 28, at 3.15 p.m., I found No. 2 feeding $1\frac{1}{2}''$ from its scar. About half of each tentacle was excised (*i.e.* the part previously noticed "feeling"), and the animal was replaced where found. On November 29, at 2.55 p.m., it was found back on its scar. A similar operation was performed on No. 5, found feeding $2\frac{1}{4}''$ from its scar, on December 12, at 3.15 p.m. On my next visit, at 2.55 p.m. on December 14, the animal was found to have regained its scar, which, by-the-by, is permanently submerged, being in a small tide-pool. It is true the tentacles were not entirely removed, as was the case with the two Granton limpets which homed after excision. It now appears to me probable that the *mantle-tentacles* may help in homing. These are small conical structures lodged in pits in the mantle edge (Harvey Gibson, *Trans. R.S. Edin.* 1885), and capable of retraction and extension. About 100 of them are present. In submerged limpets I have seen these tentacles protruded for about $\frac{1}{16}''$ beyond the margin of the shell, and executing active "feeling" movements. These were particularly noticeable in an individual which, having regained its scar wrong end on, was shuffling round into the right position. When the front end of the limpet came to point in the right direction, one side of the shell was lowered, and the mantle-tentacles on that side were withdrawn; the same events then happened on the other side. These tentacles appeared to be of two kinds, longer and shorter, the latter being two or three times as numerous. Prof. Herdman first suggested to me that the mantle-tentacles might have to do with the locality-sense, and it at any rate appears probable that they are concerned with accurate adjustment on the scar. It is worth noting that very small limpets home as well as large ones, *e.g.* No. 5 above, and much smaller ones which have fallen under my notice. Prof. Lloyd Morgan's observations, so far as they refer to knowledge of local surroundings which limpets possess, are confirmed by an experiment made on No. 1. On December 16, at 4.5 p.m., this animal was busy scraping barnacles 3" west of its scar. It was removed and placed 10 inches from home, near the top of a nearly vertical barnacled surface (on which it had been seen feeding at 3.15 p.m., November 28), which rises north of its scar. The next visit was deferred till December 26, 12.25 p.m., when the limpet was at home.

The homing faculty is not confined to *Patella*, but is also possessed by *Helcion pellucidum*. This fact is new, so far as I am aware. The animal in question eats out a sheltered home in the bulb, or more rarely in the stalk of *Laminaria*, and wanders out from this along the thallus, rasping a "track" as it goes. I found, for example, one individual at the end of an "eaten road" 3 inches long, and at the other end a very snug dwelling-place drilled out in the side of the stalk. *Helcion* mostly feeds under water. Like *Patella*, it possesses mantle- as well as head-tentacles.

The object of homing appears to be protection from the assaults of the incoming or outgoing tide. There is no danger when the animals are completely covered or uncovered. In many cases the barnacles would otherwise completely cover the rock, and afford very insecure foothold. Once washed loose, a limpet presents a very large surface liable to injury, unlike its neighbour *Purpura lapillus*, which, withdrawn into its thick operculated shell, can stand a good deal of knocking about. The force with which limpets adhere is illustrated by the fact that the five small limpets to which allusion has been made were quite uninjured by the terrible gale and high sea of December 21 and 22, to which they were fully exposed. The much thinner shell of *Helcion* is explained by the sheltered position of its home. The depressed conical shape of a limpet-shell is probably better fitted than any other to resist the waves, but this statement is made under correction.

Formation of, and Adhesion to, Scars.—An examination of the 'tween-tide rocks at Aberystwyth would readily convince the most sceptical as to the power which *Patella* possesses of excavating depressed scars. Limpets are able to adhere very tightly to a smooth surface which is much smaller than the foot, and by examination of such cases, and of specimens allowed to fix themselves to a piece of plate-glass, I have come to the conclusion that fixation is neither due to secretion of a glutinous substance, nor to the formation of a vacuum under the foot. It appears, in fact, to be a case of "adhesion," like that between two smooth glass surfaces brought very close together. The muscular foot is, so to speak, rolled out on the rock, with which it is thus brought into close contact. Prof. Michael Foster suggested to me the possibility of this method of explanation, which is most probably the correct one.

J. R. AINSWORTH DAVIS.

TERRESTRIAL HELIUM (?).

WE have received the following statement from Prof. Ramsay:—

"I have been trying for clues to compounds of argon. Mr. Miers, of the British Museum, called my attention to Hillebrand's paper on Cleveite, a rare Norwegian mineral, which Hillebrand said gave off 2 per cent. of nitrogen on warming with weak sulphuric acid. Cleveite consists chiefly of uranate of lead, with rare earths. My idea was, if the so-called nitrogen turned out to be argon, to try if uranium could be induced to combine with argon.

"The gas, on sparking with oxygen in presence of soda loses a trace of nitrogen, probably introduced during its extraction; the residue consists of a mixture of Argon and Helium! The brilliant yellow line, of which Mr Crookes makes the wave-length 587·49, is identical with the Helium line. I am collecting the gas, and shall shortly publish regarding its properties."

NOTES.

THE Bakerian Lecture will be delivered before the Royal Society on Thursday, May 9. The research upon which the lecture is to be based has been conducted by Messrs. A. Vernon Harcourt and William Esson, and the title is announced as "The Laws of Connection between the Conditions of a Chemical Change and its Amount."

AN abstract of the paper in which M. Berthelot describes his investigations of chemical combinations with argon, will be found in our report of the meeting of the Paris Academy of Sciences (p. 527).

PROF. ADOLPHE CARNOT has been elected into the Paris Academy of Sciences, in the place of the late M. de Lesseps.

THE late Mr. William Bolitho, of Gulval, Cornwall, has bequeathed £500 to the Geological Society of Cornwall, the income of which sum is to be applied each year in "the production of a gold or richly-gilded silver medal, to be presented to the member of the Society whose attainments, labours, or discoveries in geological or mineralogical science are found most deserving." He has also left a like sum for the Penzance Library.

THE death is announced of Mr. E. Turner, Chairman of the Council of the Sanitary Institute.

WE also notice the death of Dr. E. D. F. Meissel, at the age of sixty-nine. He made a number of important contributions to mathematical astronomy, and his tables of Elliptic Functions, as well as the table of Bessel's Functions, published in the *Abhandlungen* of the Berlin Academy, stand as examples of his work.

MR. H. H. HAYTER, C.M.G., the well-known statist, died at Melbourne last week. He was the first president of the economic and social science section of the Australasian Association for the Advancement of Science. His numerous and valuable statistical publications earned for him the honorary membership of statistical societies in various parts of the world.

DR. CANINI, of Leghorn, a well-known Italian specialist in diseases of children, who died recently, has, says the *British Medical Journal*, bequeathed his entire estate, amounting to 2,300,000 lire (£92,000) for the foundation of a hospital in which poor children suffering from diphtheria may have the advantages of the serum treatment gratuitously.

WE take the following news from the same source:—The late Dr. Alfred L. Loomis, of New York, has left real estate to the value of 400,000 dollars (£80,000), and personal property amounting to 600,000 dollars (£120,000). The income of 25,000 dollars (£5000) is given to the Loomis Laboratory, and whatever part of the income is not used is to be paid to the Professor of Pathology of the University of New York. A sum of 10,000 dollars (£2000) is bequeathed to the New York Academy of Medicine, the bequest to be known as the Loomis Entertainment Fund, and the interest to be used in providing entertainment for the Fellows of the Academy.

M. NILS EIKHOLM, who was at the head of the Swedish astronomical and meteorological expedition for observing the transit of Venus in 1882, has accepted a place in the Andrée balloon, which is to start from Spitzbergen for the North Pole in July 1896. The ascent is to take place from Norskoarna, the distance from which to the North Pole is about 600 miles. But it is not expected that the balloon will travel in a direct line. M. Andrée will visit France in July next, and he will probably be present at the Ipswich meeting of the British Association.

DR. M. A. VEEDER writes: "In the table of 'Days with maximum temperature not over 32° at Greenwich,' on page 174 of NATURE (February 28), the curve rises sharply and decidedly at intervals of exactly twelve years—namely, in 1854, 1866, 1878, and 1890. These years also fell in the well-known period of sun-spot and auroral minimum, but did not comprise the entire periods of such minimum in each case. There seems to be a clue here that is important, and that is in a line with the study of current phenomena of this sort in which I have been engaged, some of the results of which were presented in a paper entitled 'Periodic and Non-Periodic Fluctuation in the Latitude of Storm Tracks,' read at the Chicago Congress of Meteorology in 1893."

THE following are among the lecture arrangements at the Royal Institution, after Easter:—Prof. George Forbes, three lectures on "Alternating and Interrupted Electric Currents"; Prof. E. Ray Lankester, four lectures on "Thirty Years' Progress in Biological Science"; Prof. Dewar, four lectures on "The Liquefaction of Gases"; Dr. William Huggins, three lectures on "The Instruments and Methods of Spectroscopic Astronomy" (the Tyndall Lectures); Mr. Arnold Dolmetsch, three lectures on "Music and Musical Instruments of the Sixteenth, Seventeenth, and Eighteenth Centuries: 1. English; 2. French; 3. Italian" (with illustrations upon original instruments). The Friday evening meetings will be resumed on April 26, when a discourse will be given by Dr. John Hopkinson, on "The Effects of Electric Currents in Iron on its Magnetisation." Succeeding discourses will probably be given by the Earl of Rosse, Veterinary-Captain Frederick Smith, the Hon. G. N. Curzon, M.P., Mr. J. Viriamu Jones, Prof. Alfred Cornu, and other gentlemen.

A STRONG earthquake shock was felt at 1.16 p.m. on Saturday last at Comacchio, in the province of Ferrara, Italy. Several houses and a church were slightly damaged. At Mirabella Imbaccari, in the province of Catania, in Sicily, the earthquake caused the collapse of a building.

DR. B. BRAUNER, Professor of Chemistry in the Bohemian University, Prague, suggests to us that argon possibly exists in nebulæ. He points out that a strong argon line, measured by Mr. Crookes, has practically the same wave-length as the chief nebula line, and thinks that the line at λ 3729·8 in the "blue" spectrum of the new substance represents the line at λ 3730, found in the spectra of nebulæ and white stars.

HERR W. SIEBE has started on a botanical exploration of Asia Minor, with the special object of making collections of the almost unknown flora of Cilicia Trachea. Setting out from Cyprus, he proposes to visit Mersina in southern Asia Minor, proceeding then to the Kalykadnos Valley and the adjacent mountains, the steppe-district of Konia, the maritime district of Egerdir, and finally, in the summer, the elevated alpine region of Geigdagh.

A STORM of unusual severity passed over these islands on Sunday last. At 8h. a.m. on that day it was central over the south of Ireland, and by 6h. p.m. of the same day the centre had reached Denmark, having traversed a distance of 600 miles in ten hours, which gives an average rate of progress of sixty miles an hour. Much damage was done to life and property over the whole country; but its greatest violence was felt over the southern and midland counties. The maximum force at Greenwich was at 2h. 20m p.m., when the anemometer registered a pressure of 36 lbs. on the square foot, which is equivalent to an hourly velocity of eighty-five miles. Thunder and lightning occurred at several places in the rear of the disturbance.

The project of a great free public library in New York City has just taken shape, and been adopted by the several persons and boards of trustees interested. It contemplates the union of the Astor, Lenox, and Tilden funds, aggregating 8,000,000 dollars. The site of the library is not yet determined, owing to some restrictions on the use of the block facing Central Park, on which the Lenox Library now stands. This site is preferred if available. Boston, with its 5,000,000 dollars free library, just completed, has already taken the lead. Brooklyn has in the library of the Pratt Institute the nucleus of an admirable free library, for which a new building is nearly ready.

We are glad to learn of the continued growth and development of the Brooklyn Institute, due in great measure to the stimulus imparted by the Brooklyn meeting of the American Association for the Advancement of Science last summer. Since that time the membership of the Institute has increased many hundreds, bringing it up to very near four thousand, and making it one of the largest scientific associations in the world. Plans for a new building and museum, to cost several million dollars, have been for some time ready, and only await funds. Probably work will begin during the present season. The site is secured, and it is hoped that aid from the city will be obtained as soon as the condition of finances justify it. Meanwhile the Institute, in its geographical section, is foremost in promoting far-reaching plans of exploration toward both poles. Besides the arctic expedition mentioned in Nature last week (p. 488), a well-digested plan for antarctic exploration has been presented by Dr. Fred. A. Cook, who is already familiar with travel in the north. He proposes to start next September, equipped for a stay of three years, but with the intention of returning in two years unless accidentally detained. It seems probable that the expense of the expedition will be provided for, and that it will be the best equipped that has ever ventured into that region.

In the February and March numbers of the *Geological Magazine*, Miss Agnes Crane gives an account of the results of recent research on the geological distribution of the Brachiopoda, and their bearing on the evolution of the group. The simple *Paterina* of the Cambrian is regarded as the actual root-stock of the group, and the descent of the chief lines is traced from it, with some breaks here and there, from imperfection of knowledge. According to Beecher, almost all Brachiopoda pass through a "paterine" stage of development. *Lingula*, which (in the proper generic sense) does not occur below the Ordovician, passes in its development through a stage in which it resembles its predecessor *Obolella* of the Cambrian, and the latter is said to have a transient "paterine" stage. *Terebratulina* is also stated to pass through a "linguloid" stage, yet its branch is not regarded as derived from *Lingula*, but independently from *Paterina*. Numerous other genera are dealt with, and the paper is illustrated by two plates, one giving the genealogical tree of the Brachiopoda, and the other some examples of the relation of forms.

There is an interesting note in the *Bulletin* of the Royal Gardens, Kew, on the use of green glass in plant-houses. The use of glass of a green tint has been for half a century a characteristic peculiarity of the plant-houses at Kew, having been adopted in 1845–46 on the recommendation of Mr. Robert Hunt, F.R.S., on the ground that while admitting light and chemical power in the same proportions as white glass, it would obstruct the passage of those rays which produce scorching. Recent investigations have, however, shown that the green glass used at Kew intercepts about one-half of the effective influence of ordinary sunlight on the processes of plant-life. Of late years the increasing haziness of the sky, due to the smoke produced by the rapid extension of London to the south-west, has produced the same effect at Kew as the use of green glass; and it has become obvious that in the future the plant-houses must be so constructed as to exclude as little of the available sunlight as possible. Since 1886 the use of green glass has, therefore, been discontinued in all the houses except the fern-houses and the palm-house; and, it having been proved by experiment that even filmy ferns thrive better under white than under green light, if direct exposure to the sun is excluded, the use of green glass will now be altogether abandoned at Kew.

The action of light in producing an electric discharge through a vacuum tube has been further investigated by Messrs. Elster and Geitel, who communicated some very suggestive results to the Berlin Academy at a recent sitting. They used a "photo-electric cell," consisting of an exhausted glass globe with an anode of platinum wire and a kathode of an alloy of sodium and potassium in equivalent proportions, which is liquid at ordinary temperatures. This alloy was illuminated by a beam of white light from a piece of zircon rendered incandescent by an oxy-coal gas blow-pipe flame. This was condensed and made parallel, and then sent through a Nicol prism so as to polarise it in a certain plane. It was then found that a current passed through the cell on connecting its terminals with a battery giving some 400 volts. The strength of this current depended very much upon the angle of incidence and upon the plane of polarisation. It was greatest when the plane of polarisation was perpendicular to the plane of incidence, *i.e.* when the electric displacements constituting light took place in the plane of incidence, and when the angle of incidence was about 60°, *i.e.* the polarising angle of the alloy itself. The phenomena have probably some connection with the fact discovered by Quincke, that light polarised normally to the plane of incidence penetrates furthest into metallic sheets.

Of late years the transmission of electricity through gases has been attracting a considerable amount of attention, and numerous papers have appeared dealing with this subject, one of the last being by G. Vincentini and M. Cinelli. Their paper, which appears in the *Nuovo Cimento* (3) vol. xxxvi., deals with the transmission of electricity through the gas surrounding a wire heated to redness by an electric current. The authors first describe experiments they have made on a long platinum wire surrounded either by air or carbon dioxide. The wire was protected from draughts by a series of screens, and a movable platinum electrode, connected to a quadrant electrometer, gave the potential of the air at different distances above and below the heated wire. It was found that the potential assumed by the electrode connected to the electrometer was higher than the mean potential of the heated wire. When the current passed through the wire was sufficiently intense to heat it to incandescence, the potential of the insulated electrode when placed above the wire did not vary with the distance from the hot wire to any sensible extent, only the maximum electrification was attained at different times after starting the current, and the greater the distance from the hot wire the greater the time which elapsed before the steady state was reached. When, however, the insulated electrode is below the incandescent wire, the difference of potential decreases very rapidly with the distance, so that at 15 m.m. it almost vanishes. In order to carry on observations on other gases besides air and carbon dioxide, the authors have devised a modified form of apparatus in which the incandescent wire is placed inside a globe which is silvered on the inside. This globe has four tubuli, two of which serve for the introduction of the electrodes for the hot wire; while of the remaining two, one admits the insulated electrode, and the other a wire which is connected to the silver coating of the globe, and serves to put this to earth. The authors consider that their experiments show that the gaseous molecules which leave the surface of the incandescent platinum wire in the case of hydrogen are positively electrified, their potential being about 0·25 volt higher than the mean potential of the incandescent wire. In the case of air and carbon dioxide the increase above the mean potential of the wire is about one volt. With hydrogen at a somewhat high temperature an inversion of the phenomenon takes place, since the potential of the insulated electrode becomes less than the mean potential of the wire.

A NEW phototheodolite is described by Herr O. Ney in the *Zeitschrift für Instrumentekunnde*. The novel feature about it is the geometrical clamp, which enables the surveyor to exchange the telescope and the camera on the stand with ease and accuracy. Both are provided with three spherical feet, which rest in a hole, a slot, and a plane respectively, made of hard steel, and fixed on the stand. This seems an admirable way out of the difficulty attending the simultaneous use of telescope and camera. Other instrument-makers combine the two by mounting a telescope at the side of the camera, with a counterpoise on the other side. In one instrument the telescope lens is also used for photographic purposes. But these instruments are either too small, or the adjustment is exceedingly unstable. In Ney's phototheodolite, which is made chiefly of aluminium, provision is made for securing the camera or the telescope on the stand after it is mounted in the hole-slot-and-plane clamp, and also for the constancy of the position of the sensitive plate. With these improvements, the instrument is likely to become a most valuable aid to surveying practice.

DR. C. G. DE DALLA TORRE's useful "Catalogus Hymenopterorum" continues to make satisfactory progress. It is proposed to complete it in ten octavo volumes, exclusive of bibliography and index, which will form a separate volume; and five volumes have already been published, including vol. 1, *Tenthredinidæ* and *Uroceridæ*; vol. 2, *Cynipidæ*; vol. 6, *Chrysididæ*; vol. 7, *Formicidæ*; and vol. 9, *Vespidæ*. The remaining families may be expected to follow shortly. The subject of entomology is so vast that little progress can be made without some entomologist from time to time devoting his life to the compilation of these great key-catalogues, which are landmarks in the study of the orders of which they treat, and stand towards them in the same relation as a dictionary to a language. Moreover, such catalogues involve an amount of patient and unremitting toil that no one can appreciate who has not himself experienced it; they are frequently published at a heavy pecuniary loss, and are peculiarly liable to criticism, which may be fair and friendly in tone, or may be just the reverse. Let us hope that Dr. Dalla Torre's labours will meet with the encouragement which he deserves from the hymenopterists, whose labours he has so much contributed to lighten.

THE discovery of the use of fire dates back to the very dawn of human intelligence; therefore the study of the rites and ceremonials which are found among every race in connection with the lighting of new fires, furnishes important facts for the discussion of the primitive history of human culture. But before it is possible to apply comparative methods of treatment to the subject, exact observations are required of the details of the new fire ceremony, wherever it survives, especially in less modified, savage, or primitive peoples. This requirement is fulfilled by an article, by Mr. J. W. Fewkes, descriptive of the new fire ceremony as it exists among the Pueblo Indians of Tusayan (*Boston Soc. Nat. Hist.*, vol. xxvi. pp. 422–458, Feb. 1895). Mr. Fewkes watched two such observances of the Tusayan Indians, one in 1892, and the other in 1893. In both years active ceremonials began on November 13, and continued five days. Two other days, November 8 and 9, were devoted respectively to "smoke assembly" and "official announcement," and November 18, when all serious ceremonials had ceased, was a general holiday. On each of the five days, from November 13–17, various processions and rituals were observed, in many of which the element of phallic worship plays a not inconspicuous part. It is unnecessary to describe these performances, but one or two remarkable points in connection with the dates on which they take place, are of interest. The Tusayan Indians, says Mr. Fewkes, can neither read nor write, and are ignorant of our almanacs and calendars, nevertheless they manage to make the performances commence on the same date, within a day or two, every year, the time of year being obtained by observation of the stars. Another instance of the astronomical knowledge of such rude people as the Tusayan Indians, is afforded by the fact that the culmination of the Pleiades is used to determine the proper time for the beginning of certain rites. This is a further example of the widespread use of the Pleiades for the determination of the time for the celebration of primitive rites and ceremonials.

IT may interest our readers to know that a catalogue of the more important books published in Denmark and Norway during the year 1894 can be obtained from the Skandinavisk Antiquariat, 49 Gothersgade, Copenhagen. The catalogue contains the titles of a number of important works on various branches of science.

A NEW volume, containing the Biological Lectures delivered at the Marine Biological Laboratory, Woods Holl, in 1894, will shortly be published by Messrs. Ginn and Co. The lectures cover a wide range of subjects, most of which are prominent questions at the present time, and all of which are of special interest to teachers and students of biology.

MR. R. F. STUPART, the new Director of the Meteorological Service of Canada, has commenced the publication of a monthly weather map, showing the mean temperature and the difference from the mean average temperature, also total rain and snowfall for the month, and depth of snow on the ground on the last day of the month. It is interesting to note that an extremely cold spell prevailed over Ontario in the early part of February, some of the low readings being almost unprecedented.

MR. H. W. WILEY, the chemist to the United States Department of Agriculture, recommends the cultivation of the cassava, *Manihot utilissima*, in the most southerly of the United States. It furnishes an excellent food for men and for cattle; though, from the small proportion of nitrogen which it contains, it cannot take the place of bread-stuffs. A very good kind of tapioca may be made from it. The yield, in sandy soils, is from four to five tons per acre.

A COLOURED map, showing the density of the population of Ireland at the Census of 1891, has been prepared and published by Mr. E. E. Fournier, Bray, Ireland. The map exhibits at a glance the density of the population, and shows clearly that some of the oldest railways have had a beneficial influence in preserving or increasing the population of the districts through which they run. It is the first of a series intended to exhibit graphically the physical, social, economic, and religious features of Ireland.

"THE Statesman's Year-Book" (Macmillan and Co.)—that handy compendium of statistical and historical information relating to all the States of the world—has attained its thirty-second year of publication. Edited by Mr. J. Scott Keltie, with the assistance of Mr. I. P. A. Renwick, the volume is a standard work of reference in which the man of business can find the commercial statistics he needs, to which the politician can apply for trustworthy statements, and from which the student of geography can obtain the latest geographical information.

Dr. A. B. Meyer, of the Royal Zoological Museum at Dresden, has sent us a description of two new birds of paradise from New Guinea. (*Abh. u. Ber. d. K. Zool. u. Anthr.-Ethn. Mus. zu Dresden*, 1894–95, No. 5). One of the birds, shown in its natural size in one of the two coloured plates which illustrate the paper, possesses remarkable characteristics in the form and colour of its plumage, and in the arrangement of two very long feathers which stretch out from the head to about twice the length of the body of the bird. This bird has been named *Pteridophora alberti*, in honour of King Albert of Saxony, and the second one described and figured by Dr. Meyer has been called *Parotia carolæ*, after Queen Caroline.

The seventh volume of the *Proceedings* of the Royal Society of Victoria has reached us. The volume contains twenty-eight papers, many of them illustrated with plates, communicated to the Society during 1894. With two or three exceptions, the papers belong to the domain of natural science. Among the contributions we notice one on Tasmanian earthworms, by Prof. Baldwin Spencer, and a note, by the same author, on two new forms of marsupials obtained in Central Australia, during the visit of the Horn Scientific Expedition to the Macdonnell Ranges. The geology of Castlemaine is described by Mr. T. S. Hall, and geological notes on the country between Strahan and Lake St. Clair, Tasmania, are contributed by Messrs. Graham Officer, L. Balfour, and E. G. Hogg. The older tertiary rocks of Maude, and the palæontology of the older tertiary of Victoria, form the subjects of two separate papers, and a catalogue of non-calcareous sponges collected in the neighbourhood of Port Phillip Heads is given by Prof. A. Dendy. Mention must also be made of a paper, by Mr. R. H. Mathews, on rock paintings and carvings figured by the Aborigines of New South Wales, in caves and rock shelters; and also of one in which Mr. E. F. J. Love gives the results of observations with Kater's invariable pendulum, made at Sydney. The object of this investigation was to throw some additional light on the question of the difference between the values of g at Melbourne and Sydney. A comparison of the results obtained by the United States Coast Survey officers at Sydney in 1883, with those found by Mr. Baracchi at Melbourne in 1893, has shown that a pendulum beating seconds approximately should lose 8·58 vibrations per day, if transferred from Melbourne to Sydney. Lieut. Elblein found, however, by swinging three of von Sterneck's pendulums at the two places, that the loss was 13·48 vibrations per day. Mr. Love comes to the conclusion that the difference between the vibration numbers at Melbourne and Sydney is 12·2 per day.

The additions to the Zoological Society's Gardens during the past week include a Sand Badger (*Meles ankuma*) from Japan, presented by Mr. Frederick Ringer; two Polar Bears (*Ursus maritanus*, ♂ ♀) from the Arctic Regions, presented by Mr. John J. Hughes; a Spotted Hyæna (*Hyæna crocuta*, jv.), a Vociferous Sea Eagle (*Haliaetus vocifer*), a Black Kite (*Milvus migrans*), from East Africa, presented by Mr. T. E. C. Remington; a Black-backed Piping Crow (*Gymnorhina tibicien*) from Australia, presented by Mr. J. D. Haggard; a Raven (*Corvus corax*) British, presented by Mr. W. Hillary; a Puff Adder (*Vipera arietans*) from East Africa, presented by Dr. A. Donaldson Smith; a Chimpanzee (*Anthropopithecus troglodytes*, ♀) from West Africa, a Common Marmoset (*Hapale jacchus*) from South-east Brazil, deposited; a Purple-breasted Lory (*Eos riceniatæ*) from Moluccas, a Blue-faced Honey-eater (*Entomyza cyanotis*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

The Moon and Atmospheric Waves.—Lunar atmospheric waves, or air-tides, as they might be called, can, according to M. Bouquet de la Grye, be distinctly traced in the records of barometric pressure collected at insular stations or stations situated close to the sea, where there are no powerful local disturbances to obscure them. In a contribution to the *Annuaire du Bureau des Longitudes*, he reproduces curves of atmospheric pressure traced at Brest, St. Helena, Cape Horn, Batavia, and Singapore, which distinctly show a regular ebb and flow twice a day in accordance with the position of the moon. The amplitude depends upon the declination of the moon and upon its distance from the earth, and also upon the latitude of the place of observation. The maximum amplitude at Brest is about a quarter of an inch of water, which means a fiftieth of an inch of mercury, a small oscillation indeed, but one which is well within our limits of accurate measurement. At Batavia the maximum heights are half an hour after the passage of the moon through the upper or lower meridian. But the retardation is almost imperceptible in other places. This is probably due to the extreme mobility of the upper strata of the atmosphere, and contrasts with the great retardation experienced by the ocean tides. M. Bouquet de la Grye points out the striking analogy between the ocean tide, with an amplitude of 1 m. under the equator, in an ocean having a mean depth of 5000 m., and the atmospheric tide of 2 mm. of water in a sea of air the weight of which represents 10,000 mm. of water.

Stellar Photography.—A remarkable illustration of the value of photography in astronomical researches is afforded by a recent comparison of one of Dr. Max Wolf's well-known photographs with the same part of the sky as seen with the 36-inch refractor of the Lick Observatory. Prof. Schaeberle finds that an enlarged photograph of the region about Algol, taken with an exposure of five hours, certainly shows stars down to mag. 16·5, assuming that stars of the 17th mag. are at the limit of vision of the telescope. Making due allowance for the loss of detail in the process of enlarging, "it appears probable that practically every isolated star visible at Mount Hamilton can be photographed by Dr. Wolf, at or near sea-level, with his comparatively small telescope." (*Astronomical Journal*, No. 338). The telescope employed by Dr. Wolf has a Voigtlander lens of six inches aperture.

Standard Time in Australia.—The resolution as regards Australian standard time, adopted at Melbourne last October (see p. 278), has come into effect. Queensland, New South Wales, Victoria, and Tasmania are now all using the time of the meridian 150° E., that is, ten hours before Greenwich. Queensland was the first of the Australian colonies to take action, and there the new time came into force on the first day of this year. Mr. H. C. Russell, of Sydney Observatory, has sent us a copy of the Act which established the mean time of the meridian 150° E. of Greenwich as the standard time in New South Wales, on and after February 1. He says that "South Australia has adopted the time of the ninth hour before Greenwich."

Nova Aurigæ.—Notwithstanding the enormous velocities in the line-of-sight recorded by the spectroscope, Nova Aurigæ has given no signs of proper motion, such as can be perceived with the telescope and micrometer. Such, at least, is the result of a comparison of the measurements made in 1894 by Prof. Barnard with those made by the same observer in 1893, and by Mr. Burnham in 1892. (*Ast. Nach.* No. 3279.) The magnitude also remains pretty constant, being 10·5, on the scale adopted at the Lick Observatory. The Nova seems to be too far removed from our system to give any appreciable parallax.

NEW COMPOUNDS OF HYDRAZINE WITH FATTY ACIDS.

Compounds of several of the more important organic fatty acids with hydrazine, analogous to the aromatic hydrazides previously prepared, have been obtained by Prof. Curtius and his pupils Messrs. Schöfer and Schwan, and an account of them is published in the current issue of the *Journal für Praktische Chemie*. The hydrazides of the monobasic fatty acids are distinguished from the aromatic analogues by their greater solubility in water. In all cases they are most advantageously prepared by reacting with one equivalent of hydrazine hydrate upon the ester of the acid rather than upon the free acid itself. The esters of dibasic fatty acids react analogously with two equivalents of hydrazine hydrate, producing hydrazides which contain two NHNH groups.

Formic hydrazide, $HCO.NHNH_2$, is produced when molecular equivalents of ethyl formate and hydrazine hydrate are mixed, considerable evolution of heat occurring. When the product is allowed to stand in a vacuum for some days large tubular crystals of the pure compound separate. The crystals are transparent, very hygroscopic, and extremely soluble in water, alcohol, ether, chloroform, and benzene. They melt at 54°. Formic hydrazide does not form salts with acids; even dilute acids at once decompose it in the cold with formation of formic acid and a salt of hydrazine. The solution of the crystals in water reduces Fehling's solution and ammoniacal silver nitrate readily at the ordinary temperature. Formic hydrazide forms a crystalline compound with benzaldehyde with considerable rise of temperature and with elimination of water. The crystals of the compound, benzalformyl-hydrazine, $HCO.NH.N:CH.C_6H_5$, melt at 134°. When excess of ethyl formate is heated with hydrazine hydrate in a sealed tube to 100°–130° for some hours, another formic hydrazide, diformyl-hydrazine HCO.NH.NH.COH, is produced in the form of brilliant colourless prisms an inch or more in length. In the preparation of this beautiful compound care must be taken to strongly cool the tube during the filling with the two components, as their interaction is otherwise of a dangerously energetic character. The crystals of diformyl-hydrazine are very soluble in water, but difficultly so in alcohol, and practically insoluble in ether. They melt at 159°, and reduce ammoniacal silver solution upon warming. Dilute sulphuric acid decomposes them as readily as those of formic hydrazide into formic acid and hydrazine sulphate.

Acetic hydrazide, $CH_3.CO.NH.NH_2$, is prepared by warming equivalent quantities of acetic ether and hydrazine hydrate in a sealed tube for a few hours at the temperature of a water-bath. The product rapidly solidifies in a desiccator to a white mass of crystals. The crystals are colourless needles aggregated in leaves, and melt at 62°. They deliquesce rapidly on exposure to moist air, and are also very soluble in cold alcohol. The aqueous solution reacts neutral to litmus, and is readily decomposed into the original component substances by either acids or alkalies. The compound cannot be distilled without decomposition. The solution reduces Fehling's solution very vigorously on warming. Like the formic compound, acetic hydrazide reacts with benzaldehyde to produce an analogous crystalline compound, acetyl-benzal-hydrazine, $CH_3.CONHN:CHC_6H_5$.

Oxalic hydrazide, $\begin{array}{l}CO.NH.NH_2\\ |\\ CO.NH.NH_2\end{array}$, is produced by the action of two molecular equivalents of hydrazine hydrate upon ethyl oxalate. The reaction is a somewhat violent one, and is best moderated by the addition of a little alcohol.

The new compound separates as a white crystalline mass, which is much less soluble in water than the hydrazides of the monobasic acids, and is almost insoluble in alcohol and ether. It is deposited from solution in hot water in very long and thick needles, which decompose at 235°. The solution reduces Fehling's or ammoniacal silver solution much less vigorously than the monobasic compounds. Oxalic hydrazide is much more stable towards acids and alkalies than the last-mentioned substances. The compound may be recrystallised unchanged from dilute sulphuric acid, and concentrated sulphuric and hydrochloric acids only decompose it very slowly. If, however, concentrated hydrochloric acid is allowed to drop upon the powdered substance moistened with water, until the acid is in slight excess, a white crystalline powder is obtained which is found to consist of the hydrochloride of the hydrazide, $\begin{array}{l}CO.NH.NH_2.HCl\\ |\\ CO.NH.NH_2.HCl\end{array}$. Oxalic hydrazide reacts in an interesting manner with nitrous acid (sodium nitrite and glacial acetic acid); an energetic evolution of gas occurs, and a white powder separates. The same white substance may be obtained by acting upon oxalic hydrazide suspended in water with mercuric oxide, and decomposing the mercury compound produced with sulphuretted hydrogen, the filtrate depositing the white powder upon evaporation. Analysis indicates that the compound probably possesses the constitution, $\begin{array}{l}CO—NH\\ |\quad\ \ |\\ CO—NH\end{array}$. Succinic hydrazide, $\begin{array}{l}CH_2.CO.NHNH_2\\ |\\ CH_2.CO.NHNH_2\end{array}$, is prepared similarly to oxalic hydrazide, and crystallises in silver-like crystal aggregates which melt at 167°, and which are more soluble in water than the crystals of oxalic hydrazide. Malonic hydrazide, $CH_2\langle\begin{array}{l}CONHNH_2\\ CONHNH_2\end{array}$, is likewise obtained in a similar manner, the reaction between malonic ether and hydrazine hydrate being very vigorous even in the cold. The crystals melt at 152°. The aqueous solution reduces Fehling's solution, ammoniacal silver solution, and platinic chloride at the ordinary temperature. Both the succinic and malonic hydrazides are as stable towards acids as the oxalic compound, and each yields a hydrochloride with concentrated hydrochloric acid. Both hydrochlorides are obtained in the form of small crystals, and they melt at 203° and 197° respectively with violent evolution of gas. Succinic hydrazide reacts with nitrous acid to form an interesting compound analogous to that of oxalic hydrazide. Its simplest possible constitution is $\begin{array}{l}CH_2.CO.NH\\ |\qquad\quad\ |\\ CH_2.CO.NH\end{array}$.

Several other more complicated hydrazides are described in the memoir, but the above will afford a sufficiently comprehensive idea of the important addition to our knowledge of the hydrazine compounds which we owe to the labours of Prof. Curtius.

A. E. TUTTON.

THE AURORA OF MARCH 13.

A NUMBER of letters referring to an aurora observed on March 13, have reached us. We select from these communications a few details of value and interest.

Writing from York, Mr. J. Edmund Clark says:—

"I was in a position for observing at 9.10; the display finally ended soon after 10. The latter part was seen, very similarly, at Scarborough, 9.10. Arch, pure white (and so all through) just north of zenith; east end brighter, with well-defined, beak-like apex upon α Coronæ borealis (alt. 17°, az. 13° north of east). Upper edge just grazed ζ and η Ursæ majoris, the lower some 3° below Polaris, a little west of which it became double, the Pleiades lying in the fork, 5° or 10° from the finish at about altitude 20° or 25°, nearly due west. No auroral glow outside, nor later, except as stated. The outer curves, west end, would have met, if continued, in similar "beak" as at east end.

"9.15.[1] Lower edge through β Ursæ minoris, Polaris, and α Persei. Streamers now traversing rapidly from *east to west*, pointing to magnetic anti-pole; passed from η Ursæ majoris to Polaris in 25 to 30 seconds by watch. Constant succession, as bars of light, for some minutes; then temporary cessation, but later intermittent, until 9.45. These were entirely distinct, as is obvious, from the ordinary far more rapid flickering from horizon to magnetic anti-pole. Three rough positions of stationary forms near the Plough, Auriga, and Jupiter, projected on the B.A. Meteor Star Chart, cross at altitude 68½°, azimuth 35° (½° and 6° respectively from the true magnetic anti-pole, for York, at 68¾ and 18°).

"9.25. Streamers, often as curtain-like fringe on lower edge of arch, now less prominent. Others still streaming from east to west in the arch show no perceptible effect as they sweep by these. New set moved slowly westward, about 1° or 2° per minute.

"9.30. Lower edge again as at 9.25. Upper edge had covered Plough; arch double more or less entirely; varies fast; much fainter to east from 9.25.

"9.37. Lower edge through handle of Plough, Capella, 1° north of Mars and ⅔ on from Mars to horizon. Fringe below now brilliant, but rapid fluctuations.

"9.45. Brilliant short streamers in fringe, from Mars to α Aurigæ, and ½ on to Polaris.

"10.0. All gone but one long faint streamer from 3° to left

[1] If others have thought of recording positions at the exact quarters, some altitudes might be obtained from the four given here.

of Aldebaran up to 1° to left of Jupiter, moving slowly westwards as before."

Mr. G. W. Lamplugh observed the display at Ramsay, Isle of Man, and to him the chief feature was "the predominance of a well-defined luminous bar extending across the heavens directly overhead from one horizon to the other—from magnetic east to west.

"The stars shone through this band of pale light with scarcely diminished brightness, but it was occasionally flecked by thin clouds. When I first saw it, at 9·20 p.m., there seemed to be traces of oblique striation crossing it, and Dr. Tellet, who called my attention to the display, states that ten minutes earlier, when the bar was at its brightest, these striations gave the effect of slightly twisted folds. Another informant remarked that the bar was formed shortly before 9 p.m. by the union overhead of rays which shot upwards for the east and west.

"The light waned rather rapidly with slight pulsations, and we thought that we could detect a slow southerly drift in the band before it vanished. The western portion died out before the eastern, which remained quite definite until 9·45 p.m. Meanwhile there had been a faintly diffused illumination of the northern heavens, with occasional suggestions of radiant streamers, but the whole quite subordinate in brightness to the band overhead.

"There was a westerly breeze and a nearly clear sky, with a low cloud-bank in the north-west, at the commencement of the display, but before 9·45 p.m. the wind had backed southward, and shortly afterwards the sky became suddenly overcast, though not before the aurora had faded to a scarcely perceptible glow. Half an hour later a slight shower fell."

The Rev. S. Barber says that the aurora was visible at Westnewton, Aspatria, in great brilliancy, as a band passing nearly over the zenith from the west to the east horizon at about 10 p.m. An arch of light was seen in the north from about 8.30, and some observers saw a shorter band almost north and south preceding the great band west and east.

Mr. J. Cuthbertson saw the display at Kilmarnock, N.B., as early as 7.45, "as a broad arch of light crossing the heavens from east to west. About 7.50 it was a very luminous pencil of light in the upper part of the heavens, through which stars of the second and third magnitude were distinctly visible, As it condensed it grew brighter. About ten minutes after I first observed it, it began to fade, and was invisible before 8 o'clock, leaving a temporary brightness in the western sky."

The aurora appears to have presented features very similar to those of the aurora of November 23, 1894, observations of which were discussed by Prof. A. S. Herschel in NATURE of January 10.

THE U.S. UNITS OF ELECTRICAL MEASURE.

BY a law approved in the Senate of the United States, last July, it was enacted that the legal units of electrical measure in the United States should be as follows:—

(1) The unit of resistance shall be what is known as the international ohm, which is substantially equal to one thousand million units of resistance of the centimetre-gram-second system of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice fourteen and four thousand five hundred and twenty-one ten-thousandths grams in mass, of a constant cross-sectional area, and of the length of one hundred and six and three-tenths centimetres.

(2) The unit of current shall be what is known as the international ampere, which is one-tenth of the unit of current of the centimetre-gram-second system of electromagnetic units, and is the practical equivalent of the unvarying current, which, when passed through a solution of nitrate of silver in water in accordance with standard specifications, deposits silver at the rate of one thousand one hundred and eighteen millionths of a gram per second.

(3) The unit of electromotive force shall be what is known as the international volt, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of an international ampere, and is practically equivalent to one thousand fourteen hundred and thirty-fourths of the electromotive force between the poles or electrodes of the voltaic cell known as Clark's cell, at a temperature of fifteen degrees Centigrade, and prepared in the manner described in the standard specifications.

(4) The unit of quantity shall be what is known as the international coulomb, which is the quantity of electricity transferred by a current of one international ampere in one second.

(5) The unit of capacity shall be what is known as the international farad, which is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity.

(6) The unit of work shall be the Joule, which is equal to ten million units of work in the centimetre-gram-second system, and which is practically equivalent to the energy expended in one second by an international ampere in an international ohm.

(7) The unit of power shall be the watt, which is equal to ten million units of power in the centimetre-gram-second system, and which is practically equivalent to the work done at the rate of one Joule per second.

(8) The unit of induction shall be the Henry, which is the induction in a circuit when the electromotive force induced in this circuit is one international volt while the inducing current varies at the rate of one ampere per second.

The National Academy of Sciences was instructed to prescribe and publish the specifications necessary for the practical application of the definitions of the ampere and volt given in the foregoing, and, to meet this requirement of Congress, a special committee was appointed to consider the subject. The committee, selected from members of the Academy, was as follows:—Prof. H. A. Rowland, chairman, General H. L. Abbot, Prof. G. F. Barker, Prof. C. S. Hastings, Prof. A. A. Michelson, Prof. J. Trowbridge, Dr. Carl Barus.

The report of this committee was submitted to the Academy at a special meeting held last month, and was then accepted and unanimously adopted. We extract the following details from the report, a copy of which has just reached us.

The Ampere.

In employing the silver voltameter to measure currents of about one ampere, the following arrangements shall be adopted:—

The kathode on which the silver is to be deposited shall take the form of a platinum bowl not less than 10 centimetres in diameter, and from 4 to 5 centimetres in depth.

The anode shall be a disc or plate of pure silver some 30 square centimetres in area and 2 or 3 millimetres in thickness.

This shall be supported horizontally in the liquid near the top of the solution by a silver rod riveted through its centre. To prevent the disintegrated silver which is formed on the anode from falling upon the kathode, the anode shall be wrapped around with pure filter paper, secured at the back by suitable folding.

The liquid shall consist of a neutral solution of pure silver nitrate, containing about 15 parts by weight of the nitrate to 85 parts of water.

The resistance of the voltameter changes somewhat as the current passes. To prevent these changes having too great an effect on the current, some resistance besides that of the voltameter should be inserted in the circuit. The total metallic resistance of the circuit should not be less than 10 ohms.

Method of making a Measurement.—The platinum bowl is to be washed consecutively with nitric acid, distilled water, and absolute alcohol; it is then to be dried at 160° C., and left to cool in a desiccator. When thoroughly cool it is to be weighed carefully.

It is to be nearly filled with the solution and connected to the rest of the circuit by being placed on a clean insulated copper support to which a binding screw is attached.

The anode is then to be immersed in the solution so as to be well covered by it and supported in that position; the connections to the rest of the circuit are then to be made.

Contact is to be made at the key, noting the time. The current is to be allowed to pass for not less than half an hour, and the time of breaking contact observed.

The solution is now to be removed from the bowl, and the deposit washed with distilled water, and left to soak for at least six hours. It is then to be rinsed successively with distilled water and absolute alcohol, and dried in a hot-air bath at a temperature of about 160° C. After cooling in a desiccator it is to be weighed again. The gain in mass gives the silver deposited.

To find the time average of the current in amperes, this mass, expressed in grams, must be divided by the number of seconds during which the current has passed, and by 0·001118.

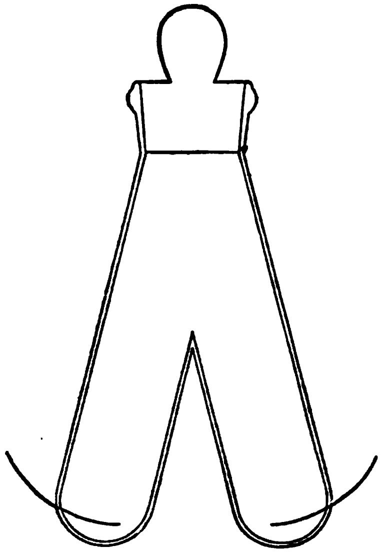
In determining the constant of an instrument by this method, the current should be kept as nearly uniform as possible, and the readings of the instrument observed at frequent intervals of time. These observations give a curve from which the reading corresponding to the mean current (time-average of the current) can be found. The current, as calculated from the voltameter results, corresponds to this reading.

The current used in this experiment must be obtained from a battery, and not from a dynamo, especially when the instrument to be calibrated is an electrodynamometer.

The Volt.

Definition and Properties of the Cell.—The cell has for its positive electrode, mercury, and for its negative electrode, amalgamated zinc; the electrolyte consists of a saturated solution of zinc sulphate and mercurous sulphate. The electromotive force is 1·434 volts at 15° C., and between 10° C. and 25° C., by the increase of 1° C. in temperature, the electromotive force decreases by 0·00115 of a volt.

To set up the Cell.—The containing glass vessel, represented in the accompanying figure, shall consist of two limbs closed at



bottom and joined above to a common neck fitted with a ground-glass stopper. The diameter of the limbs should be at least 2 centimetres, and their length at least 3 centimetres. The neck should be not less than 1·5 centimetres in diameter. At the bottom of each limb a platinum wire of about 0·4 millimetre diameter is sealed through the glass.

To set up the cell, place in one limb pure mercury, and in the other hot liquid amalgam, containing 90 parts mercury and 10 parts zinc. The platinum wires at the bottom must be completely covered by the mercury and the amalgam respectively. On the mercury, place a layer one centimetre thick of the zinc and mercurous sulphate paste described in 5. Both this paste and the zinc amalgam must then be covered with a layer of the neutral zinc sulphate crystals one centimetre thick. The whole vessel must then be filled with the saturated zinc sulphate solution, and the stopper inserted so that it shall just touch it, leaving, however, a small bubble to guard against breakage when the temperature rises.

Before finally inserting the glass stopper, it is to be brushed round its upper edge with a strong alcoholic solution of shellac, and pressed firmly in place.

ON THE NATURE OF MUSCULAR CONTRACTION.[1]

THE subject of this lecture is an inquiry into "The Nature of Muscular Contraction." Like all vital phenomena, muscular contraction is a most complicated process, composed of mechanical, chemical, thermal, and electrical changes in living matter. Hence it will be our task to become acquainted with these changes as completely and exactly as possible, and to ascertain their causal connection. Our inquiry must not be restricted to one special kind of muscle: it will have to extend to all the different forms, for there can be no doubt but that in all these cases the principle of activity is the same. Nay, it will be necessary to deal even with the other phenomena of so-called contractility, such as protoplasmic and ciliary motion, for all these different types of organic movement, however much they may differ from each other in details, are yet so connected by gradual transitions, that, to all appearance, one principle of motion, essentially the same, is applicable to all of them.

The general mechanical principle on which muscular contraction is based, will be discovered when we shall have ascertained in what way the power of shortening proceeds from the potential chemical energy which disappears upon stimulation of the muscle.

There can be no doubt as to the fact that the potential chemical energy of the component parts of muscular substance is alone the ultimate source of this power, for the existence of any other source cannot be proved. The quantity of energy which is imparted to the muscle by the stimulus is too small to be taken into consideration. The early opinion that the power required for contraction was imparted to the muscle through the medium of motor nerves has been refuted by experiments, such as, *e.g.*, on the persistence of contractility after degeneration of the motor nerves, and on the effects of direct artificial stimulation of the muscles; and it had even been refuted long ere the law of conservation of energy had thrown its light on the mutual connection between the phenomena of the living organs.

This law teaches that all the actual energy which appears in the muscle in consequence of stimulation must originate in an *equivalent* quantity of some other form of energy.

Now this form of energy is, in fact, given in the muscular substance liable to physiological combustion. The quantity of the latter is not only theoretically sufficient to produce that actual energy, but it has even been proved experimentally that during contraction that material gives birth to combinations, such as carbonic acid, in the development of which potential chemical energy must have passed into other forms of energy. As far as the phenomena have been examined *quantitatively*, they confirm the conclusion that all muscular force must be derived from chemical energy.

Hence there is no difference about all these points. But with this result we have as yet gained only a basis for the proper solution. So soon you inquire in what way, by what transformations, does the mechanical force of contraction arise from chemical energy, difficulties and differences of opinion begin to present themselves.

A great many physiologists hold, with Pflüger, Fick, and Chauveau, that muscular force is a direct manifestation of chemical attraction; others, *e.g.*, Solvay, think that it is produced through the medium of electricity; others again, following J. R. Mayer, believe that the muscle is a thermodynamic machine, not unlike our caloric or steam engines.

The Chemiodynamic Hypothesis.—The first hypothesis, according to which contraction of muscle is a *direct* manifestation of chemical attraction—we may call it the chemiodynamic hypothesis—has to assume that the molecules, on the chemical combination of which this contraction is based, are regularly arranged within the contractile substance in such a way as to make them approach each other at their combination in the direction of the axis of the muscular fibres.

I think that this hypothesis of the identity of chemical attraction and muscular force meets with a fundamental difficulty in the fact that, in a single contraction, only a relatively infinitesimal part of the muscular substance is chemically active; 70 to 80 per cent. of the muscle (and even more) consists of absorbed water, the rest contains substances (albumin, salts, &c.) which, for the greater part, so far as can be proved, are not chemically concerned in the contraction.

This quantitative composition and this minute consumption of the active muscle compel us to assume that relatively only very few molecules of the muscular substance can be considered as sources of energy, and of these again it is generally but a small part that at a certain moment perform their function.

With certain presuppositions we may calculate the quantity of matter through the chemical action of which the amount of actual energy, produced at a certain contraction, must have been generated.

[1] The Croonian Lecture, delivered by Prof. Th. W. Engelmann, at the Royal Society, on March 14.

If we prevent a muscle from doing external work during the contraction, the whole actual energy will present itself in the shape of heat. When there is but a slight contraction, the muscle of a frog, *e.g.*, will grow warmer by about 0·001° C. Supposing the specific heat of the muscle to be equal to that of water (in fact it is less), we find that for a rise of 0·001° C. in temperature a quantity of heat of 0·001 cal. is required for each gram of muscle. No matter whether this quantity of heat results from the combustion of carbohydrates, fats, or albuminous matter, it can be but an infinitesimal part of the muscular substance that produced it. If, *e.g.*, as is ordinarily supposed, the combustion of a carbohydrate into CO_2 and H_2O produced that heat, taking the heat of combustion of one gram of carbohydrate to be broadly 4000 cal., no more than a four-thousandth part of a milligram will have been consumed in each gram of the muscle. Hence only about a four-millionth part of the muscular substance could have been the source of the actual energy set free by the stimulus, and at the same time, according to the above hypothesis, have been the subject of direct attraction.

But whatever may be our conception of the size, form, position, and sphere of action of this four-millionth part in relation to the other soft, watery mass, only passively moved, I fail to understand how, through *direct chemical attraction*, this one minute part should bring about the movement of the rest of the four million parts in such a manner as it does.

The adherents of the chemico-dynamic hypothesis have not answered this objection as yet. And since they can give but an unsatisfactory account or no account at all of many other facts (I will refer to some of these facts further on), we may be allowed to cast about for some other explanation.

The Electrodynamic Hypothesis.—Since Galvani's discoveries, the electric phenomena of muscles have frequently been suspected to contain the solution of our problem. And, indeed, it is not so very difficult to mention a series of facts which seem to bear out the suggestion that the mechanical work done by the muscle may be created from chemical energy through the medium of electric forces.

There is, in the first place, the fact that muscles, when in action, produce regular electric effects. These effects are indeed the first phenomena we can observe after stimulation. They seem to begin at the very moment of stimulation, shortly before the contraction, hence they might in so far be the cause of the mechanical process.

Moreover, as du Bois-Reymond proved, the value of the electromotor force is very high, and in the active particles is probably much higher than the force of the currents we can derive from the surface of the muscle.

Add to this that the economic coefficient of the muscle may attain, just as in the case of electric motors, a considerable proportion. As much as 25 per cent. and more of the potential energy which has been consumed may be transformed into mechanical work.

However, there are weighty objections to this hypothesis also. In the first place, there is the fact that these very same electromotor forces, of equal intensity and direction, appear, under the same influences, not only in the muscles, but also in nerves, glands, and other organs, which do not possess the least contractility. Then there is the important discovery of Biedermann, that the contractility of muscles may be completely neutralised by water or etheric vapours, without doing any perceptible harm to the electromotor phenomena.

In the same way the development of the electric organs supplies us with important proofs of the independence of the electric and the mechanical processes. In most cases these organs are developed out of striped muscular fibres. Now, in this process of development, contractility is gradually lost, whereas the power of producing electrical effects attains a yet higher degree of perfection.

The Thermodynamic Hypothesis.—More probable than the chemical and the electrical hypothesis may be deemed a suggestion, first put forward by Jul. Rob. Mayer, though in an untenable form, according to which the muscle is a thermodynamic machine. Physiologists, however, generally object that this view is not compatible with the second law of thermodynamics, for we cannot expect differences in temperature in the muscle so great as this law requires they should be.

Now I venture to think that, on the contrary, we must assume exceedingly great differences of temperature in the stimulated muscle. What holds good of the whole body holds good of the muscle also; the temperature, measured with our instruments, is but an arithmetical average, "comprising an infinite number of different temperatures, pertaining to an infinite number of different points" (Pflüger).

From the fact that at the contraction an infinitesimal part only of the muscular mass is chemically active, we infer that the temperature of these particles must, at the moment of combustion, be an uncommonly high one. Great as the specific heat of muscular substance is, it would otherwise be impossible to account for a rise in the temperature of the whole mass even of 0·001° C. only.

Since each thermogenic particle is surrounded by a relatively enormous cool mass, conducting heat and diathermanous, the principal condition for the transformation of heat into mechanical work has been satisfied, and, on account of the enormous differences in temperature which we have to assume, satisfied to such a high degree, that even an economic coefficient of 30 per cent., nay, 50 per cent., and even more, seems to be theoretically possible.

Supposing we have to deal with a Carnot's cycle, the theoretical maximum Q_0 of the mechanical effect is $Q_0 = Q\frac{T_1 - T_2}{T_1}$, where Q stands for the whole quantity of heat, which from the absolute temperature T_1 is sinking down as far as T_2. Taking $T_2 = 273° + 37° = 310°$, the mechanical effect might at $T_1 = 410°$ amount to 30 per cent., when the temperature of the active particles would consequently exceed the average temperature of the normal muscle by 100° C. only.

The objection that these high temperatures must necessarily destroy the life of the muscle, since the latter becomes rigid and dies even at 50° C., is, for the same reasons, of small importance only. For it is ever but an infinitesimal part of the muscular mass that is exposed to these high temperatures. At a small distance from these furnaces of heat the temperature must have fallen so low as to be harmless. The muscle will no more be destroyed by stimulation than a steamer will be destroyed by heating the furnaces.

However likely it may thus seem that nature should avail herself of these favourable terms on which mechanical work may result from muscular heat, we have up to the present time no direct proof that this is actually the case, nor do we know in what way it takes place, if in any. But I venture to think that the proof can now be given, inasmuch as it is possible to demonstrate how, through the medium of peculiar arrangements of the material of the muscle, a transformation of chemical energy into mechanical work by means of heat not only can, but actually must, be brought about.[1]

Muscular Structure in relation to Contractility.

The Fibrils are the Seat of the Shortening Power.—For this we need firstly to pay attention to the peculiarities of the microscopical structure of muscle. All muscular fibres of all animals are composed chiefly of two parts: extremely thin, long, albuminous fibrils, and an interfibrillar plasmatic substance, the so-called sarcoplasma. The quantitative relations of both vary, but the fibrils always occur in great number, forming very often the greatest part of the whole mass of the muscle. They always run parallel to each other throughout the length of the fibres.

This fibrillar structure is also presented by all the other formed contractile substances.

Direct microscopical observation during life teaches us that the fibrils, and not the sarcoplasm, are the seat of the shortening power. The fibrils in a state of relaxation are long and thin, and often run in winding curves, but grow short, thick, and straight, in consequence of stimulation. The sarcoplasm passively follows their movements. Moreover, completely isolated fibrils can shorten.

The Fibrils are Contractile because they contain Doubly Refractive Particles.—Thus the question arises: Can there be demonstrated in the fibrils such arrangements of their material as by their mediation contractile force may originate in a thermodynamic way?

Light—*lux optimum reagens*, as Buys Ballot said—solves this

1 The empirical foundations of the views developed in this lecture will be found in "Versuche über Aenderungen der Form und der elastischen Kräfte doppelbrechender Gewebselemente unter chemischen und thermischen Einflüssen," in the Appendix of my Memoir. "Ueber den Ursprung der Muskelkraft" (2te Auflage. Leipzig. 1893. S. 54-80), and in the literature cited in the same paper.

question for us. If we examine the optic properties of contractile fibrils, with the aid of the polarising microscope, we find that all of them are double-refractive, with one optical axis parallel to the direction of contraction.

This general occurrence of double-refracting power is the more indicative of relations to contractility, since non-contractile cells, as a rule, lack double refraction, even where we meet with a fibrillar structure, as in the axis-cylinder of a nerve-fibre.

Our conjecture gains, I believe, a very high degree of probability by the following series of observations.

In the first place, the fact that contractility and double refraction in the course of ontogenesis always appear at the same time, *e.g.* in the heart of the chick, on the second day of incubation; in the muscles of the trunk and skin on the fifth or sixth day; in the muscles of the tails of tadpoles when the length of their body is 3 to 4 mm.; in the muscles of the stalk of Vorticella, and in cilia so soon as these organs become visible.

Another evidence seems to me to be afforded by the behaviour of the striated muscles. Here the fibrils consist of the doubly-refractive sarcous elements and the singly-refractive material which joins these, the two alternating regularly. The two are wholly different as regards their optical, mechanical, and chemical properties; and these properties, moreover, during contraction, change in an opposite way. Hence the functions of the two must be of a different kind. And since the changes of form, volume, &c., of the doubly-refractive parts during contraction prove that in each case these parts must be the seat of contractile power, the single-refractive junctions will most probably have another function. We will come back to these changes further on.

A third evidence is afforded by the observation that the specific force of contraction in different muscles is, in general, greater, the better developed the power of double refraction, comparison, of course, in each respect being made with parts of the same thickness.

In the development of the pseudo-electric organs of *Raja* out of striated muscular fibres, one of the signs of the incipient change of structure and function is the vanishing of double refraction in the sarcous elements. In an early stage of development this vanishing is, with *Raja clavata*, the very first and the only sign that the fibre is about to be transformed from a contractile into an electric organ.

But particularly significant seems to me to be the behaviour of the obliquely striated muscles of Molluscs and other Invertebrata. Here the doubly refractive fibrils do not run parallel to the axis of the fibre, but describe spiral lines round it; and during a contraction the steepness of the curves decreases, so that the angle formed by the longitudinal axis of the fibril and the longitudinal axis of the fibre may increase from 5° in the relaxed state to 60°, and even more, in a state of powerful contraction. But the optic axis of the fibril, instead of assuming, in this case, a more oblique position also, as might be expected on morphological grounds, remains parallel to the longitudinal axis of the fibre, and consequently to the direction of shortening of the fibre. Hence it is not the morphological axis of the fibrils, but the optical axis of their doubly refractive constituents, which coincides with the direction of the contracting force.

Contractility a General Property of Doubly Refractive Bodies.—More than a score of years ago I pointed out the fact that even non-muscular elements, elements not possessing irritability in the physiological sense of the word, nay, even lifeless, unorganised elements which are uniaxial doubly refractive, may, under certain influences, contract in the direction of the optical axis, all thickening at one time, and contracting with a force and quickness and to an extent rivalling that of muscles, if not surpassing it. Instances of this are the fibrils of the connective tissue, of the tendons, and of the cornea, and others. The same contractile power was found by von Ebner in a great many other doubly-refractive histological elements, nay, even in substances capable of absorption and thereby made doubly refractive, *e.g.*, dried colloid membranes; and finally by Hermann, in fibrils of fibrin.

I have in this way shown that singly refractive, or only feebly doubly refractive histological elements, such as the fibres of elastic tissue, obtain, in the same way as caoutchouc, the power, when made doubly refractive by extension, of contracting under certain influences, and further that the force of shortening will generally be greater in proportion to the amount of the double refraction thus artificially produced.

Since, according to Mitscherlich's discovery, similar changes of form may be observed in doubly refractive crystals, we have apparently to deal with a property pertaining to all doubly refractive bodies as such.

Heat as a General Cause of Contraction of Doubly Refractive Elements.—Now, the influence which in all these cases is able to evoke the mechanical energy of shortening is *elevation of temperature.* Refrigeration has the opposite effect.

Particularly instructive is the thermal contraction of the fibrillar connective tissue, on account of its similarity to muscular movement, even with regard to details.

In tendons and many membranes the fibrils, as well as those of most muscles, are arranged into bundles, all, or nearly all, parallel to each other. For this reason such objects are extremely well fitted for a closer examination of the phenomena of movement. The most suitable material I know is furnished by the catgut strings of violins, which chiefly consist of such bundles, running in steep spiral lines, round the longitudinal axis of the string. They are distinguished from the greater number of naturally occurring objects by their very regular cylindrical shape and their elasticity. On these properties is based their suitability for musical purposes, especially for the so-called "perfect fifth" ("Quintenreinheit").

The Muscle-Model.—With the aid of such a string we can compose a model which in a simple way explains how in the muscle mechanical energy of contraction may result from heat without any perceptible rise of the average temperature of the muscle.

A piece of an *E* string of a violin, about 5 cm. long and previously swollen in water, is fastened to the end of the short

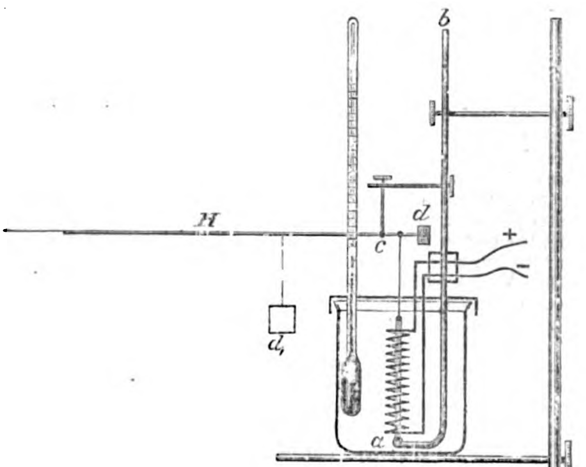


FIG. 1.

rigid arm of a steel rod, while the upper end of the string is fixed to the shorter arm of a lever, turning round an horizontal axis.

To this string different tensions may be imparted by weights or springs, acting upon the lever.

Round the string, but without touching it, runs for a length of about 20 mm., and in about twenty curves, a spiral of thin platinum wire. The ends of this may be connected with the two poles of a Grove or Bunsen battery of three or more cells. The rod, bearing the lever string and spiral wire, is placed in a glass of about 50 c.c. contents, filled with water of about 55–60° C., and closed at the top by an ebonite lid. Through an aperture in the lid, a thermometer is placed in the water in such a position that it will remain at a distance of about 1 cm. from the spiral wire.

The string is now observed for some minutes at a tension of 25 or 50 grammes and at a constant temperature until no further change in the position of the lever can be discerned. If we now close for some seconds the circuit of the battery through the spiral, *the lever rises. Upon opening the circuit, it falls. The thermometer in the glass indicates a hardly perceptible rise in temperature, or no rise at all.*

We see the doubly-refractive string of our model corresponds to the doubly-refractive muscular particle, which we suppose to be the seat of the force of contraction, and therefore may be called "*inotagma*"; the water in the glass represents the watery isotropic substance round the inotagma, doing duty as refrigerant; the spiral wire supplies the place of the chemically active *thermogenic* molecules; the closure of the galvanic circuit corresponds with the process of the stimulation of the muscular element.

The movements may be inscribed on a rotating cylinder. We then obtain curves of the same character as contraction-curves of muscles.

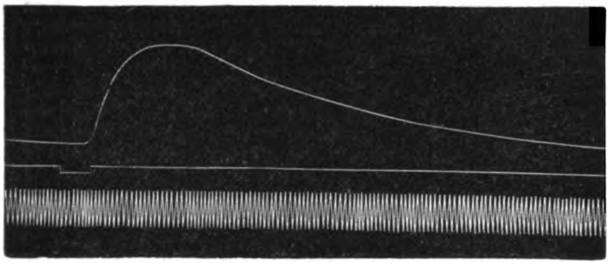

FIG. 2.

Such a *chordogram* presents, like a myogram, three periods, viz.:—

(1) A period of latent energy, the duration of which, just as with the muscle, decreases with the increasing energy of the stimulus (*i.e.*, with the intensity and duration of the electric current), with rising temperature and with decreasing load.

(2) A period of augmenting energy, in which contraction takes place with a rapidity, first increasing, afterwards diminishing, the contraction being, within certain limits, more rapid and the larger in extent the stronger the stimulation.

(3) A period of declining energy, in which the string relaxes with a gradually decreasing rapidity.

Further Comparative Researches on the Thermal Contraction of Lifeless Double Refractive Bodies and the Physiological Contraction of Muscle.—The points of resemblance between our model and a muscle extend much further yet, and amongst other points to peculiarities which seem to bear important testimony to the identity of the mechanical process in the two cases.

Such a resemblance I find, in the first place, in the fact that the strength of *the shortening power, developed by a certain stimulus, increases with the load* within certain limits. Both muscle and string present the paradoxical phenomenon that, under a stimulus of equal energy, heavier weights may be lifted higher than lighter ones.

Neither the chemical nor the electrical hypothesis of the origin of muscular force can give a sufficient explanation of this fact. On the basis of our theory, on the contrary, it can be predicted, because every influence which augments the doubly-refractive power must raise the power of contraction.

Now, von Ebner has proved experimentally that the force of double refraction of tendons and also, between certain limits, of muscles, increases with the load. The same is the case with fibres of elastic tissue and with caoutchouc, and with these also the contractile power increases with the load. The differences of force thus depending on the load are by no means insignificant.

Connected with this point is another fact, viz. that the force of shortening produced in our model by means of a given rise of temperature, is the smaller the more the string has already contracted. The maximum of force is, at all events, displayed when the extension of the string is brought by the whole load being applied at once at the very beginning of the heating, not after the string has already contracted with a smaller load.

The very same thing, as Schwann's experiments showed many years ago, holds good of muscle. On the hypothesis of chemical attraction we should decidedly expect the reverse: viz. increase of force with an increasing mutual approach of the combining molecules; so also in the same way on every other hypothesis which pronounces contraction to be caused by attractive powers increasing in inverse proportion to the square of distance.

In the fact discovered by Schwann, Johannes Müller thought he had found a refutation of the old electro-dynamic hypothesis of Prévost and Dumas, as well as a valid reason for assuming a fundamental relation between the vital power of contraction and physical elasticity.

However, as Hermann has observed, we might in this case get over the difficulty by supposing that between or in the length of the parts attracting each other, there are elastic layers opposing that attraction with increasing force. It is evident that our view of the matter does not require such an auxiliary hypothesis, because, in accordance with Eduard Weber, we regard muscular contraction as only a special case of elastic shortening.

A closer experimental comparison of the changes undergone, on the one hand, by the elasticity of our string during thermal shortening, and, on the other hand, by muscular elasticity during physiological contraction, will teach us that, in each case, the changes are of exactly the same kind.

As regards striated muscles, it was Eduard Weber who, by his classic researches, established that their extensibility increases during contraction. The same is now proved to hold good of strings and other organic doubly-refractive substances during thermal shortening.

The curve of lengthening of all these objects inclines more sharply towards the abscissæ of the loads the higher the temperature. Both curves converge, and may finally even cross, *i.e.* a certain load being exceeded we do not get contraction but lengthening as the effect of heating.

This circumstance explains the fact, sometimes observed by E. Weber, that living, tired, heavily-loaded muscles of frogs, lengthen instead of shorten as a result of electric stimulation. Considered from other theoretical points of view, this observation seems so paradoxical that its very validity has been questioned by some physiologists, but in the face of the direct and exact measurements of so scrupulous an observer and inquirer as Eduard Weber, we have no right to do this. According to our view of the origin of muscular force this fact is not paradoxical at all, but might be foreseen.

The decrease of the shortening power and the increase of extensibility with increasing thermal contraction is, in the case of our lifeless doubly-refractive objects, accompanied by a decrease in the power of double refraction. According to von Ebner's careful measurements, the same thing is the case with muscles during vital contraction. We may consider this fact, too, as an important proof of the fundamental resemblance between the process of contraction in our model and in the muscle, and at the same time as a further evidence of the existence of a causal relation between double refraction and contractility in general. But it is the physicist's task, and not the physiologist's, to penetrate further into the relations between optic and elastic properties. The physiologist may deem his purpose attained when he succeeds in tracing a certain vital phenomenon back to processes which may also be observed in lifeless bodies.

However, though we should, perhaps, be inclined to infer from the foregoing that we have successfully acquitted ourselves of this task with regard to muscular contraction, we will be careful not to overlook the numerous important respects in which a muscle as a *living* body, that is, one subjected to constant chemical transformation, differs from our lifeless strings. The study of these differences is most instructive, since it throws a new light on a series of processes nearly allied to contraction, especially on the phenomena of *rigor mortis* and *tonus* of muscle.

But before entering into this we shall first have to meet another important objection to our views. It is based upon the absolute amount of muscular force. This amount may, as you know, be very high. Human muscles at the strongest tetanic contraction can shorten with a force of about 10 kilogrammes to 1 sq. cm. transverse section. Now such a force must, according to our view, be produced by a small part only of the transverse section of the muscle.

With a maximal tetanus, it is true, the temperature of the whole muscle does rise 1° C. or more. Hence there are, perhaps, 1000 times more particles chemically active than with a moderate simple contraction, where the temperature rises 0·001° C. only. Consequently, during such a tetanus, a much greater part of the muscular substance—perhaps 1000 times as much—will be heated to such a degree as is required for an obvious contraction of the inotagmata. But even in this case the greater part of the whole substance will be only moved passively.

Can such very important mechanical powers as we are obliged to assume in the inotagmata be evolved through the thermical contraction of doubly-refractive bodies? Do we not, as Fick says, in making such a supposition, go too far beyond the bounds of legitimate analogy?

Of course nothing but the measurement of the forces developed by lifeless doubly-refractive bodies under thermal contraction will decide this question. I have made many of these measurements on various objects, and I think the results afford us a refutation of the objection. Strings, moist but not yet contracted through lying in water, with a diameter of 0·7 mm., and loaded with 1 kilogramme, lifted up the weight in a perceptible degree when rapidly heated up to 130° C.; that is to say, they exerted a force about twenty times at least as great as the maximum force of a human muscle of the same thickness.

Still greater forces may be exerted by strips of caoutchouc rendered in a high degree doubly refractive by strong extension. Even by merely heating from 20° to 40° C. powers could be produced sixty times as great as the maximum afforded by human muscles of the same transverse section.

Hence we may sufficiently account for the greatest display of force in the muscle, without having to attribute to the inotagmata higher elastic forces than we observe in highly extended threads of caoutchouc of the same thickness, nay, without even having to assume temperatures reaching the degree necessary for the coagulation of albumin.

It is a pity that we are not able to subject the isolated doubly-refractive parts of the muscle in an unimpaired condition to the influence of heat. Together with the elevation of temperature there occur changes in the chemical processes, and therewith in the material composition and mechanical properties, of the whole muscle substance, which complicate the changes dependent only on the heating of the doubly-refractive particles, or even prevent our clearly recognising them.

Tetanus and Rigor by Heat.—Living muscles, when being *gradually* heated, will, as you know, contract tetanically so soon as the temperature has attained a height which is but little below 50° C. This so-called *tetanus of heat* passes by prolonged heating into the lasting contraction of *rigor*, in this case combined with definitive loss of irritability.

This contraction through heat agrees at so many points with physiological contraction, especially with physiological tetanus, that it was held to be a last manifestation of muscular life. Such points of resemblance are, *e.g.*, the amount and the force of shortening, which in both cases are at least of the same order, and the increased production of heat, carbonic acid, and a fixed acid.

No doubt in this case a very important and general rise of temperature of the contractile particles will take place so soon as rigidity begins to announce itself. Consequently, according to our hypothesis, we must expect a strong and general contraction of the inotagmata.

That the force, with which the muscle as a whole will shorten, is not quite so great as with physiological tetanus, is sufficiently explained by the fact that the inotagmata do not contract simultaneously, and by the increase of internal resistance which occurs, due to coagulation and precipitation in the muscle plasma during the development of rigidity by heat. The latter circumstance seems to explain, too, why the rigid muscle does not perceptibly lengthen, or lengthens very little, upon cooling.

Turgescence by Absorption as a General Cause of Contraction of Doubly-refractive Organised Elements.—On a closer examination, however, we find that matters are still more complicated, and likewise that there is still an important circumstance which, besides the rise of temperature of inotagmata, may act as a cause of contraction, even of permanent contraction. This circumstance, the fundamental importance of which to muscular contraction was disclosed a score of years ago by a rigorous microscopical examination of the processes taking place in the muscle fibres during contraction, is the *turgescence of the doubly-refractive elements by the absorption of watery liquids.*

All histological elements possessing doubly-refractive power tend, even at an ordinary low temperature, to shorten in the direction of the optical axis when their volume is enlarged by the absorption of a watery fluid, and to lengthen when their volume diminishes by loss of liquid. The extent, power, and rapidity of the changes of form depend on the nature and on the dimensions of the turgescent object, and on the nature and quantity of the absorbed liquid.

For the examination of these relations our violin strings again yield fit material. A long series of measurements has now shown that there is a very far-reaching resemblance between contraction by turgescence and thermal and physiological contraction. I may mention the marked extent of the shortening, the high value of the force of contraction, its increase with the initial tension and its decrease with increasing shortening, the increase of extensibility, the decline of refractive power and of doubly-refractive property. The resemblance is by no means exclusively of a qualitative, but also of a quantitative kind.

A change of form generally takes place when the composition of the absorbed liquid changes, and it is of great importance to our question that even the slightest changes of composition can cause marked contractions and great mechanical effects.

Unloaded *E* strings, *e.g.*, contract in pure water to nine-tenths, and in water which contains 0·25 per cent. only of lactic acid to three-fifths of the initial length. At 15° C. they exert, in the first case, forces of about 80 g., in the second of about 110 g. By absorbing a 0·25 per cent. solution of lactic acid at initial tensions of 5, 215, and 425 g. there were exerted powers of 115, 350, and 490 g. respectively, *i.e.* forces very much higher than a muscle of the same thickness can produce during tetanus.

Upon neutralisation or dilution the old length and volume return. The doubly-refractive fibrils, or the sarcous elements of muscles, contract considerably also under the same conditions, swelling at the same time; this is the case even with muscles which have been killed in alcohol. In such instances I measured in the striated fibres of insects shortenings to 50 per cent. and more.

Since, according to many inquirers, lactic acid is formed during the rigor of striated muscles, and at all events the reaction of the muscular plasma becomes acid, the doubly-refractive elements must necessarily swell more and tend to shorten, and this contraction will remain until the acid has been neutralised or removed by diffusion.

Similar results will follow in other cases of rigor characterised by shortening and by the production of much acid. Nay, in the bloodless muscle even a physiological stimulation, when sufficiently strong and long, may be expected to produce a lasting shortening, on account of the gradual increasing acidity. Indeed, the well-known incomplete relaxation of such muscles seems to me to be a symptom of this *chemical contraction*, as it may be called, in contrast with the *thermal.*

In a muscle in which the blood stream is maintained this will not so easily take place, not even under a strong and prolonged stimulation, because the acid is immediately neutralised or removed through diffusion. Even in the isolated, bloodless muscle the acid, which is produced by stimulation, may, in the beginning at least, be rendered harmless through the very large quantity of non-acid fluid absorbed by the muscle. Consequently we must expect in these cases an immediate and complete relaxation after contraction. The facts agree absolutely with these suppositions.

It is, perhaps, not unnecessary to remark that all these observations would also hold good if the material affecting the turgescence were not lactic acid, but another substance arising during the chemical action in the muscle, *e.g.* water.

The different parts played by "Thermal" and by "Chemical" Contraction in the different kinds of Muscular Contraction.—But now the question may be raised, Is not physiological contraction due to turgescence solely?

We have all the more reason to put this question, since we can prove that in the physiological contraction of striated muscle-fibres the doubly-refractive layers swell at the cost of the watery isotropic layers. The microscopical examination of active living muscles and of fixed waves of contraction has proved this fact beyond all question, however much the opinions of different observers may diverge on other points. The swelling would, moreover, account for the slight decrease of muscular volume observed in strong tetanic contraction. For, according to the experiments of Quincke, the absorption of water by organised bodies generally leads to a slight condensation.[1] By this condensation further heat is developed, and this heat might, by raising the temperature of the doubly-refractive elements, be partially transformed into mechanical energy, and in this way contribute to the production of muscular force.

Yet I cannot consider this explanation as sufficient for all the facts. The same argument which in our eyes seems to dispose of the hypothesis of the identity of chemical attraction and muscular force, viz. the infinitesimally small quantity of substance which is chemically active during a simple contraction, seems to me to present a fundamental difficulty here also. It is hard to understand how through a change in the material composition, effected at one infinitesmal point within a soft watery substance, the whole mass should shorten and thicken, *unless there proceeds from the centre of chemical activity a considerable amount of kinetic energy throughout the substance.*

The microscopic appearances which prove the turgescence of the doubly-refractive elements during a contraction, do not exclude a direct thermo-dynamical effect. For the almost complete identity in the changes of form, and of the optical and mechanical properties which the doubly refractive constituents of all histological elements undergo during chemical and thermal contraction, seems to bear out the hypothesis, that in the thermal shortening of doubly-refractive elements, through the absorption of watery fluid, we get a shifting of solid and liquid substances analogous to that of turgescence. With most of the microscopical appearances, especially the so-called fixed contraction waves, we have, moreover, to do with a high degree of tetanic contraction, or even with rigor, in which, on account of the greatly increased chemical action, a chemically-caused turgescence may have combined in a considerable degree with the thermal contraction.

Hence, we may conclude that chemical contraction by turgescence of the inotagmata is most likely a constant concomitant of the thermal contraction of living muscle, but that compared with the latter, in a single contraction at least of striated fibres, the former is of little or no consequence as regards the shortening effect.

Chemiotonus and Thermotonus.—Both processes will probably also take part in varying proportion in the *tonus* of muscle, which in some cases will approach more to pure *chemiotonus*, in others more to pure *thermotonus.*

Causes of the Relaxation of Muscle. Theoretical Considerations. Conclusion.—With regard to the *relaxation* of muscle, according to our theory this must be caused either by cooling, or by the withdrawal of water from the doubly-refractive particles. Indeed, we have found that generally doubly-refractive histological elements, even if they be lifeless like our violin strings, lengthen again upon cooling after they have been contracted by heat, and that they lengthen upon neutralisation or diffusion, after they have been contracted by absorption at an ordinary temperature.

In a normal relaxation the muscle seems to return completely to its initial state. Of course its store of energy has diminished in proportion to the quantity of mechanical work and heat which have proceeded from it, but, on account of the relatively infinitesimal quantity of substance which is thereby consumed, this return will necessarily seem to be complete even in the case of the isolated muscle.

When analysing the phenomena of relaxation more exactly, we shall light on several possibilities, the discussion of which would be very interesting with regard to the theory of muscle-life. I shall restrict myself to the phenomena of the relaxation following on *thermal* contraction.

Here, in the first place, we might conceive that the doubly-refractive inotagmata are destroyed in the thermal shortening, so that each of them performs its function once only. The lengthening of the muscular fibrils would then probably be caused solely by the elastic powers of the parts passively extended or compressed by the shortening of the inotagmata. Upon a fresh stimulation other inotagmata would, in consequence of the combustion of other thermogenic molecules, be active, perish, &c. Through the activity of the formative matter of the living muscle-fibre, the place of the lost inotagmata would be continually or periodically filled by others, probably through the same process of organic crystallisation by which during ontogenesis the doubly-refracting particles in the muscle are produced and disposed.

Against this hypothesis, however, or at least against its general validity, various objections may be put forward. I will mention two only of the most important of them.

There seems to be no doubt but that the doubly-refractive particles of the muscle consist of an albuminous substance, and that they together make up a sensible part of the whole albumin of the muscle-fibrils. In that case it would be most improbable that a great increase of muscular work should not at all, or very slightly only, increase the elimination of nitrogen. To account for this, we should have to recur to an auxiliary hypothesis, and assume either that the nitrogenous remainder of the destroyed inotagma is retained within the body—perhaps in the muscle—for purposes of anabolism, or, which is most improbable indeed, that other organs saved just as much albumin as was decomposed above the normal quantity during the contraction of the muscles.

A second objection consists in the fact that after heating tetanising muscles until they are rigid, the doubly-refractive power of the sarcous elements will be found still very great.

The other possibility is that the inotagmata may be preserved, and consequently on cooling may return to their former state, and therefore will do work by shortening as often as we choose. In this case muscle would not only seem to offer, but would offer in fact, a most striking resemblance to a thermodynamic machine, the solid particles of the framework of which are not destroyed through the chemical process producing the actual energy. No more than such a machine would the muscle require a perpetual renewal of the framework for the continuation of its activity; it would only want a periodic supply of fresh heating material.

This representation, as you see, will sufficiently account for the fact, which would otherwise remain surprising, that muscular work has such a small influence on the elimination of nitrogen. The facts of microscopic observation also agree with it.

But a further discussion of the two possibilities would lead us too far. The purpose of this lecture was not to record a complete inquiry into all the phenomena of muscular activity. I have wished chiefly to draw attention to a series of facts which I hold to be of great importance for a deeper insight into the essence of muscular contractility, in so far as they prove the existence of certain material dispositions and processes (admitting of closer experimental examination), by means of which mechanical work may be generated in the muscle by chemical energy.

[1] In the thermal contraction of tendons and strings I have not yet been able to convince myself of a decrease in volume.

THE SNAIL FAUNA OF THE GREATER ANTILLES.

THE West Indian Archipelago has long been known to present some interesting problems in the distribution of its land fauna. These peculiarities, it will be remembered, led Wallace to infer the previous existence of a land connection of the greater islands with one another and with the mainland; while others have claimed that the islands have always been distinct, and have been colonised by the agency of currents, winds, and other indirect means of dispersal. An interesting contribution on this subject has recently appeared in the form of a study of the distribution of the West Indian land and fresh-water molluscs, by Mr. C. T. Simpson, of the U.S. National Museum, from whose paper we extract the following conclusions. A considerable portion of the land snail fauna of the Greater Antilles seems to be ancient and indigenous. There appears to be good evidence of a general elevation of the Greater Antillean region, probably some time during the Eocene, after most of the important groups of snails had come into existence. At this time the larger islands were united, and were connected with Central America by way of Jamaica and possibly across the Yucatan Channel. There was then a considerable exchange of species between the two regions. At some time during this elevation there was probably a landway from Cuba across the Bahama plateau to the Floridean area, over which certain groups of Antillean land molluscs crossed. The more northern isles of the Lesser Antilles, if then elevated, have probably been since submerged. After the period of elevation there followed one of general subsidence, and first Jamaica, then Cuba, and afterwards Haiti and Puerto Rico were separated. The connection between the Antilles and the mainland was broken, and the Bahama region, if it had been previously elevated above the sea, was submerged, the subsidence continuing until only the summits of the mountains of the four Greater Antillean islands remained above the water. Then followed another period of elevation, which has lasted no doubt until the present time, and the large areas of limestone uncovered (of Miocene, Pliocene, and post-Pliocene age) in the Greater Antilles have furnished an admirable field for the development of the groups of land snails that survived on the summits of the islands. The Bahamas and the Lesser Antilles were subsequently raised above the surface, and have been colonised by forms chiefly drifted in the former case from Cuba and Haiti, and in the latter case from South America, while a few stragglers have been carried by sea no doubt from the Greater Antilles, and have settled on the more northern of the Windward Islands.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A DEPUTATION from the Association of Head Masters of Higher-Grade and Organised Science Schools was received on Thursday last, by Mr. Acland, at the offices of the Science and Art Department; Major-General Sir John Donnelly being present at the interview. The deputation was the outcome of a very large and representative meeting of the association, held at Derby, to consider the new rules for organised science schools lately issued by the Department. The importance of the new regulations lies in the fact that under them a system of secondary schools will be inaugurated and carried on under the control of, and supported to a great extent by, the Science and Art Department. The organised science schools at present in existence include nearly all the more important higher-grade schools, the day schools of technical institutions, and a considerable number of grammar schools. The principal changes proposed in the new rules are the partial substitution of inspection for examination, the introduction of special courses of instruction for women students, the inclusion of a fair proportion of literary work in the curriculum, and the addition to it of practical work in physics and biology. A long discussion, lasting over two hours, took place, at the end of which Mr. Acland stated that he hoped to be able to meet the wishes of the deputation with regard to many of the points raised, and promised, at the end of a week or ten days, to make a definite statement of the alterations the Department would be prepared to make.

GEOMETRICAL Drawing has hitherto been included in Science Subject I. (Practical, Plane, and Solid Geometry) of the Science and Art Department. It has just been decided, however, to make Geometrical Drawing a separate subject under the Art portion of the Department's Directory; so the syllabus of the Elementary Stage of Science Subject I. will in future include only plane geometry, solid geometry, and graphic arithmetic. The changes will come into force for the session 1895–96.

THE Senate of Glasgow University have resolved to confer the degree of Doctor of Laws on the following:—Sir John Neilson Cuthbertson; Mr. James G. Fraser, Fellow of Trinity College, Cambridge; Mr. W. E. H. Lecky; Mr. David Robertson, Millport; Dr. T. E. Thorpe, F.R.S.; Surgeon-Major Lawrence A. Waddell, I.M.S., Bengal.

THE ninth Session of the Edinburgh Summer Meeting is arranged to take place in August. Prof. Geddes and Mr. William Sharp lecture in the section of Philosophy, Social Science, and Anthropology; and the prospectus also includes the names of M. Demolins, editor of the *Science Sociale*, of Dr. Wenley, Dr. Delius, and others. Under Civics and Hygiene are the names of Dr. Dyer, M. Paul Desjardins, M. Elisée Reclus, Dr. Irvine, Miss Jane Hay, and Dr. Stephens. Mr. Goodchild and Mr. Herbertson undertake the department of Geography in its widest sense; while Mr. J. Arthur Thomson and Mr. Turnbull have charge of the Biology. There will be many other features of interest, including a series of educational conferences.

THE Professorship of Natural History at the Royal Agricultural College, Cirencester, rendered vacant in December last by the death of Prof. Harker, has now been filled by the appointment of Mr. Theodore T. Groom, late Scholar of St. John's College, Cambridge, and Lecturer and Demonstrator at the Yorkshire College, Leeds. Mr. Groom at one time occupied the Cambridge table at the Zoological Station, Naples, where he successfully carried out some valuable researches, the results of which were communicated to the Royal Society of London, and published in their *Philosophical Transactions*. The chair of Natural History at the College has been filled by a succession of very able men, among whom, in addition to Prof. Harker, may be mentioned such names as Buckman, McNab, and Thiselton-Dyer.

SCIENTIFIC SERIALS.

American Journal of Science, March.—The Appalachian type of folding in the White Mountain Range of Inyo County, California, by C. D. Walcott. In the broad palæozoic area between the Sierra Nevada on the west and the early palæozoic shore-line on the east (Colorado) a period of folding and thrust-faulting was followed by a period of vertical faulting, which displaced the strata that had been folded and faulted in the preceding epoch. The extent and character of this disturbance can only be determined by a careful study of each of these mountain ranges for a distance of over five hundred miles east and west, and probably one thousand miles north and south.—The succession of fossil faunas at Springfield, Missouri, by Stuart Weller. The rocks studied are beds of grey limestone with lenticular chert concretions, and form part of the Mississippian series. The faunas of the lower part of the section may be correlated with the Burlington faunas of Iowa, and those of the upper part with the Keokuk faunas. The whole series of faunas is continuous, and the whole series of rocks should be designated by a single name. The term Osage, suggested in 1891 by H. S. Williams, is recommended.—Drift boulders between the Mohawk and Susquehanna rivers, by A. P. Brigham. The Archæan and the more northern Palæozoic fragments are strewn over the whole district at all altitudes, but diminishing southward in size, and sparse in amount on the highest hills, especially to the southward, where the tops of the ranges are often surprisingly free from transported material. Actual reduction of the general surface towards base level doubtless proceeded rapidly during glacial time, but even then the process was rapid only in the geological sense, and the result a minute fraction of what has been accomplished since the region became a land surface.

Bulletin of the American Mathematical Society, vol. i. 5. (New York, February 1895.)—On a certain class of canonical forms, by Mr. R. A. Roberts, is a paper, read before the Society at its December meeting, which treats of an interesting class of theorems occurring in the consideration of algebraical quantics.—"Hayward's Vector Algebra" is a review, by Prof. M. Böcher, of the algebra of coplanar vectors and trigonometry, which deals out praise and its opposite in about equal proportions.—Apolar triangles on a conic is a very interesting paper by Prof. F. Morley.—The remaining short notices comprise an instance where a well-known test to prove the simplicity of a simple group is insufficient, by G. H. Miller, and an account of the Lobachevsky Memorial Volume, 1793–1893. Amongst the notes is a bare statement of Prof. Cayley's death.—The usual new publications list concludes the number.

Symons's Monthly Meteorological Magazine for March contains another striking proof of the severity of the frost in February last, as shown by the temperature of the earth at Camden Square, in the north-west of London. The thermometer with its bulb one foot below the surface was first read on January 1, 1871. Prior to 1895, it was never below 32°, and only reached that point in 1880. But in February last there were twelve consecutive days on which the thermometer was below 32°. In country districts, the frost penetrated to a much greater depth, and this subject will probably be referred to in a future number of the magazine. A careful observer at Berkhamsted states that the frost there penetrated to a depth of 1 foot 8 inches.

Internationales Archiv für Ethnographie, Band. vii. Heft v. and vi. 1894.—Prof. H. H. Giglioli, in his "Notes on some remarkable Specimens of Old Peruvian 'Ars Plumaria,'" gives a description of two very fine head-dresses in Ancient Peruvian feather-work, which are illustrated by a beautifully executed coloured plate. It is strange, as the author points out, "that the specimens of old Peruvian 'ars plumaria' unearthed from the hundreds of huacas, excavated but too often by vandalic treasure-seekers, have not attracted more attention." The best specimens of feather-mosaic were made in the sixteenth and seventeenth centuries, and the art has now practically died out.—Mr. S. H. Ray abstracts and annotates "Some Notes on the Tannese," by Rev. W. Gray. Mr. Gray has been a missionary in Tanna for twelve years, and so he can speak from adequate personal knowledge; he gives information on dress, circumcision, political organisation, war, kava, religion, social organisation and marriage, the calendar, the winds, and language. This is a valuable supplement to Dr. Codrington's monograph; the section on religion is of especial value. Dr. H. Ten Kate describes and illustrates a collection of ethnographical objects from the Timor Group. The supplement to vol. vii. of the *Archiv* is an account of the Năng, or the Siamese shadow-figures in the Völkerkunde Museum in Berlin, by Dr. F. W. K. Müller. A transcription and translation (in German) of the rhymes of the drama is given, which is a fragment of the Râmâjana. It is illustrated by eleven plates, eight of which are coloured. Vol. viii. commences with the conclusion of Dr. Ten Kate's paper, which is illustrated by four plates. This part is of more general interest, as it deals partly with the religion and the sacred animals of the Timorese and other Indonesians; the author agrees with Pleyte, that the snake cult is indigenous to Indonesia, and is not borrowed from India. There is a useful little table of the distribution of certain objects.—S. K. Kusnezow writes on the death-cult of the Tscheremisse (a Ural-Altaiic people on the Volga, near Kazan). These numbers of the *Archiv* contain the usual valuable notes and bibliography.

SOCIETIES AND ACADEMIES.

London

Royal Society, January 17.—"On Slow Changes in the Magnetic Permeability of Iron." By William M. Mordey.

The conclusions to which the observations lead, so far as they have gone, are:—

(1) The effect is not fatigue of the iron caused directly by repeated magnetic reversals—it is not "progressive magnetic fatigue."

(2) Neither magnetic nor electric action is necessary to its production.

(3) It is a physical change resulting from long-continued heating at a very moderate temperature.

(4) It appears to be greater if pressure is applied during heating.

(5) It is not produced when the iron is not allowed to rise more than a few degrees above the ordinary atmosphere.

(6) It is similar to the effect produced by hammering, rolling, or by heating to redness and cooling quickly.

(7) The iron returns to its original condition on re-annealing.

(8) It does not return to its original condition if kept unused and at ordinary atmospheric temperatures, whether the periods of rest are short or long.

March 7.—"The Action of Heat upon Ethylene, II." By Prof. Vivian B. Lewes.

From the results of the experiments described in the paper it is stated that:—

(1) The initial decomposition of ethylene by heat is very rapid, and requires but a short flow through a heated containing vessel, such primary decomposition, however, being but slowly completed, owing to secondary reactions, which tend to reform ethylene.

(2) Dilution has but little effect in retarding the decomposition of ethylene, unless it be very large.

(3) Increase in rate of flow diminishes the amount of decomposition when the heated area is small, but rapidly diminishes in effect as the length of flow through a heated area increases.

(4) The decomposition of ethylene is chiefly caused by radiant heat, the effect of which is very great as compared with the decomposition due to contact with heated surfaces.

March 21.—"The Cause of Luminosity in the Flames of Hydrocarbon Gases." By Prof. Vivian B. Lewes.

The facts which appear to be established in this paper are:—

(1) That the luminosity of hydrocarbon flames is principally due to the localisation of the heat of formation of acetylene in the carbon and hydrogen produced by its decomposition.

(2) That such localisation is produced by the rapidity of its decomposition, which varies with the temperature of the flame and the degree of dilution of the acetylene.

(3) That the average temperature of the flame due to combustion would not be sufficient to produce the incandescence of the carbon particles within the flame.

In a paper on the action of heat upon ethylene, brought before the Royal Society this spring, the author showed that the decomposition of ethylene into acetylene and simpler hydrocarbons was mainly due to the action of radiant heat, and was but little retarded by dilution, whilst he has shown in this paper that the acetylene so produced requires a considerable increase in temperature to bring about its decomposition when diluted, and it is possible with these data to give a fairly complete description of the actions which endow hydrocarbon flames with the power of emitting light.

When the hydrocarbon gas leaves the jet at which it is being burnt, those portions which come in contact with the air are consumed and form a wall of flame which surrounds the issuing gas. The unburnt gas in its passage through the lower heated area of the flame undergoes a number of chemical changes, brought about by the action of radiant heat emitted by the flame walls, the principal of which is the conversion of the hydrocarbons into acetylene, methane, and hydrogen. The temperature of the flame quickly rises as the distance from the jet increases, and a portion of the flame is soon reached at which the heat is sufficiently intense to decompose the acetylene with a rapidity almost akin to detonation, and the heat of its formation, localised by the rapidity of its decomposition, raises the liberated carbon particles to incandescence, this giving the principal part of the luminosity of the flame; whilst these particles, heated by the combustion of the flame gases, still continue to glow, until finally themselves consumed, this external heating and final combustion adding slightly to the light emitted.

Any unsaturated hydrocarbons which have escaped conversion into acetylene before luminosity commences, and also any methane which may be present on passing into the higher temperatures of the luminous zone, become converted there into acetylene, and at once being decomposed to carbon and hydrogen, increase the area of the light-giving portion of the flame.

"On the Changes in Movement and Sensation produced by Hemisection of the Spinal Cord in the Cat." By C. D. Marshall.

"On the Analysis of Voluntary Muscular Movements by certain new Instruments." By Dr. W. R. Jack.

"On the Spark Spectrum of Argon as it appears in the Spark Spectrum of Air." By Prof. W. N. Hartley, F.R.S.

Chemical Society, March 7.—Dr. Armstrong, President, in the chair.—The following papers were read:—Dimethylketohexamethylene, by F. S. Kipping. This substance is a colourless oil boiling at 174–176°, and is prepared by distilling calcium αα'-dimethylpimelate with soda-lime.—The use of barium thiosulphate in standardising iodine solution, by R. T. Plimpton and J. C. Chorley. Barium thiosulphate, BaS_2O_3, H_2O is well adapted for standardising iodine solution, inasmuch as it keeps well, has a high molecular weight, and is readily acted on by iodine.—The melting points of racemic modifications and of optically active isomerides, by F. S. Kipping and W. J. Pope. Dextro-rotatory and racemic π-monobromocamphor melt at the same temperature, and the melting point of the one is not depressed by the presence of the other isomeride; the same is true of the inactive and dextro-rotatory π-monochlorocamphors.—Phenyl ethers of methylene- and ethylene-glycols. Synthesis of α-methylbutyrolactone, by E. Haworth and W. H. Perkin, jun. A number of phenyl ethers of methylene- and ethylene-glycol have been obtained by the use of sodium phenate; α-methylbutyrolactone has been synthesised from ethylic sodiomethylmalonate.—Methylisobutylacetic acid, $CHMe_2.CH_2.CHMe.COOH$, by W. H. Bentley and M. W. Burrows. This acid was prepared by the distillation of methylisobutylmalonic acid, which in turn was synthesised from ethylic sodiomethylmalonate and isobutyl bromide.

Geological Society, March 6.—Dr. Henry Woodward, F.R.S., President, in the chair.—A new ossiferous fissure in Creswell Crags, by W. L. H. Duckworth and F. E. Swainson. The fissure explored by the authors is about 30 feet above the level of the artificial lake at Creswell Crags. At the top occurred a white earth (with human and other remains) passing down into a red sand with remains of fox, badger, roe-deer, and other mammals. Beneath the latter deposit, and separated from it by a fairly sharp line of demarcation, came the cave-earth proper with palæolithic implements and bones of *Rhinoceros tichorhinus*, *Bison priscus*, *Ursus spelæus*, *Hyæna*, *crocuta* var. *spelæa*, and *Cervus tarandus*. The authors suppose that this cave-earth was derived from an older deposit, and had been transported to its present place by water, though there is evidence that the transport had been from no great distance. Consequently they followed the fissure inwards, until brought to a stop by a mass of travertine, which they penetrated with a small hole. They hope to explore the fissure beyond this travertine on a future occasion.—Notes on the chemical composition of some oceanic deposits, by Prof. J. B. Harrison and A. J. Jukes-Browne. The authors formerly experienced great difficulty in comparing their analyses of the oceanic deposits of Barbados with those of modern oozes made by Dr. Brazier. Since then Dr. Murray has placed samples of recent red clay and *Globigerina*-ooze at their disposal, and these were analysed by Prof. Harrison and Mr. John Williams. The results of analysis of the red clay were arranged as follows:—Argillaceous constituent 67·85 per cent., pumiceous matter 23·26 per cent., organic constituents 5·88, and adherent sea-salts 3·61 per cent. The authors found that the argillaceous constituent was not a mixture of an orthosilicate of alumina and hydrated peroxide of iron, having the proportion of silica to alumina as 14 to 12, but a more highly silicated compound in which the proportions were as 33 to 12. It was in fact a ferruginous earth, such as would result from the decomposition of palagonite and of a basic volcanic glass, fragments of which were frequent in the Pacific red clays. The pumiceous matter was the débris of an acid pumice containing 7 per cent. of soda, and apparently therefore the pumice of a soda-felsite. Comparing the analyses of the recent red clay with those of Barbadian red clays, they find the differences to be such as would result from mixtures of the palagonitic earth with various acid and basic pumices. A mixture of the palagonitic earth with the pumiceous dust which fell on Barbados in 1812 would have a composition closely corresponding to that of the oceanic clay of Barbados. The recent calcareous ooze closely resembled the more calcareous "chalks" of the Barbadian oceanic series, but the latter contained much colloid silica and fine clay. The differences between the analyses of the recent ooze and of English chalk, when certain allowances are made, were found to be but small. The recent calcareous ooze contained many more *Globigerina*-tests than tertiary or mesozoic chalks, but it is suggested that this is due to our possessing only the surface-layers of the *Globigerina*-ooze. In one important respect all the different kinds of deposit which were examined resembled one another, namely, in the infinitesimally small quantity of quartz which they contained. The authors' examination of the recent oceanic deposits, and a comparison of them with the raised Barbadian deposits, only increased their conviction that the latter were of truly oceanic origin.

Linnean Society, March 7.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. A. Henry was admitted a Fellow.—On behalf of Sir Joseph Hooker, the Secretary exhibited a bronze medal struck in honour of the late Alphonse de Candolle.—Mr. J. E. Harting exhibited a remarkable head and horns of *Cupra ægagrus* recently obtained by Mr. F. C. Selous in Asia Minor, and made remarks on the geographical distribution of this and other allied species.—Mr. G. F. Scott Elliot, who had been absent from England since September 1893, on a botanical exploration of Mount Ruwenzori and the country to the north of the Albert Edward Nyanza, gave an account of his journey and of the results, geographical, botanical, zoological, and political, obtained by him. The country lying north-east of the Victoria Nyanza was described as a large, rolling, grassy plain, some 6000 feet above sea-level, and well adapted for colonisation. He went west from the Victoria Nyanza to Mount Ruwenzori, which is said to have an altitude of 18,000 feet, and spent four months in exploring that district under the great disadvantage of a dense cloud hanging over the mountain the greater part of the day, which often prevented the party from seeing more than fifty feet ahead. The sides of the mountain were clothed at the base with a thick growth of trees resembling the laurel of the Canary Islands; above that, bamboos to the 10,000-feet level; and above that again what the explorer could only liken to a Scotch peat moss in which the traveller sank at every step a foot or more. Large trunks like those of *Erica arborea* of the Canary Islands, but indicating trees 80 feet high, were noticed. Amongst other plants found were a *Viola*, a *Cardamine*, a gigantic *Lobelia*, attaining a height of five or six feet, and a species of *Hypericum* resembling that found in the Canaries; indeed, the similarity of the flora to that of the Canary Islands was remarkable. Mr. Scott Elliot ascended Mount Ruwenzori to the height of 13,000 feet, finding evidence of animal life and numerous insects to a height of 7000 feet. Above 10,000 feet his Swahili porters could not sleep without injury to their health, and it was only with a reduced number of men that he was able to ascend another 3000 feet. Amongst the animals specially mentioned was a species of water buck (*Cobus*), a new chameleon, a new snake, and several new insects.—The Secretary then read an abstract of a paper by Dr. Maxwell T. Masters, on the genus *Cupressus*, illustrated by a number of plants and cuttings which had been forwarded by Messrs. Veitch, Mr. Moore, of Glasnevin, and Dr. Acton, of Kilmacurragh.—Dealing with the zoological collections made during the recent expedition of Mr. Theodore Bent to Southern Arabia, Messrs. Kirby, Gahan, and Pocock presented papers on the insects and arachnida which had been obtained, some of which were described as new.

Royal Meteorological Society, March 20.—Mr. W. N. Shaw, F.R.S., delivered a lecture on "The Motion of Clouds considered with reference to their mode of formation," which was illustrated by experiments. The question proposed for consideration was how far the apparent motion of cloud was a satisfactory indication of the motion of the air in which the cloud is formed. The mountain cloud cap was cited as an instance of a stationary cloud formed in air moving sometimes with great rapidity; ground fog, thunderclouds, and cumulus clouds were also referred to in this connection. The two causes of formation of cloud were next considered, viz. (1) the mixing of masses of air at different temperatures, and (2) the dynamical cooling of air by the reduction of its pressure without supplying heat from the outside. The two methods of formation were illustrated by experiments. A sketch of the supposed motion of air near the centre of a cyclone showed the probability of the clouds formed by the mixing of air being carried along with the air after they were formed, while when cloud is being formed by expansion circumstances connected with the formation of drops of water on the nuclei to be found in the air, and the maintenance of the particles in a state of suspension, make it probable that the apparent motion of such a cloud is a bad indicator of the motion of the air. After describing some special cases, Mr. Shaw referred to the meteorological effects of the thermal disturbance which must be introduced by the condensation of water vapour, and he attributed the violent atmospheric disturbances accompanying tropical rains to this cause. The difference in the character of nuclei for the deposit of water drops was also pointed out and illustrated by the exhibition of coloured halos formed under special conditions when the drops were sufficiently uniform in size.

PARIS.

Academy of Sciences, March 18.—M. Marey in the chair.—Attempts to produce chemical combinations with argon, by M. Berthelot. Argon has been submitted to the action of the silent discharge under the conditions described in the author's "Essai de Mécanique chimique," t. ii., pp. 362–363. The apparatus used was that described in the "Annales de Chimie et de Physique" [5], x., pp. 79, 76, and 77. With benzene vapour, argon is absorbed though more slowly than nitrogen. 87 per cent. of the volume of argon employed in the experiment entered into combination. As the total volume of argon at disposal was but 37 c.c., the products were too small in quantity to allow of any extended investigation into their nature. They appear to be similar in character to the products obtained with nitrogen and benzene. A yellow, resinous, odorous substance condensed on the surface of the two glass tubes; this substance decomposed on heating, yielding an abundant carbonaceous residue and volatile products which reddened litmus paper.—On the lacunæ in the zone of small planets, by M. O. Callandreau.—Transformations of fibrin by the prolonged action of dilute saline solutions, by M. A. Dastre.—On the variations of terrestrial latitudes, by M. F. Gonnessiat.—On the theory of a system of differential equations, by M. A. J. Stodolkievitz.—On a general definition of friction, by M. Paul Painlevé.—On Fourier's problem, by M. Le Roy.—Absorption of light in uniaxial crystals, by M. G. Moreau. The symmetry of uniaxial absorption is not so complete as the theory of the ellipsoid of absorption indicates. The dissymmetry is greater as the crystal is more birefringent.—On the potential of an electrified surface, by M. Jules Andrade.—Apparatus imitating the movements executed by certain animals in turning round without external fulcra, by M. Edm. Fouché. The explanation of the movements of a cat, enabling it to always fall on its feet, given by M. Guyou, is completely borne out by the successful reproduction of the rotatory movement with a strictly mechanical model.—The catoptric and symmetrical objective, by M. Ch. V. Zenger.—On a class of secondary batteries, by M. Lucien Poincaré. The author describes a secondary battery with mercury for poles and sodium iodide in concentrated solution for electrolyte. The mercury iodide formed remains in solution, and the sodium forms an amalgam with the mercury. On discharge the yield is more than 90 per cent. of the theoretical. The battery is not affected by short circuiting or the particular manner of its discharge, but is unlikely to be practically used on account of the expensive nature of the materials, and the necessity of removing the amalgam from contact with the liquid if the battery is to remain long charged.—On the effect of an alternating electromotive force on the capillary electrometer, by M. Bernard Brunhes.—Thermochemical carbon battery, by M. Désiré Korda. By the action of carbon on barium peroxide during the reduction of the latter to monoxide, an E.M.F. of nearly 1 volt is produced when arranged as a cell. In the case given an internal resistance of 13·6 ohms was found. A similar arrangement with copper peroxide, the latter being separated from the carbon pole by dry, pure potassium carbonate, gave 1·1 volt with an internal resistance of 3·2 ohms.—Action of nitrous oxide on metals and metallic oxides, by MM. Paul Sabatier and J. B. Senderens. A table is given showing the comparative reactions of N_2O, NO, and NO_2, and air on a series of metals and oxides. The deduction is drawn that oxidations by means of N_2O are caused by the direct action of this gas without preliminary decomposition into its constituents.—Researches on the heats of combination of mercury with the elements, by M. Raoul Varet.—On the isomeric states of the oxides of mercury, by M. Raoul Varet. It is shown that yellow and red oxides dissolve in dilute HCN with liberation of the same amount of heat, and hence the transformation of yellow into red oxide gives no appreciable thermal effect.—On the heat of formation of some compounds of iron, by M. H. Le Chatelier.—On the chlor-aldehydes, by M. Paul Rivals. A thermochemical paper.—On a mercuric combination of thiophene, permitting the estimation of the latter in commercial benzene and its extraction therefrom, by M. G. Denigès. A very stable combination of mercury and thiophene, having the composition $(SO_4Hg.HgO)_2SC_4H_4.H_2O$, is obtained by treatment of thiophene with an acid solution of mercuric sulphate (made by dissolving fifty grams of mercuric oxide in 200 c.c. of pure sulphuric acid diluted with a litre of distilled water). On account of its insolubility and ease of formation, this compound may be used for the detection of traces of thiophene in benzene and for the purification of benzene.—On the amorphous state of melted substances, by M. C. Tanret.—Derivatives of active α-hydroxybutyric acid, by MM. Ph. A. Guye and Ch. Jordan. A paper giving optical rotations and products of asymmetry.—The production of wine and the utilisation of fertilising principles by the vine, by M. A. Muntz.—On the decortication of wheat, by M. Balland.—On the parts taken respectively by purely physical and by physiological actions in the disengagement of carbonic acid by muscles isolated from the body, by M. J. Tissot.—Therapeutic action of currents of high frequency (autoconduction of M. d'Arsonval), by MM. Apostoli and Berlioz. These currents have a powerful influence on the nutritive activity of the tissues, and hence are of first importance in the treatment of many functional troubles, caused by defective nutrition.—New application of the graphic method to music, by MM. A. Binet and J. Courtier.—Histological researches on the development of the Mucorini, by M. Maurice Léger.—On the geology of Ossola (*Alpes Lépontines*), by M. S. Traverso.—On an application of photography to oceanography, by M. J. Thoulet.

VERWORN ON GENERAL PHYSIOLOGY.

Allgemeine Physiologie. Ein Grundriss der Lehre vom Leben. Von Max Verworn. (Jena: Fischer, 1895.)

THIS handsome and well-illustrated volume of some six hundred large octavo pages, by a young German physiologist already favourably known by his special researches, is ambitious in design but praiseworthy in purpose. The author complains of the too narrow character of most of the physiological inquiries and writings of the present time; and not without some justice. A cursory reader of a modern text-book of physiology (of my own, for instance), might easily come to the conclusion that most of our current physiological doctrines had been arrived at by the exclusive study of the frog, the rabbit, and the dog, with occasional help from that of the horse, of a fish, of a bird, and of man. All the wealth of opportunity for observation and experiment offered by the innumerable other forms of life, seems to be neglected. And there follows naturally the inference that physiology would gain a healthier tone and broader grasp, by widening the field of its study. Years ago the great Johannes Müller, in his immortal work, took such a broad survey; later on, Carpenter followed the same course in his "Comparative Physiology," a work to which I, at least, owe much; and now Dr. Verworn attempts to present, in a general view, the light which the multitudinous special researches of more recent days have shed on the fundamental phenomena of life.

A very little reflection will show that when the meaning of the term physiology is carried beyond the bounds which academic conditions have fixed for it, it becomes difficult to say what parts of the knowledge of living beings are not embraced by it. A physiologist, withdrawing himself from the immediate demands of the schools, and brooding over the many aspects of his science, cannot help feeling that all inquiries into the phenomena of life end by taking the form of physiological inquiries. While morphological facts may in the first instance, and for a while, be regarded by him chiefly as helps towards the solution of special physiological problems, he cannot help believing that the ultimate interpretation of the phenomena of form must be based on the principles of that fundamental physiology, which, for want of a better word, we may call molecular. And, even at the present time, imperfect as physiology as yet is, some of us may think that some modern morphological speculations have gone astray, through heed not being given to what even a narrow imperfect physiology is already able to teach.

Hence, Dr. Verworn, taking as the title of his book "General Physiology," has naturally been led to dwell on many topics which are not to be found in a treatise of narrower scope. After a very brief historical sketch, and a chapter on the composition or nature of living matter, in which he discourses on the "cell" and its constituents, and on the physical and chemical properties of living matter, as well as on the differentials of living and lifeless matter, he proceeds to the consideration of the elementary phenomena of life. These he treats under the heads of change of substance (metabolism), change of form, in which such topics as heredity, adaptation, cell division, reproduction and the like are dealt with, and change of energy. Then follows a chapter on "The General Conditions of Life," in which, among other matters, he treats of the origin of life on the globe, and the history of death. "Stimuli and their effects" are next discussed, and the final chapter is headed the "Mechanism of Life."

Even six hundred goodly pages furnish all too small a room for such a treatment of each of the many and varied topics handled in them as would in each case appear adequate to those who had made them the objects of special study. Moreover, the author, as he states in the preface, has striven to write in such a way that the reader should not be easily wearied; and the practised writer knows that a simple way of not wearying the reader is by a light touch, so to brush away all difficulties as to lead the reader to think he grasps clearly that which, in reality, no one truly understands. The author further, as he also states, addresses himself not to physiologists, or even to biologists, exclusively, but also to the cultured general reader; and when a discussion about an abstruse physiological topic has to be so conducted as to please the ear of the cultured general reader, the special physiologist naturally finds the discussion spoiled by things which to him seem essential, being left out, and by things which to him seem unimportant, or even irrelevant, being dwelt upon at length. It would be ungracious, therefore, to find fault with the particular way in which the author handles that or that of the many themes with which he deals. For the same reason, hesitation may be felt in objecting to the prominence given in the work to definitions, some of which a captious critic might urge had something of the mark of barrenness, or to the frequently occurring judicial "summing up" in paragraphs emphasised by spaced type; or to the abundant "generalisations," some of which may be contested, while others appear to draw perilously near to platitudes. The work, as a whole, must commend itself highly to those morphologists who desire to learn the more general and fundamental results of recent physiological inquiry; for the author has woven into his work the very latest news from the physiological laboratory. On the other hand, the physiologist, whose activity has been too much limited to the study, by complicated instruments of precision, of the phenomena of the higher animals, who has moved too exclusively in what some take pleasure in hall-marking as "horological physiology," will largely profit by having his attention directed to the many physiological questions which arise in the course of morphological investigations, started by observations recorded, for the most part, in periodicals or works not falling within his ordinary reading. As especially interesting, perhaps, may be mentioned the chapter on stimuli and their effects, as illustrated by the study of the simplest forms of life, and the discussion on the part played by nuclei in the development of physiological phenomena, in both of which matters the author is able to appeal largely to his own observations. Very suggestive also is the exposition of the doctrine of assimilation and dissimulation and of its applications, which forms a large part of the chapter dealing with "the mechanism of life."

The author claims for his work, that it is essentially an exposition of "cellular physiology." I am myself inclined to think that he exaggerates the value of this point of view. The idea of the cell, important as it has been, and still is, when we deal with the cell as a morphological unit, seems to me of much less importance when we deal with it as a physiological unit. But I pass this over, in order to join issue with the author on two other matters. He speaks "of the impotence of the physiology of to-day, when brought to face the simplest processes of life," and writes as if all the knowledge which, especially during the last thirty years, has been gained by the application of exact physical and chemical methods to the study of the phenomena of life, simply led to the end of a blind alley. He urges that, while we are rapidly approaching perfection in these things, we yet are impotent in face of the deeper problems. He even goes very near repeating the taunt of the Philistine, "With all your boasted progress, you are still unable to tell us *what life is*," with, however, the difference that he uses the taunt in order to incite physiologists to adopt other methods of inquiry. I venture to think that in this the author is quite wrong. Not only has the progress of physiology, due to the use of exact methods, been remarkable during the last half-century or so, but also by those methods we have been drawn measurably nearer the inner and hidden mysteries. To take one instance among many, the application of exact physical methods to the study of muscles, so far from having brought us to a point beyond which we cannot go, seems just now to be opening up the way to fruitful conceptions of the intimate nature of muscular contraction—conceptions which would have been impossible in the absence of the knowledge gained by the graphic method. Two armies, from two different sides—one physical, the other chemical—are attacking that difficult—to some it seems impregnable—fortress. They have already gained many of the outworks; they are pressing on, drawing nearer to each other; and when they touch hands, they will do that which will put to shame all scoffs at their impotence.

Then again, the author finds fault with the preponderant attention given by physiologists to the study of the higher vertebrate animals; he blames them for their comparative neglect of the lower and, especially, of the lowest invertebrate forms. It is not for me, who in my rash youth had wild dreams of building up a new physiology by beginning with the study of the amœba, and working upwards, to say one word against the experimental investigation of the lower forms of life. But experience and reflection have shown me that, after all, the physiological world is wise in spending its strength on the study of the higher animals. And for the simple reason that in these, everything being so much more highly differentiated, the clues of the tangles come, so to speak, much more often to the surface, and may be picked up much more readily. Taking again, as an instance, the molecular processes which give rise to the movements of animals, and which appear under such forms as that of amœboid movement, and that of the contraction of a striated muscle, I venture to think that the very apparent simplicity of the former is an obstacle to our getting a real grasp of its inner nature, and that by our studies of the complex muscle, we are drawing nearer to such a grasp than we could ever have done by observations confined to the phenomena of the amœba itself. And so in many other instances. The study of the lower forms of life is, in reality, more difficult than that of the higher forms; and the latter naturally comes first. At the same time the author will have the sympathy of all, if his contention be limited to the assertion that the full fruition of physiological truth can only be reached by the careful study of all forms of life, whether high or low; this, indeed, his own special investigations have already shown, and in this sense the contribution to a "general physiology," which his present volume offers, is gladly welcomed by us all. M. FOSTER.

NERNST'S THEORETICAL CHEMISTRY.

Theoretical Chemistry, from the Standpoint of Avogadro's Rule, and Thermodynamics. By Prof. Walter Nernst, Ph.D. of the University of Göttingen. Translated by Prof. Charles Skeele Palmer, Ph.D. of the University of Colorado. Pp. xxv.–697. (London: Macmillan and Co. 1895.)

NO one can compare the knowledge we possess to-day of the conditions and general laws of chemical change with the state of our knowledge ten years ago, without being much impressed by the enormous advances made in the last decade. Accurate and generalised knowledge of physical chemistry did not exist ten or twelve years ago. What is practically a new science has arisen, based on the work of such men as Guldberg and Waage, van't Hoff, Ostwald, Arrhenius, Nernst, Raoult, Gibbs, and Thomsen, who built upon the foundations laid by Dalton, Avogadro, Berthollet, Faraday, Helmholtz, Thomson, and Clausius. The special mark of the new science is that it has been produced, to use the words of Nernst, "by the co-operation of two sciences which hitherto have been, on the whole, quite independent of each other." One hardly knows whether to speak of *physical chemistry* or *chemical physics*.

The text-book of this new science is Ostwald's "Lehrbuch der Allgemeinen Chemie." Notwithstanding the thoroughly satisfactory character of that work, there was room for another book which should treat the subject in less full detail, and which should pay especial attention to the data and the conceptions that have been systematised and applied in a general way. Prof. Nernst has written exactly the book that was wanted; and this book now appears in a form which brings it within the reach of all English-speaking students.

The *Theoretical Chemistry* of Prof. Nernst deals with (1) the universal properties of matter, (2) the atom and the molecule, (3) the transformations of matter, and (4) the transformations of energy. The first section treats of (1) the gaseous, (2) the liquid, (3) the solid, state of aggregation, (4) the physical mixture, and (5) dilute solutions. The second section is devoted to (1) the atomic theory, (2) the kinetic theory of the molecule, (3) the determination of molecular weight, (4) the constitution of the molecule, (5) physical properties and molecular structure, (6) the dissociation of gases,

(7) electrolytic dissociation, (8) the physical properties of salt solutions, (9) colloidal solutions, and (10) the absolute size of molecules. Sections three and four are concerned with the subject of affinity. The author treats that part of this subject which is connected with the transformations of matter under the headings: (1) the law of chemical mass-action, (2) chemical statics in (*a*) homogeneous, and (*b*) heterogeneous systems, (3) chemical equilibrium in salt solutions, and (4) chemical kinetics. In dealing with the energetics of chemical affinity, Prof. Nernst treats of (1) the applications of the first law of heat, (2) temperature and (*a*) complete, (*b*) incomplete, chemical equilibrium, (3) temperature and the velocity of reactions, (4) heat and chemical energy, (5) electro-chemistry, (6) photochemistry. An appendix contains accounts of the more important developments of theoretical chemistry in the year 1893.

The ground covered by the book is evidently very large, and very different from that traversed by the books on theoretical chemistry published ten years ago.

Theoretical chemistry, as understood by Nernst, is based on Avogadro's law, and van't Hoff's extension of that law to dilute solutions, the law of mass-action, and the laws of thermodynamics. It would not be very far from the truth to say that the book is concerned with the meaning of the sign of equality in chemical equations, and that the connotation of that sign is elucidated by applications of the laws of Avogadro and van't Hoff, and the law of mass-action, bound together and lighted up by the laws of thermodynamics.

The essential characteristics of the book, so far as I can judge, are the exceeding clearness in the statement of each problem of theoretical chemistry, the cutting out of irrelevant issues, and then the binding together of the apparently detached discussions into an harmonious whole by the application of the general principles of the molecular-atomic theory, and of chemical energetics.

The treatment of *osmotic pressure* may be chosen as an illustration of these characteristics of Prof. Nernst's book. The meaning of the term *osmotic pressure* is made clear on pp. 118–119, by the description of a theoretical experiment on the diffusion of sugar in aqueous solution through a semi-permeable partition fitted with a movable piston. Unfortunately, the translator has rendered *Lösungsmittel* by "solvent material"; had he used the term "solvent" (as he does in some other passages), the meaning would have been better conveyed. Then follow lucid paragraphs on the methods of measuring osmotic pressure (I wish the translator had not allowed the phrase to pass, "ether containing considerable benzene"), admirably illustrating the bearings on this problem of determinations of vapour-pressures, boiling points, and freezing points. Having thus, by adhering strictly to the problem under discussion, arrived at a clear conception of osmotic pressure, the author proceeds, in a few brief and clear paragraphs, to consider the circumstances which condition the osmotic pressures of solutions, viz. the concentration of the solution, the temperature, the nature of the dissolved substance, and the nature of the solvent. The outcome of the matter is then summed up in the statement—*the lowering of the freezing point of a dilute solution is proportional to the number of molecules of the dissolved substance.* This summary at once suggests an inquiry into the range of applicability of the law of osmotic pressure, and the laws of solution in general; and the inquiry leads to a statement of van't Hoff's extension of the law of Avogadro. The experimental determination of molecular weights by the application of the van't Hoff generalisation is described (pp. 224–231) in that part of the book which deals with the determination of molecular weights. When the author comes to treat of dissociation he returns to the subject of osmotic pressure, and shows how an application of the hypothesis of dissociation to salts in dilute aqueous solutions leads to a far-reaching theory of chemical change, and he propounds this theory in a clear and practical manner. In one of the chapters dealing with thermochemistry (pp. 565–567), the author, following van't Hoff, brings the subjects of osmotic pressure and electrolytic dissociation within the range of thermodynamical methods, and, by a fundamental equation, connects the equilibrium of a chemical system with such conditions as temperature, pressure, and dissociation. Had Prof. Nernst been tempted to discuss such a side issue as the part played by the solvent in bringing about electrolytic dissociation, he could not have arrived at the very general results to which his strictly accurate and limited method of inquiry have led him. He does, indeed, devote a paragraph or two to this matter of the action of the solvent (*e.g.* pp. 232, 444). He is careful to note the great interest and importance of the question; at the same time he draws attention to the fact, often overlooked, that no definite answer can be given to questions regarding the existence of compounds of molecules of the solvent with molecules of the dissolved substance by the study of the osmotic pressures of dilute solutions, because the existence of such compounds would not affect the osmotic pressures of fairly dilute solutions.

Prof. Nernst dismisses the so-called *hydrate theory of solution* in a short and somewhat contemptuous paragraph (p. 444); he speaks of this conception as having no theoretical basis, as having led to no general laws, and as based on an uncritical examination of experimental data.

A very admirable feature of the book is the care taken to warn the student against drawing unsound and inapplicable deductions from sound generalisations. For instance, at the beginning of the chapter on the physica properties of salt solutions (p. 331), the statement is enunciated that *the properties of an aqueous solution of a salt are made up, additively, of the properties of the free ions.* And then the illegitimate and misleading inferences which may be, and some of which have been, deduced from this generalisation are noted in a few sentences, before the true meaning and applicability of the statement are developed.

I should like to deal at length with the author's treatment of the law of mass-action, and the many applications and developments of this law; but space forbids. Among the applications of the law of mass-action I would ask the student to note that which serves to explain the discrepancies among the values for the *strengths* of acids obtained by Ostwald by employing different methods of measurement (p. 438).

The volume literally abounds in suggestions; new light is thrown on almost every question of theoretical chemistry. When this book becomes generally known and studied by English chemists, it seems to me it will be impossible for any of them to refuse to acknowledge the marvellous advances which have been made in the science by the introduction of the conception of electrolytic dissociation.

I would recommend every student of advanced chemistry to study this work. Merely to glance through it is little use: it must be studied laboriously; and it will well repay the labour. Of course there are weak parts in the book. I think the treatment of *the constitution of the molecule* is too sketchy; and chapter vi. of Book iv., on *electrochemistry*, should, in my opinion, have been either expanded or omitted.

Of the translation it is difficult to speak advisedly. I think the translator has attempted an impossible task, the task, namely, of literally changing German into English. If the meaning of sentences in one language is to be conveyed in another language, it seems to me that a paraphrase, not a so-called literal translation, is needed. The task of translation must have been extremely difficult; the subject-matter is complicated, and German is not a language distinguished by its lucidity. The meaning of the original is conveyed on the whole; but the sentences read strangely. See, for instance, the most peculiar sentence near the bottom of page 591. There is an extraordinary sentence about plucking fruit from stepping-stones, on p. 354. Several cases of absolute mistranslation are to be found; for instance, the sentence in italics in the ninth and tenth lines from the bottom of p. 254, and the sentence at the beginning of Book iii., p. 353. *Beliebig* is sometimes translated "casual," sometimes "selected."

I admit the great difficulty of the task undertaken by the translator: as I have said, he has generally succeeded in conveying the meaning of the original; but I think the rendering into English might have been at once more accurate, more elegant, and more readable.

M. M. PATTISON MUIR.

OUR BOOK SHELF.

Bird Notes. By the late Jane Mary Hayward. Edited by Emma Hubbard. Pp. 181. (London: Longmans, Green, and Co. 1895.)

Catalogue of the Birds of Prey (Accipitres and Striges). By J. H. Gurney, F.Z.S. Pp. 56. (London: R. H. Porter, 1894.)

A DAINTY book is Miss Hayward's, the pretty little process-blocks, representing a number of our common birds, matching the short sketches of avian habits. The lamented author had a "deep-rooted love of the beauty of the world." She was a close and unwearied watcher of bird traits, and her notes possess the charm of all original observations. From a scientific point of view, the chief failing of many of the notes is that they endow the birds too largely with human consciousness. Mrs. Hubbard recognises the objection, and says something in favour of this "anthropomorphism"; but while such fancies are poetically attractive, and may be psychologically justifiable, they must always be of less value than the facts which give them birth.

The ornithological papers of the late Mr. J. H. Gurney were both numerous and important, and in the volume under notice we have further evidence that the son worthily carries on his father's interest in the collection at Norwich Museum. All the birds of prey (hawks and owls) in the Museum were catalogued by Mr. J. Reeve, the veteran custodian, and from this MS. catalogue, and his father's "List of Diurnal Birds of Prey," Mr. Gurney has compiled the list of Accipitres and Striges. According to the list of the former order, the total number of existing species of diurnal birds of prey is now 470, of which at least 89 are only sub-species. The total number of existing species of owls is placed at 268, of which 87 appear to be only sub-species.

Before each bird's name, in the two lists, a letter is placed to mark the zoological region to which it belongs, on Mr. Sclater's classification. A striking testimony to the efficiency of this system is given by Mr. Gurney, in the following words: "The way in which these several divisions [Mr. Sclater's] are justified by the Birds of Prey, and especially by the Diurnal Birds of Prey, is remarkable, and if they were to be decided afresh by that class of birds alone they could not very well be improved upon. Seven-eighths of the Raptores are found in one region only—*i.e.* not in more than one; and the region which has the greatest number is the Neotropical or South-American region, which contains 181 Hawks and Owls."

The whole of the Raptorial collection of Norwich Museum is now being transferred to Norwich Castle; and the completeness of the collection can be judged from the fact that it comprises 403 out of the total of 470 accepted species and sub-species of Accipitres, and 195 out of 268 known species and sub-species of the order of Striges. Mr. Gurney may well be proud of the collection, and of the fine Castle Museum in which it is housed.

Prince Henry the Navigator. By C. Raymond Beazley, M.A., F.R.G.S. (Heroes of the Nations Series.) (Putnam's Sons).

IN this most interesting and valuable book, Mr. Beazley shows us clearly the growth of geographical knowledge, carrying his researches back earlier even than 130 A.D., he tells us that the first maps and charts of the old world are due to Eratosthenes and Strabo. Ptolemy succeeded them, improved their work, and, where knowledge failed him, made errors himself; the author writes thus of his great chart: "Never was there a clearer outrunning of knowledge by theory, science by conjecture, than in Ptolemy's scheme of the world (*c.* A.D. 130)."

We gather much information concerning Greek and Arabic geographers, of the early Christian pilgrims, and of the discoveries of the Norsemen. Throughout the book, we watch, as it were, the growth and improvements of the maps and charts. We see the expansion of geography due to the crusades and land travel. Finally we are brought to Prince Henry the Navigator himself. From youth upwards, retired and studious, he withdrew himself at the age of twenty-one to his Naval Arsenal at Sagres, and devoted the rest of his life to the accomplishment of his three chief objects—"to discover, to add to the greatness and wealth of Portugal, and to spread the Christian faith." We can but marvel at this great man, at the untiring energy with which he worked, but still more at the greatness of that work.

Mr. Beazley has treated the subject in a very thorough and interesting manner, and the numerous maps form a most important part of the book; they date from 130 A.D.–1492. No pains have been spared to make the subject quite clear to the student. All through the book we see how the dominion of the sea has been continuously enlarged by the perpetual application of science to the art of navigation.

W.

An Elementary Treatise on Theoretical Mechanics. Part iii. Kinetics. By Alexander Ziwet, Assistant Professor of Mathematics in the University of Michigan. (New York: Macmillan and Co., 1894.)

THE first two parts of this excellent treatise have already been noticed in these columns; this third part keeps up to the same excellence, and we look forward to a sequel, in the absence of any indication that the treatise is yet complete.

We think the author would have done well to have followed the opinion of his American colleague, Prof. T. W. Wright, and to have reserved absolute measurements to the Metric system of units, while using gravitation units only with the British foot and pound. These last units are too insular and provincial ever to be employed in cosmopolitan problems where results have to be translated into absolute measure; and James Thomson's word, *poundal*, is never likely to be of any practical use.

Lagrange's and Hamilton's general dynamical equations are expounded with clearness and elegance; the application of the principle of the Conservation of Areas to the paradoxical motion of a kitten, let fall by his feet a short distance above a table, has excited considerable discussion recently at the Paris Academy of Sciences; this problem would provide the author with an illustration of the methods of generalised coordinates.

The copious list of authorities at the end of the chapters is a valuable feature of the book. G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Destruction of the Seismological Observatory at Tokio, Japan.

I REGRET to say that a letter, which has just arrived from Tokio, informs me that Prof. John Milne has lost all his valuable seismographic instruments, with his library and many manuscripts, through a fire which has occurred at his house and observatory. Prof. Milne wishes me to announce that his address-book has been destroyed, but he will be able to forward vol. iv. of the *Seismological Journal* to those entitled to it, if they will send in their names to him, "care of the *Japan Mail* office, Yokohama." He further wishes me to state that he has 600 damaged copies of the Seismological Society's *Transactions*, and that from these he will be happy to complete sets. Applicants for the copies of the *Transactions* should address Prof. Milne, care of the Geological Society, Burlington House, London, W.

I am sure that scientific men all over the world will feel the deepest sympathy with Prof. Milne in his great and, indeed, irreparable loss. He was preparing to return to Europe when the fire occurred, and he wishes to appeal to all who can furnish him with separate copies of papers relating to earthquake phenomena, to replace, so far as is possible, those he has lost by the destruction of his library. JOHN W. JUDD.

April 1.

On Mersenne's Numbers.

IN 1644 the mathematician Mersenne asserted that out of the 56 primes not < 257, there were only 12 primes, viz.:—

$$q = 1, 2, 3, 5, 7, 13, 17, 19, 31, 67, 127, 257,$$

which, taken as *exponent* (q), make the number $N = (2^q - 1)$ also prime. No proof was published, and even up to now, this statement has only been partially verified: the verification is still one of the difficult problems of higher arithmetic. According to a paper by Mr. W. W. Rouse Ball, in the *Messenger of Mathematics*, vol. xx. p. 34, Mersenne's statement has been verified for the 18 prime values of $q < 60$, and for 14 higher values, and one additional number N has been shown to be prime by Prof. Seelhoff, viz. when $q = 61$. This left 23 cases unverified, viz. 3 supposed to be prime (when $q = 67, 127, 257$), and the remaining 20 supposed to be composite (when $q = 71$, 89, 101, 103, 107, 109, 137, 139, 149, 157, 163, 167, 173, 181, 193, 197, 199, 227, 229, 241).

I have recently discovered the verification of one of the latter, viz. that

$$(2^{197} - 1) \text{ is divisible by } 7487.$$

This can be readily verified directly by the method of Congruences.

It has also been verified by actual division by Mr. R. Tucker (Sec. London Mathematical Society), who has kindly sent me the quotient consisting of 56 figures. The mode of *discovery* of this factor has been communicated to the London Mathematical Society, and will be sent to one of the mathematical journals. ALLAN CUNNINGHAM.

Tan-Spots over Dogs' Eyes.

I TRUST you will allow me to point out that the drift of my letter on the above subject in NATURE, vol. l. p. 572, has not been fully apprehended. Hitherto we seem to have no very clear cases in which we can actually trace the operation of "natural selection." I think, when examined, this will be found to be an instance.

The spots appear to have arisen in the dog as comparatively recent permanent markings—for protective purposes—after semi-domestication. As Mr. Worthington G. Smith says, they are not seen among wild animals allied to the dog.

They appear to have arisen since the original Red Dog—be he Dhole, Pariah, or Dingo—became pied, and at times *black*, through domestication. It is only on a black coat that the tan-spots would be conspicuous, and simulate eyes.

Perhaps Mr. A. R. Wallace may throw light on the matter. The spots seem to be the only really permanent marking among dogs, and are now being bred out. S. E. PEAL.

Sibsagar, Asam, February 19.

MR. PEAL's suggestion appears to be a probable one, and is supported by Mr. Worthington Smith's observations (NATURE, vol. li. p. 57). The spots may have been protective to the animals during sleep, causing them to look as if awake. The reason that they do not occur in wild dogs may be that the latter conceal themselves when sleeping, which the half-domesticated animals were not able to do.

ALFRED R. WALLACE.

THE AGE OF THE EARTH.

SINCE physicists do not seem to be in complete accord on the question of the time which has elapsed since the earth first permanently crusted over, it may perhaps be as well to investigate the evidence to be obtained from a study of stratified deposits.

One of the first to raise a remonstrant voice against the philosophers who demanded practically unlimited time was Sir Archibald Geikie, whose original discussion of the data known regarding the present working of rivers gave us the fraction $\frac{1}{6000}$ as representing the annual rate at which the Mississippi is lowering its basin. The surprise with which this result was received is now almost forgotten, in an unquestioning acceptance. The question of the rate of deposition was next treated by Dr. Haughton, in the year 1880, with his usual mathematical severity. Dr. Haughton, however, preferred to take into consideration six other great rivers besides the Mississippi, and thus obtained the fraction $\frac{1}{3090}$ as representing the average thickness of rock which is annually worn away from the terrestrial surface by the denudation of rivers. But the proportion of sea-bottom to land surface is as 145 : 52, so that if the suspended sediment be spread evenly over the sea-floor, the average rate of accumulation will be $\frac{1}{8616}$ of a foot per annum. The maximum thickness of the stratified series was estimated by Dr. Haughton to be 177,000 feet, and thus if the rate of deposition in the past was on the whole uniform and the same as that of the present, this thickness of rock would have required a period of 1,526,750,000 years for its accumulation. Dr. Haughton is not a uniformitarian, consequently he divided this number by 10. Dr. Wallace next made what must be considered a great step in advance, by pointing out that the sediment which is carried into the sea is not deposited uniformly over the whole sea-floor, but, as the *Challenger* dredgings clearly showed, along a comparatively narrow marginal tract. Instead, therefore, of multiplying $\frac{1}{3090}$ (the yearly rate of denudation) by $\frac{52}{145}$, he divided it by $\frac{1}{19}$ (the proportion of the area of maximum deposition to the area of denudation), and thus obtained 28 millions as the number of years required for the accumulation of 177,000 feet of rock.

A further correction was next made by Mr. C. Davison, who showed that the fraction $\frac{1}{3090}$ is obtained by an error in arithmetic, and that the true value is $\frac{1}{2400}$. Introducing this fraction into Mr. Wallace's calculation, we obtain in round numbers 22 millions of years, a close approximation to the result, deduced from physical considerations, by Mr. Clarence King.

Of late years considerable additions have been made to our knowledge of the thickness of the systems of stratified rock, and I present the following table as representing the maximum thickness of all known formations down to the base of the Cambrian, a definite horizon marked, as is well known by the occurrence of fossil remains of most of the great subdivisions of the Invertebrata:—

System.	Thickness in feet.	First appearance of
Cambrian ...	... 16,000	
Ordovician	... 14,000	
Silurian ...	... 14,000	... Fish
Devonian ...	... 20,000	
Carboniferous	... 21,000	... Amphibians
Permian ...	... 12,000	... Reptiles
Trias ...	... 13,000	... Mammals
Jurassic ...	... 8,000	
Cretaceous	... 14,000	
Eocene ...	... 12,000	... Eutheria
Oligocene	... 12 000	
Miocene ...	... 6,000	
Pliocene ...	... 2,000	
	164,000	

The total thickness is 164,000 feet, lying in a fairly continuous series, and calculating by Mr. Wallace's method, this leads to the conclusion that, in round numbers, 21 millions of years have elapsed since the beginning of Cambrian times. The truth of Mr. Wallace's argument depends on the assumption that an area of maximum deposition retains a constant position during the existence of a geological system. This is no doubt approximately the case, but so far as it is not, the deviation from stability will render Mr. Wallace's estimate deficient. On the other hand, as Mr. Wallace himself recognised, the area of maximum deposition does not extend uniformly round the coast line, but is concentrated, if one may so speak, near the mouths of rivers: the effect of taking this into account will far more than compensate for any shifting of the area. It is unnecessary to do more than point out that deposits, where they attain their maximum thickness, are of a more or less deltaic nature, and were probably deposited near the mouth of large rivers, in seas more or less land-locked. From investigations in which I am now engaged, I am led to conclude that where systems attain their maximum thickness, accumulation may have proceeded at the rate of one foot in a century, or even more rapidly.

The question largely depends on the relative size of areas of denudation and deposition: an objector to my estimate may urge that accumulation at this rate involves the existence of areas of denudation of much larger dimensions than the map will find room for. It is worth while to inquire into this, and a single example will suffice. Let us consider the coal measures of the British Isles. Suppose they cover, to the depth of half a mile, a circular area 300 miles in radius, having its centre somewhere over Anglesey, their volume will thus be 141,372 cubic miles; add to this 15,876 cubic miles for the deposits of greater thickness occurring over the North of England, and South Wales and Somersetshire. This gives a total thickness of 157,248 cubic miles. But since the maximum thickness is 12,000 feet, these will have accumulated, according to our assumption of 1 foot in a century, in 1,200,000 years. The coexistent area of denudation affords $\frac{1}{2400}$ of a foot of sediment per annum, or ·00000008 cubic mile per square mile yearly. In 1,200,000 years this will amount to nearly $\frac{1}{10}$ cubic mile per square mile; and thus the 157,248 cubic miles of sediment in the coal measures will have required a land surface 1,572,480 square miles in area for their supply. This will be represented by a circular area with a radius of 707 miles, and that an area of land several times these dimensions may have existed north and west of the British Isles during carboniferous times, is an assertion which most geologists will be prepared to defend.

So far as I can at present see, the lapse of time since the beginning of the Cambrian system is probably less than seventeen millions of years, even when computed on an assumption of uniformity, which to me seems contradicted by the most salient facts of geology. Whatever additional time the calculations made on physical data can afford us, may go to the account of Pre-Cambrian deposits, of which at present we know too little to serve for an independent estimate.

No one can regard without satisfaction the introduction into Lord Kelvin's argument of well-ascertained data as regards the melting points and other properties of rocks. Dr. Joly finds the melting point of basalt to be even lower than that of diabase, viz. 815° C., a result in accordance with that found by other investigators. These facts, though of great assistance in supporting the short chronologists of the earth's age, may prove embarrassing when the question of the physical state of the interior of the earth is ready for reconsideration. Dr. Joly finds the value of dt/dp for basalt to be 0·006, and for diabase, according to Carl Barus, it is 0·021 at 1200° C.; in either case the temperature gradient gains on the melting point gradient rapidly enough to show that, at no great distance beneath the surface of the earth, the interior, if it consist of such rocks as these, is in a state of liquidity. Geologists in general would probably be glad to purchase an internal liquid shell at a cost of several millions of years. Would not, however, the admission of the existence of liquid shells in the interior of the earth, deprive the mathematical argument, as at present formulated, of all validity?

W. J. Sollas.

THE ANNIVERSARY OF THE CHEMICAL SOCIETY.

The anniversary meeting of the Chemical Society was held at the Society's rooms, on Wednesday March 27, when the following officers and Council were elected:—

President, Dr. A. G. Vernon Harcourt, F.R.S. Vice-Presidents (who have filled the office of President), Sir F. A. Abel, K.C.B., F.R.S., Dr. H. E. Armstrong, F.R.S., Dr. A. Crum Brown, F.R.S., W. Crookes, F.R.S., Dr. E. Frankland, F.R.S., Sir J. H. Gilbert, F.R.S., Dr. J. H. Gladstone, F.R.S., Dr. H. Müller, F.R.S., W. Odling, F.R.S., Dr. W. H. Perkin, F.R.S., Lord Playfair, K.C.B., F.R.S., Sir H. E. Roscoe, F.R.S., Dr. W. J. Russell, F.R.S., and Dr. A. W. Williamson, F.R.S. Vice-Presidents Dr. E. Atkinson, Horace T. Brown, F.R.S., Prof. F. R. Japp, F.R.S., Ludwig

Mond, F.R.S., C. O'Sullivan, F.R.S., and Prof. W. C. Roberts-Austen, C.B., F.R.S. Secretaries, J. Millar Thomson, and Wyndham Dunstan, F.R.S. Foreign Secretary, Prof. Raphael Meldola, F.R.S. Treasurer, Dr. T. E. Thorpe, F.R.S. Council, Dr. P. Phillips Bedson, Bennett Hooper Brough, Prof. Harold Dixon, F.R.S., Dr. Bernard Dyer, R. J. Friswell, Otto Hehner, Dr. F. Stanley Kipping, Herbert McLeod, F.R.S., W. A. Shenstone. Dr. Thomas Stevenson, Dr. W. P. Wynne, and Prof. Sydney Young, F.R.S.

Prof. Armstrong, F.R.S., the retiring President, delivered his address, in which he gave an account of the work of the Society during the past year. The Faraday Medal was presented to Lord Rayleigh for the distinguished services he has rendered to chemical science through the discovery of argon. Lord Rayleigh responded in a few words, sharing the honour bestowed on him with Prof. Ramsay. The President then called on Prof. Ramsay, who laid before the Society an account of the discovery of Helium in Clèveite, and on Mr. Crookes, who described it spectroscopically. (These two communications will be found in another column.) In the evening the Fellows and their guests dined together at the Hôtel Métropole. Among those present were:—

Dr. H. E. Armstrong, the Right Hon. Jas. Bryce, M.P., President of the Board of Trade; the Right Hon. A. J. Balfour, M.P., Sir Henry Roscoe, M.P., Mr. A. Vernon Harcourt, Lord Rayleigh, Sir Walter Prideaux, Clerk of the Goldsmiths' Company; Dr. W. J. Russell, Mr. T. F. Blackwell, Master of the Salters' Company; Prof. Odling, Sir Owen Roberts, Mr. Carteighe, Mr. Lavers Smith, Dr. W. H. Perkin, Prof. Thorpe, Dr. J. H. Gladstone, Mr. W. Crookes, Dr. Stevenson, Mr. C. E. Groves, Prof. McLeod, Prof. Percy Frankland, Prof. Rücker, Prof. Dunstan, Dr. Atkinson, Prof. Ramsay, Prof. Emerson Reynolds, Prof. Dewar, Sir H. Gilbert, Prof. Smithells, Prof. Tilden, Dr. Wynne, Mr. Alex. Siemens, Prof. Thomson, Mr. Thiselton-Dyer, Dr. Hugo Müller, Mr. Norman Lockyer, Sir P. Magnus, Prof. Meldola, Dr. W. H. Symons.

A full report of the speeches made at the dinner appeared in the *Times* of the following day, and we are indebted to it for the following extracts:—

In proposing the toast of the Houses of Parliament, the President, Dr. H. E. Armstrong, remarked with reference to argon, that the discovery which Lord Rayleigh and Prof. Ramsay had made was not a chance discovery, but was the outcome of twelve years of hard work on the part of Lord Rayleigh in pursuit of the fourth decimal. The interest in the newly-discovered argon would undoubtedly be an abiding one, and it was believed that its development would be one of the most extraordinary discoveries that had been made in our time. He also referred to the discovery of Helium by Mr. Norman Lockyer, and its recent identification by Prof. Ramsay and Mr. Crookes.

Mr. Bryce, in responding to the toast, said: Physical science, and particularly chemical science, very frequently came in contact with the work of the administrators of the Government, and hardly a day passed by when they were not connected in some way with electricity or chemistry. He had been greatly impressed by the progress made in the quantity of science teaching, which had in some places almost ousted the literary side of teaching. In spite of that large quantity of science teaching, however, the Universities had not yet provided adequate means for the preparation of science teaching; and although there were a great many men teaching scientific knowledge and teaching it well, enough had not been done to give them a systematic training and to make them not only scientific men, but skilful, finished, and experienced teachers of science as a special branch of instruction. A good deal remained to be done in that way.

Mr. Balfour made the speech of the evening in proposing "Prosperity to the Chemical Society." In the course of his remarks, he said: In the last speech to which we listened with so much pleasure, the President of the Board of Trade reminded us that his department—one of the most important departments in the Government—was brought face to face and in the closest relation to science almost every day in connection with one or other of the great practical questions with which it has to deal. Undoubtedly that is so, but I think he will probably agree with me when I say that we politicians—he and I who are engaged in the work of every-day political conflict—cannot boast that we or those whom we represent are in the position of using science as the handmaid of great national purposes, or that we have the power to turn it and direct its great forces whither we will. For my own part, though the last thing I wish to do is to suggest that the work of practical politicians is other than a work which takes the highest qualities of a man, still I have to admit, on looking back on the history of civilisation, that if we want to isolate the causes which, more than any other, conduce to the movements of great civilised societies, you must not look to the politicians of the hour on whom, it may be, all eyes are fixed; you must look to those who, often unknown by the multitude, whose work, it may be, is never properly realised by the men of their country till after they are dead—you must look on them and on their labours to find the great sources of social movements. It is to those who, very often with no special practical object in view, casting their eyes upon no other object than the abstract pure truth which it is their desire to elucidate, penetrate further and further into the secrets of nature and provide the practical man with the material upon which he works—these are the men to whom, if you analyse the social forces to their ultimate units, we owe most, and to produce such men, and to honour such men, and to educate such men, does the Society, whose health I am now proposing, devote its best energies. I do not think, so far as I am acquainted with scientific history, that Englishmen need fear that they have been behind the rest of the world in evolving those root ideas which are the sources of great discoveries, which are themselves great discoveries, and which are, too, the sources and roots of other great discoveries. It may be, however, that though, as a nation, we have been as productive as other nations—I put it modestly—in the men of genius who have made these fundamental discoveries, we have not, as a nation—and I do not think we have—sufficiently realised how great a bearing theory in these modern days must necessarily have upon practice if we are to keep pace with the rest of the world. We have produced great theorists—none greater. We have produced men of great practical genius—none greater. I am not sure, however, that at this moment we are not behind one at least of the great nations of the continent, perhaps more than one, in the art of combining theory and practice—in the art of so welding together in a great organic and self-supporting whole the man of genius, who at one end of the scale discovers a new law of nature, and the man of practice, on the other hand, whose business it is to turn these discoveries to account. I do not venture upon a subject upon which, after all, I am not wholly competent, and I will not develop this subject at greater length; but I should like to do what I can to dispel the prejudice which certainly exists at this moment in certain influential quarters against technical education properly understood. Technical education properly understood, suffers greatly under technical education improperly understood, and there is so much nonsense talked upon this subject, there is so much money uselessly spent, there are so many things taught to persons who do not want to learn them, and which, if they did want to learn them, they could by no possibility turn to practical account, that it is no matter of astonishment that some persons are disposed to say that "technical education is only the last bit of political humbug, the last new scheme for turning out a brand new society; it is worthless in itself, and not only is it worthless, but it is exceedingly expensive." While I think that those who object to technical education have their justification, it yet remains true that if you include, as you ought to include, within the term technical education, the really scientific instruction which would turn scientific discoveries to practical account—if that is what you mean, or what you ought to mean, by technical instruction, then there is nothing of which England has at this moment any greater need, and there is nothing which, if she, in her folly, determines to neglect it, will more conduce to the success of her rivals in the markets of the world, and to her inevitable abdication of the position of commercial supremacy which she has hitherto held. I do not deny that manufactures and commerce have received an immense amount of gain from theoretical investigations, and, as everybody will admit who has even the most cursory acquaintance with, let us say, the history of discoveries in electricity and magnetising power, science has been the means of great gain through industrial development. While both these things are true, I am the last person to deny that it is a poor end, a poor object for a man of science to look forward to of merely making money for himself and other people. After all, while the effect of science on the world is almost incalculable, that effect can only be gained in the future, as it has only been gained in the past, by men of science pursuing knowledge for the sake of knowledge and for the sake of knowledge alone; and if I thought that by anything that had dropped from me to-night I had given ground for the idea that I looked on science from what is commonly called a strictly utilitarian point, that I measured its triumphs by the number of successful companies which it had succeeded in starting, or by the amount of dividends which it gave to capitalists, or even by the amount of additional comfort which it gave to the masses of population, I should greatly understate my thought; but I know that this great Society, while it has in view these useful objects, still puts first of all the pursuit of truth as its object and as the cause to which every man of science pays his devotion. Truth, not profit, must necessarily be the motto of every body of scientific men who desire to be remembered by posterity for their discoveries. These things can be done only from a disinterested motive, and it is because I believe that societies like the great Society I am addressing do more than any other organisation to attain that great object, because I think they bring together men engaged in congenial pursuits, because the stimulus of minds brought close to other minds with honourable motives, and the honourable rivalry of men engaged in the same great task, must lead to an enormous expansion of our knowledge of the secrets of nature, that I, as an outsider, not belonging to your body, but in the name of the public for which I venture to speak, wish you all success and all prosperity.

The President briefly responded to the toast.

Mr. Vernon Harcourt proposed "Learned Societies," coupled with the name of Lord Rayleigh, who briefly responded.

Sir Henry Roscoe proposed "The Visitors," and Sir Owen Roberts and Prof. Rücker responded.

Dr. W. J. Russell proposed "The President," who concluded with the toast of "The Secretaries," coupled with the name of Prof. Thomson.

SIR HENRY CRESWICKE RAWLINSON, BART.

HENRY CRESWICKE RAWLINSON was descended from the family of Rawlinsons who, in the last century, settled down at Chadlington, in the county of Oxford; he was born April 11, 1810, and in 1862 he married Louisa Caroline Harcourt, daughter of Henry Seymour, of Knoyle, Wilts, and he died on March 5 last. At the early age of seventeen he went out as cadet to India, and in a very short time made himself an excellent Persian scholar; in 1833 he was sent to Persia, his fine command of the language of that country, no doubt, influencing his selection by "John Company." For six years he served diligently, and filled many military posts in the great cities of Persia, and he succeeded in infusing something nearly akin to order in the forces of the "King of Kings." In 1839 the relations between England and Persia became "strained," and Rawlinson left the country for Afghanistan; in 1840 he was appointed Political Agent of the Indian Government in Kandahar, a post which he held until 1842. During these years he wielded the sword as often as the pen, and his courage and personal bravery in the field made him a terrible opponent of the wily Afghan. In 1844 he was sent to Bagdad as H.B.M.'s Consul for Turkish Arabia, and in 1851 he was made Consul-General, the importance of Bagdad being, thanks to Rawlinson's labours, fully recognised. In 1855 he was made Crown Director of the East India Company, and in 1856 he was promoted to the dignity of K.C.B.; two years later he was elected Member of the India Council, and in 1859 he was sent to Teheran as Minister Plenipotentiary. He represented in Parliament for a short time (1865–1868) the borough of Frome, but a Member's life offered no attractions to him.

The above brief statement of facts will indicate sufficiently the abilities of Rawlinson, who was a man equally able as a statesman, diplomat, and soldier; but there is yet another side of him of which nothing has been said, and it is that of the scholar. Before Rawlinson had been five years in India, he had read the greater part of the literature of Persia, and he was even at that time (1832) a skilled and fluent talker in Persian; long passages from the finest poets he had learned by heart, and his conversations were so full of extracts from them, that a native once described his talk as "a garden of pearls in metre." From modern Persian to the ancient language is, relatively, but a step, and when Rawlinson found himself in Persia in 1833, he turned his mind to the study of the remains of the kings who had cut their records in the rocks in the cuneiform characters. So far back as 1835, he copied the tablets at Hamadān, and without the help of books, or even any knowledge of the alphabet worked out by Grotefend in 1802, by making the same guesses as Grotefend, he identified correctly the names of Hystaspes, Darius, and Xerxes. In 1836 he collated the first paragraphs of the great Behistun inscription with the tablets at Elwend, and identified the old Persian forms of the names Arsames, Ariaramnes, Teispes, Achaemenes, and Persia; by this time he had made an alphabet of eighteen characters. Early in 1837 he had copied all the other paragraphs of the Behistun inscription, and in the winter of that year he sent to the Royal Asiatic Society his translation of the two first paragraphs which recorded the genealogy and titles of Darius Hystaspes. Without any desire to belittle the work of other investigators, we must say that these would have been inexplicable if the systems of transliteration followed by Grotefend and Saint Martin had been employed, and whatever else may be theirs, Rawlinson's discovery at this period of the phonetic values *kh*, *b*, *m* and *n* is beyond all doubt. About this time he decided that the translation of the Persian cuneiform texts could only be effected by a knowledge of Zend, and he set to work to master the contents of the work of Anquetil du Perron and M. Burnouf's commentary on the Yacna, which was, however, not in his hands until 1838; he obtained some assistance, too, from a priest of Yezd, who translated for him some Zend MSS. In 1838 Rawlinson discovered the phonetic values of *h*, *w*, *i*, *v*, *th* and *jh*, and in 1839 he had practically settled the alphabet, which in all essential points agreed with that of Lassen, published in his *Alt-persischen Keilinschriften*. Here must be noted the fact that Rawlinson never contested the priority of alphabetical discovery with Lassen, even though there is abundant proof that all he owed to Lassen was a single phonetic value; but what he did claim, and claim rightly, was the credit of having translated literally and grammatically two hundred lines of cuneiform writing which contained historical statements of the greatest value, *for the first time*, as early as 1839. In this year, while he was putting the final touches to his work, political necessity caused him to be sent from Persia to Afghanistan, and his studies were so much interrupted during the next five years, that he was unable to publish the result of his labours until 1847.[1]

Meanwhile the mound of Kouyunjik, which marks the site of the palaces of ancient Nineveh, was being explored by Mr. Layard, and the mound of Khorsabad, some few miles off, had begun to yield splendid results to its talented excavator, M. Botta. That Kouyunjik formed part of old Nineveh was always well known, and so far back as 1820 Mr. Rich picked up three fragments of clay tablets inscribed in cuneiform writing. As soon as Rawlinson could obtain copies of the inscriptions dug out by Mr. Layard, he devoted himself to the study of them, and the practical outcome of these labours were his publications:—"A Commentary on the Cuneiform Inscriptions of Babylonia and Assyria; including readings of the inscription on the Nimrud Obelisk, and

[1] In the tenth volume of the *Journal of the Royal Asiatic Society*. (London, 1847.)

a brief notice of the ancient kings of Nineveh and Babylon," London, 1850; and "Outline of the History of Assyria," London, 1852; and "Notes on the Early History of Babylonia," 1854. He had also in 1850 and 1851 revised the "Inscriptions in the Cuneiform Character from Assyrian Monuments," which Mr. Layard published in 1851. Curiously enough, though Rawlinson's translation of the Behistun inscription was accepted generally, there were many, and Sir G. C. Lewis was among them, who stated unhesitatingly that the cuneiform inscriptions had not yet been accurately deciphered, and we owe it to Mr. Fox Talbot that this view was proved to be erroneous. Rawlinson had undertaken to publish a series of cuneiform texts with English translations of the same for the Trustees of the British Museum, and Talbot, having obtained a set of the plates of the text of the great Tiglath Pileser inscription, began to work at an independent translation which, when finished, he sent in a sealed packet to the Council of the Royal Asiatic Society, pointing out that if his own translation and that of Rawlinson, when it appeared, should agree, a strong proof of the accuracy of Rawlinson's system would be established. The Council appointed a Committee consisting of Dean Milman, Whewell, Gardner Wilkinson, Grote, Cureton, and Prof. Wilson as examiners, and they asked Rawlinson, Oppert and Hincks to send in versions of the same inscription by a certain date. Talbot's arrived first, Rawlinson's next, Hincks's next, and Oppert's next; the last two scholars could not, however, translate all the inscription for want of time. The four independent translations[1] were carefully examined, and it was found that they agreed as to general sense in a marvellous manner, and the Committee rightly judged that the decipherment of the cuneiform inscriptions was a *fait accompli;* Rawlinson, however, translated the whole text, while his three competitors left passages here and there unrendered.

In the matter of publication, Rawlinson's greatest work was undoubtedly the "Cuneiform Inscriptions of Western Asia" in five vols. folio, which he prepared for the Trustees of the British Museum; here he supplied material for generations of workers, and gave the proofs of his knowledge and ability in cuneiform matters, which have justly earned for him the title of "Father of Assyriology." Between the years 1858 and 1875 he largely assisted his brother Prof. Rawlinson in his works on Oriental history, and a large share of whatever credit attaches to them is due to him. His last published translation was that of the cylinder of Cyrus, which recorded his conquest of Babylon; it appeared in the *Journal of the Royal Asiatic Society*, new series, vol. xii. (1880) p. 70. As was to be expected, honours were showered upon Rawlinson from all parts of the civilised world. He was elected to a Trusteeship of the British Museum—a much coveted honour—in 1876; Oxford, Cambridge, and Edinburgh gave him honorary degrees; Prussia awarded him the "Ordre pour le Mérite"; and the Academies of other countries elected him to Memberships. In summing up his labours, it is hard to say whether he did most for cuneiform scholarship, or to advance the interests and empire of Her Britannic Majesty in the East. Small-minded men, wishing to lessen Rawlinson's merits, have harped upon the fact that Lassen made his alphabet before Rawlinson; but this he freely admitted, only saying in reply that he never saw it until 1839. That Rawlinson was the first European who translated cuneiform inscriptions, is beyond all doubt, and from first to last, *i.e.* from 1835 to 1895, he exercised a wise and beneficent influence over cuneiform studies which cannot be overrated. His position in Persia gave him unrivalled opportunities, which he used to the best of his ability, and as Consul of Bagdad from 1844 to 1855, his strong but silent power was freely exerted on behalf of Mr. Layard while carrying on his work at Kouyunjik; beyond all doubt is it the fact that he has done more for cuneiform research and excavation than any other man living or dead. It must never be forgotten, too, that he was the only early excavator who had fully qualified himself to understand his work, and of them all he was the only one who could read cuneiform. He was a fine example of the English soldier, now only too rare, for to the bravery of the warrior he added the courtesy of the diplomat, and a wide knowledge of Oriental countries, languages, and history; his modesty was as great as his learning was deep. His ready wit and honest straightforwardness made him a favourite at every Oriental Court, and helped greatly to bring his plans to a successful issue; and his fearless bearing and manly love of warlike exercises attracted to him the admiration of the Indian and Persian soldiers who came in contact with him. His tolerance led men, both in the East and in the West, to confide in him, while his natural good-heartedness often made them like him as much as they trusted him. Other Englishmen have left behind them in the East fame for a certain exploit, or renown as great horsemen, &c., but no man was more feared and liked throughout the East than Henry Creswicke Rawlinson. He was a thorough Englishman, and with him English interests were paramount everywhere; he never forgot, too, in spite of his gracious bearing to all, that he was a trusted servant of the "Right Honourable John Company Sahib Bahadur." Wherever he went he impressed his personality in a marvellous degree, and an idea of the reputation which he left behind him in Bagdad may be gained from the remark which an old native of that city made to a British merchant some years ago. "Sahib, in the days of Rawlinson Sahib, may God lengthen his life, if you had put an English hat on the head of a dog and sent him through the bazaar, the Turks would have made way for him and bowed to him on the right and left as he passed, and now they spit on us as they pass us."

NOTES.

WE are glad to learn that Prof. Huxley is now rapidly recovering from his recent attack of influenza.

REFERENCE was made last week to the activity and great development of the Brooklyn Institute of Arts and Sciences. Among the most successful of its recent enterprises must be counted the establishment of a summer school of biology by the sea. The first session was held in July and August 1890, at Cold Spring Harbour, on the north shore of Long Island, in a building lent by the New York Fish Commissioners. The school annually increased in size and importance, and a specially designed laboratory, capable of accommodating fifty students, was last year opened for work in the same locality. The laboratory is well arranged for the purposes of lectures and practical instruction, and possesses private laboratories for investigators, a library, aquaria with running water, both salt and fresh, boats, microscopes—indeed everything needed to make profitable a summer at the sea-shore. It is impossible to over-estimate the advantages which marine laboratories afford for the purpose of biological instruction; and America may be congratulated upon the successful inauguration of an institution specially adapted to subserve this important end.

WE drew attention a short time ago (NATURE, vol. xlix. p. 597) to the fact that the late Sir W. Macleay had willed to his executors the sum of £12,000, for the foundation of a chair of Bacteriology in the Sydney University. The terms of the bequest provided for a six months' course on the subject, to be binding on every student before being admitted to a science or medical degree at the University. Pending the inability of the Senate to accept, within a month after notice of the legacy, the conditions contained in a memorandum annexed to the will, the legacy was to be void, and the sum given over to the Linnean Society of New South Wales, for the endowment of research in bacteriology. On receiving the money, the senators, the majority of whom are lawyers, have sought a judicial interpretation of the words "six months' course," and have secured the handsome endowment to themselves, on the ruling of Court, for disposal on their own terms. What they will do with it remains to be seen. Sir W. Macleay had been a member of the Senate, and his impression of its conduct may be gauged from the fact that in bequeathing this very legacy he took especial pains to protect his executors against that which he termed "its very uncertain views." In this he has failed! "Sharp practice" may be a conventional, but it is hardly a befitting term for the behaviour of the Senate, which thus expresses the gratitude of a colony for the devotion of a life and fortune to the advancement of science and scientific education.

We understand that the Macleay memorial volume is selling very slowly. Its promoters are considerably to the bad on the undertaking,

Dr. Doberck would be glad if astronomers who notice shooting stars having radiants south of the equator, will send their observations for discussion to the Hong Kong Observatory, where some attention is being paid to southern shooting stars.

General Sir George Chesney, to whom belongs the credit of originating and organising the Royal Indian Engineering College at Coopers Hill, died on Sunday.

Prof. Ludwig Schläfli, the well-known Swiss mathematician, has just died at Berne, at the age of eighty. In 1853 he was appointed professor of mathematics at the University of Berne, where he first acted as *privat-docent*, but some time ago he gave up his post on account of his advanced years.

Messrs. Sotheby, Wilkinson, and Hodge will include the original autograph manuscript of Gilbert White's "Natural History and Antiquities of Selborne" in their sale commencing April 22. Several passages in the manuscript have not been published, and the whole has never passed out of the possession of the lineal descendants of the author.

The Geologists' Association have arranged an excursion to the Tertiary Beds of the Isle of Wight, during Easter, under the direction of Mr. R. S. Herries and Mr. H. W. Monckton. The party will leave London next Thursday, and will return on the following Tuesday.

The Liverpool Marine Biology Committee have appointed Mr. J. C. Sumner, from the Biological Laboratory of the Royal College of Science, South Kensington, as Curator of the Port Erin Biological station.

Dr. Jentink, of Leyden, has recently drawn attention to the scantiness of trustworthy evidence concerning the distribution of the two species of Rhinoceros which inhabit the Malay archipelago. It is sometimes stated that both species (*R. sumatrensis* and *R. sondaicus*) are to be found in Borneo, Sumatra, and Java; but it appears that nothing can be maintained with absolute certainty at present, except that *R. sondaicus* inhabits Java, and *R. sunatrensis* both Sumatra and Borneo. It is clearly desirable that any authentic information bearing upon this point should be brought to light, if yet unpublished.

The Biological and Microscopical Section of the Academy of Natural Sciences of Philadelphia have just sustained a severe loss by the sudden death of Dr. George A. Rex. Dr. Rex was the highest authority an the Myxomycetes in the United States. He was the author of numerous species, which, owing to his extreme conservatism, will doubtless continue to bear his name. Many forms, new to him, remained in his collection unnamed for years, and were only published when he had thoroughly convinced himself that they were really new to science. Although he was interested principally in the Myxomycetes, he was an earnest student of the lower orders of fungi, and an ardent admirer of everything beautiful in microscopic nature.

We have also to record the deaths of a number of other scientific workers in the United States. Dr. Darwin G. Eaton died in the evening of March 17, aged seventy-two. He was prominent as an instructor in the Packer Institute and in the Long Island College Hospital. His works belong chiefly to chemistry and astronomy. He was twice a member of Government parties to observe eclipses of the sun. Dr. P. H. Van der Weyde died a few hours later, on the 18th ult. He was born at Wymeguen, Holland, in 1813, and removed to New York in 1849. He taught in the University of the City of New York, at Cooper Union, and Girard College. Dr. Henry Coppee, acting president of Lehigh University, died March 20, at Bethlehem, Pa., aged seventy-five years. He was elected Regent of the Smithsonian Institution in 1874. Mr. Isaac Sprague, well known as a botanist and artist, and illustrator of botanical works, died at Wellesley Mills, Mass., March 13.

We notice the announcement of the death of Mr. A. G. More, who for many years exercised an influence of a special kind on the zoologists and botanists of Ireland as an authority to whom they implicitly referred questions on the subject of the determination of the species of Irish birds and Irish plants. Under the modest title of "Contributions towards a Cybele Hibernica," in conjunction with the late Dr. David Moore, he published in 1866 an excellent account of the geographical distribution of plants in Ireland. Another good piece of work by him was his list of Irish birds, published in the year 1885, in connection with the collection in the Dublin Science and Art Museum, and in 1887 he published an excellent guide to the Natural History Department of the Museum. He succeeded Dr. Carte as Curator of that department, but illness compelled him to retire in 1887, after twenty years' service.

The annual banquet of the Institution of Civil Engineers took place on Wednesday, March 27, a distinguished company being present. Sir Robert Rawlinson, K.C.B. (the President) occupied the chair, and among the guests were the Duke of Cambridge, the Duke of Teck, the American Ambassador, the Marquis of Salisbury, Sir John Fowler, Sir Frederick Bramwell, Sir Redvers Buller, Mr. C. T. Ritchie, Sir F. A. Abel, Sir George Stokes, Sir Courtenay Boyle, Sir John Donnelly, Mr. Henry Kimber, M.P. (Master of the Merchant Taylors' Company), Dr. Anderson, Sir B. Baker, Mr. C. Barry, Prof. Forbes, Dr. Frankland, Mr. Hawksley, Dr. Kennedy, Sir G. L. Molesworth, Mr. Preece, Mr. Rennie, Prof. Roberts-Austen, Sir David Salomons, Prof. Unwin, Mr. Walmisley, and Mr. Yarrow. The Marquis of Salisbury, in proposing the toast of "The Institution of Civil Engineers," dwelt upon the system of sanitary military reform set on foot by Sir Robert Rawlinson, and which has had such benefical results. He continued:—The system has yet some advance to make, and I hope some day the civil engineers, if the military engineers do not do it, will remove the reproach of typhoid fever from our barracks. But an enormous distance has been traversed by the genius of civil engineers, and by none more than by the President who occupies your chair; and I think it has reacted on civil society. We never really took in hand the sanitation of our civil population until we had been taught by necessity, by the evils attacking our military forces, and the remedies that were adopted, to confront those evils; and the result of the last forty years of sanitary exertion on the part of civil engineers, is one of the most splendid triumphs in the history of any profession which has adorned this country. You have done what many a continental nation wishes it could imitate you in doing. You have driven cholera from your shores. It can no longer make any impression upon us, and year by year the health of the population grows, the sanitary reforms increase, and you have converted all those who once doubted to believe in the sanitary character of the maxims which you inculcate and the methods which you propose.

MAJOR CARDEW's report on the circumstances attending the accidents which have lately occurred in London, in connection with electric light mains, has been published in a Parliamentary paper. The accidents were of two kinds—those due to severe electric shocks caused by strong electrification of the surface of the ground, and those resulting from explosions in the street boxes through which the electric light mains run. In the City cases investigated by Major Cardew, the immediate causes of the accidents were: the breaking down of the insulation of a high pressure main in a street box, causing the formation of a powerful electric arc between the outer conductor of this main and the end of an iron pipe, forming a conduit for the mains, which projected into this box, and the consequent charging of this pipe to a dangerous extent; and the presence of gas in the Electric Light Company's pipes and street boxes to an amount which formed a highly explosive mixture afterwards fired by the electric arc. In the case of explosions in the St. Pancras district, it was suggested that the explosive gas was derived from the sewers, and also that it was hydrogen generated by electrolytic action. Major Cardew could find, however, no trace of such action, and, after careful consideration of the evidence and his own investigations, he concludes that the explosions were caused by the firing of a mixture of coal-gas and air by an electric spark. No time should, therefore, be lost in removing these two existing causes of danger, namely, the possibility of an accumulation of coal-gas in the conduits and that of the occurrence of an electric spark at the mains, whether the mains be insulated or of bare copper strip, such as is used by the St. Pancras Vestry. This Vestry has previously had their attention drawn to the necessity of efficient ventilation, but have failed to remedy the defects. The inquiry elicited the fact that there are only eleven ventilating pipes and three ventilating covers to street boxes for a total length of six and a half miles of conduit, a proportion quite inadequate for the immediate escape of gas from the conduits. Major Cardew recommends that accumulation of gas should be prevented by thorough ventilation, by making the sides and bottoms of street boxes impervious to gas, and by filling up the boxes as far as practicable with incombustible material. It is to be hoped that the Board of Trade will see that his recommendations on this and other sources of danger are acted upon.

THE New York Academy of Sciences, on Wednesday, March 13, repeated the experiment, begun last year, of giving an annual exhibition, with very gratifying results. Numerous scientific instruments were exhibited; the apparatus which excited most general interest being one for testing and photographing the voice.

A MEETING of the Institution of Mechanical Engineers will be held on Wednesday evening, April 24, and Friday evening, April 26, at 25 Great George Street, Westminster. The discussion will be resumed, on the Wednesday evening, upon the governing of steam engines by throttling and by variable expansion, by Captain H. Riall Sankey. The third report to the Alloys Research Committee will be presented by Prof. W. C. Roberts-Austen, C.B., F.R.S., and also appendices to it on the elimination of impurities during the process of making "best selected" copper, by Mr. Allan Gibb, and on the pyrometric examination of the alloys of copper and tin, by Mr. Alfred Stansfield. The anniversary dinner will take place on Thursday evening, April 25.

THE New York signal service office, a branch of the United States weather bureau, has just been removed from the Equitable building, No. 120 Broadway, which has been its headquarters for twenty-four years, to the new Manhattan Life Insurance Company's building, No. 66 Broadway, which is now one of the highest buildings in the world. The bureau will occupy the twenty-first, twenty-second, and twenty-third stories in the tower, and the observations will be made at a height of 356 feet above the street, or 380 feet above tide water. The old quarters were only 185 feet from the street. The equipment will all be new, and will include electric signal lights, which can be seen as far as Asbury Park and Fire Island. When the weather bureau was established in 1870, it occupied the top floor of a building in Wall Street for a few months. On the completion of the Equitable building, that was selected as then the highest in the city, but the rapid growth of tall office buildings all around has made it undesirable as an observing station. Even the present lofty quarters will soon be overtopped by the building of the American Surety Company, twenty-seven stories high, on the corner of Broadway and Pine Streets, between the Equitable and the Manhattan buildings.

EXTENSIVE geological researches have been made by Russian mining officers, as well as by professors of the Tomsk university, in connection with the Siberian railway, which, as is known, has already been completed as far as the Irtysh, opposite Omsk. Numerous layers of coal have been found in the basin of the Irtysh, but none of them have any industrial value. Rich palæontological collections, which very well characterise the age of the coal-bearing deposits of the Kirghiz Steppe, have, however, been made out at Bez-tyube. The best coal was found at Kuu-cheku, 40 miles from Karaganda, but it is too far from the railway (375 miles) to have an immediate practical value. The great difficulty which the builders of the railway have to contend with is the total absence of building stone in these lowlands, covered with clays and sands. Thus, for the building of the bridge over the Irtysh, near Omsk, new carlies had to be opened higher up the river, but the cost of extraction and transport was so great that most of the stone required for the bridge is brought by rail from Chelyabinsk, a distance of nearly 500 miles.

THE Society of Naturalists at the St. Petersburg University which celebrated last year its twenty-fifth anniversary, has issued an excellent volume containing a review of its five-and-twenty years' activity. Each branch (zoology, physiology, botany, and geology) is treated by a specialist, and the reviews show at a glance what has been done in each of these divisions of science; while the work of botanical, zoological, &c., exploration of the Russian Empire which has been accomplished by members of the Society, is represented on two maps. It is sufficient to say that the White Sea, the Caspian Sea, the Aral-Caspian and the Altai expeditions, which have so often been mentioned in these columns, the Crimea and the Neva Permanent Committees, and the Solovetsky biological stations, are the work of the Society. The volume is adorned by a good portrait of the late Prof. K. Th. Kessler, the founder of the Congresses of the Russian Naturalists and Doctors, and also of the Societies of Naturalists at all the

Russian Universities. The Society, which began twenty-five years ago with 74 members only, has now 374 active and 25 honorary members.

The Kazan Society of Naturalists at the Kazan University, which was founded in 1869, has also issued a similar anniversary volume, in which the review of work done in botany is especially valuable, as it has been written on the above plan. The volume contains also an index of all papers published in the twenty-seven volumes of its *Bulletin* and *Memoirs*, the titles of the papers being given both in Russian and German.

An old estimate of the frequency of earthquakes was that no a day passed without a shock being felt somewhere on the earth. In a new determination (*Comptes rendus*, vol. cxx. pp. 577–579), M. de Montessus de Ballore obtains a much higher figure. Dividing all the registers we possess into historical, seismologica and seismographical, and assuming the latter to be perfect, he finds, by comparing the different classes for the same region, that in the first 96·24 per cent., and in the second 84·48 per cent., of the total number of shocks escape record. In a group of well-studied earthquake districts, with a combined area of 11,691,000 sq. km., the average yearly numbers of shocks for the three classes are 341·35, 878·57, and 2222·24 respectively. Hence, multiplying by the proper factors for the first two classes, it would appear that the total number of shocks actually occurring in the above area must be estimated at 16,957 a year, or one in every half-hour.

In several papers of great interest (*Atti della R. Acc. dei Fisiocritici*, Siena, vol. v., 1894), Prof. G. Vicentini describes his new seismometrograph erected at Siena, and the seismic record obtained with it from February to July, 1894. The in strument consists of a heavy pendulum, 1½ m. in length and 50 kg. in mass, the base of which is connected with one end of a very light vertical magnifying lever. The other end of this lever is connected with the ends of two light horizontal levers placed at right angles to one another. These magnify the original movement of the ground seventy times, and trace fine lines on two strips of smoked paper moving at the rate of 2 mm. a minute. With this arrangement the heavy mass, it is found, remains stationary during vibrations of the ground, and the trace ceases simultaneously with the removal of the disturbing cause. For seismic purposes, the instrument possesses several advantages, especially the small cost of working and the rapid movement of the paper bands. In the plates accompanying the papers, copies are given of the traces produced by passing carriages, by strong gusts of wind, and by several earthquakes, the most beautiful being those of the Japanese earthquake of March 22, the Greek earthquake of April 27, and the Constantinople earthquake of July 10.

Surgeon-Captain R. H. Elliot, of the Indian Medical Service, has recently reinvestigated the value of strychnine as an antidote against snake poison in the most thorough manner. He experimented chiefly with cobra poison, but also with the venom of Russell's viper and the krait, using frogs, lizards, ducks, fowls, hares, guinea-pigs, dogs, goats, pigs, and monkeys as test animals. He confirms the results of Drs. D. D. Cunningham and A. A. Kanthack, that strychnine is not an antidote against snake poison.

That the German Cholera Commission has worked most energetically is shown by the voluminous documents now appearing in the *Arbeiten aus dem Kaiserlichen Gesundheitsamte*. A detailed inquiry has been held into all the various outbreaks of cholera which occurred in Germany between the latter part of the years 1892 and 1893, respectively, and the mass of minute incidents thus collected have been brought together, and cover considerably over 600 quarto pages. The Hamburg inquiry not unnaturally occupies the largest volume, and is extensively illustrated with diagrams, &c. The Commismission has succeeded in producing a most important and valuable contribution to the study of epidemiology, and their labours on cholera must long be regarded as the standard work on the subject. We only wish that influenza, which is now far more constantly with us, and claims such an increasing number of victims, might be subjected to the same crucial inquiry; possibly then, as in the case of the later outbreaks of cholera in Germany, we might be in a position to take some steps to effectually check its apparently capricious career.

A new contrivance for reading the position of the pointer in sensitive balances is described by W. H. F. Kuhlmann in the *Zeitschrift für Instrumentenkunde*. It has often been attempted to save time by accurate readings with the aid of a telescope or microscope, but none of those methods have been found to answer the purpose of the practical chemist or physicist. Herr Kuhlmann's contrivance is at once simple and effective. The pointer moves *behind* the divided scale, and the face of the latter is turned towards a concave cylindrical mirror attached to the central column of the balance. This mirror can be adjusted to face the observer, who sees in it a magnified image of the pointer rapidly moving across the magnified scale. It is thus made possible to graduate the scale much more finely than heretofore. The pointer must be very fine at the end, but any danger of its being damaged on that account is obviated by the fact of its moving between the scale and the mirror. Another improvement, described by Dr. Classen in the same number, is an arrangement for exchanging objects and weights without opening the balance case. This is accomplished by making a portion of the scale pans detachable. Each scale pan consists of a set of bent rods. One of these, bent into an irregular shape, can be lifted out and conveyed on a circular rail to the other scale pan, the latter undergoing this operation at the same time. A double weighing is no more troublesome than a single weighing, and the advantages of the method, especially when absolute weights are required, are obvious.

The phenomenon of polyembryony, or the development of two or more embryos in a single seed, has been the subject of several investigations. It has been shown that it may be due to the division of the nucellus, or to the fusion of two ovules, or to the presence of several embryo-sacs in one ovule. Further, Strasburger has found that it is often to be accounted for by the ingrowth of some cells of the nucellus into the embryo-sac, which there develop into adventitious embryos; in other cases he ascertained that two egg-cells are normally present in the embryo-sac, which on fertilisation give rise to two embryos. Finally, Dodel and Overton showed that it was possible for the synergidæ to develop into embryos. More recently, M. Tretjakow, in a short but interesting paper (*Ber. d. Deutsch. Bot. Gesell.*, February 1895) describes yet another cause of polyembryony. In *Allium odorum*, in addition to the normal embryo formed from the egg-cell, not infrequently the antipodal cells also give origin to embryos. Sometimes only one of these develops, but M. Tretjakow has observed all three antipodal cells start into growth and give rise to three embryos. These antipodal embryos commence their development immediately after the fertilisation of the egg-cell, and the cell-divisions, at least in the earlier stages, correspond exactly with those in the embryo formed from that cell. The Russian author, accepting the view that the antipodal cells are homologous to the vegetative cells of the prothallia of ferns, compares these antipodal embryos with those arising by apogamy on fern prothallia.

IN the course of a few remarks made by Prof. D. E. Hughes, F.R.S., at the recent banquet given by the staff of the National Telephone Company, some points in connection with the early history of telephony were mentioned. The text of the speech is published in the *Electrical Engineer* for March 22, and the following note from it is interesting. Prof. Hughes said:—The earliest record of a perfect theoretical electric telephone, was contained in Du Moncel's "Exposée des Applications," Paris, 1854; when M. Charles Bourseul, a French telegraphist. conceived a plan of conveying sounds and speech by electricity. Suppose, he explained, "that a man speaks near a movable disc sufficiently flexible to lose none of the vibrations of the voice, that this disc alternately makes and breaks the current from a battery; you may have at a distance another disc which will simultaneously execute the same vibrations." Unfortunately M. Bourseul did not work out his idea to a practical end, but these few words contain the shortest possible explanation of the theory of the present telephones.

IT is now exactly thirty years since Prof. Hughes first experimented with a working telephone. In 1865, being at St. Petersburg in order to fulfil his contract with the Russian Government for the establishment of his printing telegraph instrument upon all their important lines, he was invited by his Majesty the Emperor Alexandre II. to give a lecture before his Majesty, the Empress, and Court at Czarskoi Zelo, which he did; but as he wished to present to his Majesty not only his own telegraph instrument, but all the latest novelties, Prof. Philipp Reis, of Friedericksdorf, Frankfort-on-Maine, sent to Russia his new telephone, with which Prof. Hughes was enabled to transmit and receive perfectly all musical sounds, and also a few spoken words, though these were rather uncertain, for at moments a word could be clearly heard, and then from some unexplained cause no words were possible. This wonderful instrument was based upon the true theory of telephony, and it contained all the necessary organs to make it a practicable success. Its unfortunate inventor died in 1874, almost unknown, poor, and neglected; but the German Government have since tried to make reparation by acknowledging his claims as the first inventor, and erecting a monument to his memory in the cemetery at Friedericksdorf.

SINCE the enunciation by Virchow, in 1858, of his theory of cellular pathology, much attention has been given to the study of this unit. Nearly all the unsolved problems of medical science involve, in one way or another, the consideration of some one of the functions of the cell. At the Philadelphia Academy of Natural Sciences, on February 5, Dr. C. L. Leonard directed attention to a new method of studying one of these functions. The method consists in making a consecutive series of instantaneous photomicrographs of the same microscopic field, taken at definite intervals, so that a comparative study of the series can afterwards be made. The results obtained by this method are the elimination to a greater extent of the personal equation of the observer, the procuring of incontestable proof of phenomena observed, the extension of the observations over any length of time, and the possibility of studying the changes occurring over the entire field at any one moment. The method also enables the student to study the condition of a fresh, living, unstained specimen for any length of time, in fields taken at definite intervals. So far Dr. Leonard has confined the greater part of his study to cell motion as exemplified in the movements of the red and white blood corpuscles. He exhibited to the Academy a number of photomicrographs illustrating the amœboid motion of the white blood corpuscle, and also showing motion in the red blood corpuscle. Some of the photographs seem to show that diapedesis is not a filtration due to pressure, but is due to a truly amœboid motion and power of the red blood corpuscles. Further photographs illustrated the position of the corpuscles within the capillaries, and showed the presence of nuclei in the red corpuscles of the frog while in the living tissues.

AT a recent meeting of the Paris Academy, M. Désiré Korda read a paper on a "thermo-chemical carbon cell." The author finds that if barium peroxide is heated to redness in contact with a carbon plate, the oxide becomes reduced to baryta, and a difference of potential of about one volt is produced, the carbon plate being negative. A similar result was obtained with cupric oxide as soon as a layer of potassium carbonate was placed between the oxide and the carbon, the difference of potential in this case amounting to 1·1 volts. The experiments were in each case performed by connecting a plate of gas-retort carbon by means of a platinum wire to one terminal of a Richard voltmeter, and placing on the carbon a few c.c. of the salt. A platinum wire dipping in the salt served to complete the circuit. On heating the carbon to a dull red heat in a Bunsen flame, a violent effervescence takes place, carbon dioxide being evolved, and the voltmeter shows a deflection corresponding to about 1 volt. This deflection remains constant as long as any of the higher oxide is left.

READERS of Mr. Edward Step's books and magazine articles on popular botanical subjects, will be pleased to learn that he has written a pocket-guide to British wild flowers, to be published by Messrs. Frederick Warne and Co. The title of the book will be "Wayside and Woodland Blossoms."

THE fourth part of "Dissections Illustrated" (Whittaker and Co.), by Mr. C. Gordon Brodie, containing sixteen magnificent plates drawn and lithographed by Mr. Percy Highley, has just appeared. Students of human anatomy could hardly desire a handbook in which typical dissections are more clearly displayed than they are in Mr. Brodie's work, which has now been completed. The whole work contains seventy-three coloured plates, drawn to two-thirds natural size.

THE Zoological Society of France has just published a new edition of the "Rules of Nomenclature of Organised Beings adopted by the International Congresses of Zoology (Paris, 1889; Moscow, 1892)." A copy will be sent gratis to every professor of zoology or comparative anatomy, director of a museum, library or laboratory, or assistant in the same, also to every learned society, upon application to the general secretary, M. le Dr. R. Blanchard, 7 Rue des Grands Augustins, Paris.

THE valuable work in zoology, carried on in H.M. Indian Marine surveying steamer *Investigator*, under Commanders A. Carpenter and R. F. Hoskyn, is already known to many biologists, and Part I. of the illustrations referring to it, now obtainable through Mr. Bernard Quaritch, should make it known to more. The Part contains seven splendid photo-etchings representing twenty-six remarkable fishes, and five illustrative of Crustacea. The former were prepared under the direction of Mr. A. Alcock, and the latter under the direction of Mr. J. Wood-Mason.

PROF. S. H. VINES' "Students' Text-book of Botany" (Swan Sonnenschein and Co.), the first half of which was reviewed in these columns in October last (vol. l. p. 613), has just been published in its complete form. In addition to the sections mentioned in our notice, the work now contains descriptions of the Phanerogams, and the part on the physiology of plants. The whole volume makes a comprehensive textbook of botany possessing many excellent features, and of the usefulness of which there can be no question. It is a pity that so very many literal errors should have been overlooked while the work was passing through the press. The page of errata which precedes the contents is not the sort of thing one looks for in a new book.

The first *Bulletin* of the Bohemian Academy of Sciences, founded in 1890 by the Emperor of Austria, has just been issued. It contains no less than twenty-three separate memoirs many of which are beautifully illustrated with coloured and other plates, amongst which we may specially mention the twelve successfully-executed photographs illustrating some bio-chemical studies by MM. Kruis and Raýman. There are French, German and Italian communications, so that the *Bulletin* may with justice be called "International." Science is very variously represented, and we find contributions in the departments of mathematics, biology, chemistry, geology, physics, physiology, and bacteriology. The committee of publication is to be congratulated, not only on the high standard of the original work here brought together, but also on the successful manner in which they have produced this journal. In addition to the plates, the printing and paper are both excellent.

The Report of the Council of the Scottish Meteorological Society, on March 27, shows that the work of the Society is extending. A new station has been established in connection with the Society at Kingussie, Inverness-shire, the instruments for which were supplied chiefly by Mr. John Anderson. The station is under the management of Dr. De Wattville, who commenced the observations on January 1. The work at the two Ben Nevis observatories, made both with the eye and continuously recording instruments, has been carried on with the same zeal and success as in previous years. Much work has been done in the offices in Edinburgh and Fort-William in recopying, on daily sheets, the hourly observations of the two observatories, in connection with an examination of a comparison of the two sets of observations in their bearings on the storms and weather of North-Western Europe. This examination has been recently commenced by Dr. Buchan. The subject is divided into these several parts—cyclones; anti-cyclones; small differences of temperature between top and bottom, including inversions of temperature; very large differences of temperature; great dryness of air at the top; marked differences of wind at top and bottom, both as regards direction and force; relations to reported storms at the lighthouses; conditions under which very diverse readings of the two barometers occur. In each of these cases the weather charts of Europe at the time are thoroughly examined from various points of view. Several of the points examined have already been investigated to some extent; but what is now attempted to be done is an inquiry into their relations to each other. The importance of the inquiry consists in the fact that the high-level station dealt with is situated right in the general path of the cyclones of North-Western Europe, whereas the other high-level stations of Europe that have been used in similar investigations are altogether outside that path. Dr. Buchan has a stupendous piece of work under way, and we trust that it may soon be brought to a successful termination.

The additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*, ♀) from South Africa, presented by Mr. H. W. Weguelin; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. W. H. Hayner; a Pardine Genet (*Genetta pardina*) from West Africa, presented by Mr. George Danes; a Palm Squirrel (*Sciurus palmarum*) from India, presented by Mrs. Henry Jones; a Short-tailed Wallaby (*Halmaturus brachyurus*, ♀) from Queensland, presented by Mrs. L. Thompson; a Vulpine Phalanger (*Phalangista vulpina*, ♀) from Australia, presented by Master John Simonds; a Bronze-winged Pigeon (*Phaps chalcoptera*, ♂) from Australia, presented by Lady Buchan Hepburn; a Grey-breasted Parrakeet (*Bolborhynchus monachus*) from Monte Video, presented by Mr. Rowland Ward; an Egyptian Jerboa (*Dipus ægyptius*) from North Africa, an Oak Dormouse (*Myoxus dryas*), South European, presented by Dr. G. L. Johnson; a Cape Viper (*Causus rhombeatus*) from South Africa, presented by Mr. J. E. Matcham; a Hoolock Gibbon (*Hylobates hoolock*, ♂) from Assam, two Gazelles (*Gazella dorcas*, ♂ ♀) from Nubia, an Oak Dormouse (*Myoxus dryas*), South European, deposited; a Brazilian Three-banded Armadillo (*Tolypeutes tricinctus*, ♂) from Brazil, a Variegated Bittern (*Ardetta involucris*), a White-spotted Rail (*Rallus maculatus*), a Sooty Rail (*Rallus rythyrhynchus*), a Rosy-billed Duck (*Metopiana peposaca*), four Burrowing Owls (*Speotyto cunicularia*) from South America, purchased.

OUR ASTRONOMICAL COLUMN.

Comet *e* 1894 (Swift).—The general resemblance of the orbit of this comet to that of De Vico's, 1844 I, was noticed very soon after its first appearance (Nature, vol. li. pp. 132, 160). Mr. Barnard was, fortunately, able to determine the place of the comet on five nights at the end of January, when it was "most excessively faint and difficult, about 10" to 15" in diameter," as seen with the 36-inch refractor. These observations have enabled Dr. Chandler to revise the elements of the orbit, and to undertake a discussion of the possible identity with the comet of 1844 (*Astronomical Journal*, No. 338). Dr. Chandler points out that in view of the numerous close family resemblances among the periodic comets, we can distinguish between similarity or identity in the present case only by actual calculation of the principal planetary perturbations. He has accordingly calculated the perturbations, and he finds that "both in direction and approximate amount these changes are uniformly of the character required to reconcile the differences between the observed orbits of the comets 1844 I and *e* 1894." Some of the results are shown in the following table, the elements for the 1844 comet being those of Brünnow:—

	1844 I	*e* 1894 Before perturb.	*e* 1894 Observed.
Longitude of perihelion	278° 48′·6	283° 7′·5	296° 34′·1
" " node	64 20	60 24	48 40·7
Inclination	2 54·9	2 53·1	2 57·9
Eccentricity	0·61765	0·60282	0·5719
Period	5·466 years	5·615 years	5·863 years.

Dr. Chandler considers this to be "sufficiently demonstrative of the high probability of identity to justify a more refined calculation at a proper future time." As to future observations of the comet, he is not very hopeful. "The present perihelion distance will probably be changed by Jupiter in 1897 to one considerably beyond the orbit of Mars, so that unless a favourable reversion of the change of brilliancy which apparently took place between 1844 and 1894 should occur, it will in all likelihood hereafter be invisible; at least until, at some future approach to the critical point of disturbance near longitude 165°, simultaneously with Jupiter, it shall be thrown into a path in which, near perihelion, it will be again in reach of our telescopes."

A Possible New Satellite of Neptune.—In the course of a series of micrometric measures of the satellites of Uranus and Neptune, Prof. Schaeberle observed a suspicious object near to Neptune on September 24, 1892, when the seeing was exceptionally fine (*Astronomical Journal*, No. 340). The star or satellite was so faint that it was near the limit of vision of the 36-inch refractor of the Lick Observatory. During an hour and forty minutes, the total change of position angle was 2° greater than could be accounted for by the geocentric motion of the planet with reference to a fixed star, and this strengthens the idea that the object observed may have been a second satellite. At the time of observation the distance from the planet's centre was 24"·4. Prof. Schaeberle now somewhat reluctantly publishes these facts in connection with his measures of the known satellite, as he has not on any subsequent occasion been able to detect any object in the neighbourhood of Neptune in apparent orbital motion about the planet. The unusual clearness and steadiness of the night of September 24, 1892, however, is not considered to have been equalled in the later observations.

PROFESSOR MENDELÉEFF ON ARGON.

AT the meeting of the Russian Chemical Society, on March 14, Prof. Mendeléeff made some interesting remarks on the relations of argon to the periodic system. His views are summed up as follows in a proof-issue of the *Proceedings* of the Society:—

"As regards argon we must consider, first, whether it is a chemical individual, or a mixture, and then, whether it is a simple or a compound body. The supposition that it be a mixture, lies beyond all probabilities; it is contradicted by the researches of Olszewski into the liquefaction and solidification of argon. The supposition that it may be a compound has also little in its favour. The remarkable inactivity of argon testifies in favour of its being a simple body, although there are, of course, some compounds, also endowed with the same property to some extent. The spectrum of argon, too, is characteristic of a simple body.

"Taking it as a simple body, we must then consider its possible atomic weight, the weight of its molecule being near to 40 (although, probably, a little over 40, because of a slight mixture of nitrogen with the argon). The atomic weight of argon evidently depends upon the number of atoms which its molecule contains. We must, therefore, consider the series of possible molecular formulæ: A, A_2, A_3, . . . A_n.

"Upon the first supposition, A, the atomic weight of argon would be about 40, and, like cadmium and mercury, it would be a monatomic gas.

"In favour of this supposition we have the specific heat ratio at constant volumes and pressures, K, found by Rayleigh and Ramsay to be near to 1·66, *i.e.* to the value which is considered as characteristic for monovalent gases. It must, however, be borne in mind that K varies for compound molecules, even when these last contain the same numbers of atoms; thus, for most bivalent gases (nitrogen, oxygen, &c.) K is near to 1·4, while for chlorine it is 1·3. This last figure makes one think that K depends not only upon the number of atoms in the molecule, but also upon chemical energy, that is, upon the stock of internal motion which determines the chemical activity of a body, and the quantity of which must be relatively great with chlorine. If, with the chemically-active chlorine, K is notably less than 1·4, we may admit that for the inactive argon it is much more than 1·4, even though the molecule of argon may contain two or more atoms.

"If we admit that the molecule of argon contains but one atom, there is no room for it in the periodic system; because, even if we suppose that its density is much below 20 (although this is very unlikely to be the case, and the contrary could rather be surmised), and that the atomic weight of argon should fall between the atomic weights of chlorine and potassium, the new body ought to be placed in the eighth group of the third series; but the existence of an eighth group in this series could hardly be admitted. In fact, an eighth group is characteristic of the large periods; and it establishes a link between the metallic elements of the seventh groups of the even series, with the metallic elements akin to them, of the first groups of the uneven series. It appears, therefore, very unlikely that the atomic weight of argon might be about 40.

"Upon the second supposition (A_2), its atomic weight would be about 20, and in such a case argon would find its place in the eighth group of the second series, *i.e.* after fluorine. But the same objections as above could then be raised. Fluorine and sodium are, moreover, strikingly unlike to each other. However, it must be said in favour of this hypothesis that it would have the advantages of analogy, by giving a new eighth group to an even series. If we take also into consideration that the typical series are possessed of several peculiarities, we may be justified, to some extent, in supposing that the atomic weight of argon is 20, this hypothesis being already much more probable than the former (A = 40).

"If we suppose, further, that the molecule of argon contains three atoms, its atomic weight would be about 14, and in such case we might consider argon as condensed nitrogen, N_3. There is much to be said in favour of this last hypothesis. First of all, the concurrent existence of nitrogen and argon in nature; then, the fact that many of the bright lines of the two spectra are very near to each other. Then, again, the inactivity of argon would be easily explained, if it originates from nitrogen, N_3, with giving up heat. And finally, the fact of its having been obtained, though in a relatively small quantity, from artificially obtained nitrogen. The supposition of Rayleigh and Ramsay, according to which argon has been disengaged in this last case from water, is very probable, but at any rate it is not yet proved. The hypothesis of argon being condensed nitrogen might be tested by means of introducing boron, or titanium, into an atmosphere of argon, strongly heated, and through which electric sparks would be passed.

"If we suppose, next, that the molecule of argon contains four or five atoms, its atomic weight will be 10, or 8, and in such case there is no room for argon in the periodic system.

"And finally, if we admit that its molecule contains six atoms, and that its atomic weight is 6·5, we must place it in the first series. In such case, it would probably take its place in the fifth group. Accordingly, the suppositions that argon is condensed nitrogen, N_3, or that, containing six atoms in the molecule, its place is in the first series of the system, appear to be the more probable ones, if it is a pure simple chemical body.

"From a letter received by D. I. Mendeléeff from Prof. Ramsay, it appears that the investigation of argon is being continued, and that the body finds its place in the periodic system; but the ultimate results of the researches of the two authors, who have brought before chemistry such an important new problem, and given it such an exemplary investigation, are not yet known."

TERRESTRIAL HELIUM (?).

WE referred last week to Prof. Ramsay's discovery of another new gas obtained from cleveite. The following papers, by Prof. Ramsay and Mr. Crookes, on this subject were communicated to the Chemical Society at its anniversary meeting.

Prof. Ramsay's paper was as follows:—

In seeking a clue to compounds of argon, I was led to repeat experiments of Hillebrand on clèveite, which, as is known, when boiled with weak sulphuric acid, gives off a gas hitherto supposed to be nitrogen. This gas proved to be almost free from nitrogen; its spectrum in a Plücker's tube showed all the prominent argon lines, and, in addition, a brilliant line close to, but not coinciding with, the D lines of sodium. There are, moreover, a number of other lines, of which one in the green-blue is especially prominent. Atmospheric argon shows, besides, three lines in the violet which are not to be seen, or, if present, are excessively feeble, in the spectrum of the gas from clèveite. This suggests that atmospheric argon contains, besides argon, some other gas which has as yet not been separated, and which may possibly account for the anomalous position of argon in its numerical relations with other elements.

Not having a spectroscope with which accurate measurements can be made, I sent a tube of the gas to Mr. Crookes, who has identified the yellow line with that of the solar element to which the name "Helium" has been given. He has kindly undertaken to make an exhaustive study of its spectrum.

I have obtained a considerable quantity of this mixture, and hope soon to be able to report concerning its properties. A determination of its density promises to be of great interest.

The spectrum of the gas was next discussed by Mr. Crookes, who said

By the kindness of Prof. Ramsay I have been enabled to examine spectroscopically two Plücker tubes filled with some of the gas obtained from the rare mineral clèveite.[1] The nitrogen had been removed by "sparking." On looking at the spectrum, by far the most prominent line was seen to be a brilliant yellow one apparently occupying the position of the sodium lines.

[1] Clèveite is a variety of uraninite, chiefly a uranate of uranyle, lead, and the rare earths. It contains about 13 per cent. of the rare earths, and about 2·5 per cent. of a gas said to be nitrogen.

Examination with high powers showed, however, that the line remained rigorously single when the sodium lines would be widely separated. On throwing sodium light into the spectroscope simultaneously with that from the new gas, the spectrum of the latter was seen to consist almost entirely of a bright yellow line, a little to the more refrangible side of the sodium lines, and separated from them by a space a little wider than twice that separating the two sodium components from one another. It appeared as bright and as sharp as D_1 and D_2. Careful measurements gave its wave-length 587·45; the wave-lengths of the sodium lines being D_1 589·51, and D_2 588·91. The differences are therefore—

	Wave-lengths.	Differences.
D_1	589·51	
		0·60
D_2	588·91	
		1·46
New line	587·45	

The spectrum of the gas is, therefore, that of the hypothetical element Helium, or D_3, the wave-length of which is given by Ångström as 587·49, and by Cornu as 587·46.

Besides the Helium line, traces of the more prominent lines of argon were seen.

Comparing the visible spectrum of the new gas with the band and line spectrum of nitrogen, they are almost identical at the red and blue end, but there is a broad space in the green where they differ entirely. The Helium tube shows lines in the following positions:—

	Wave-length.	
(*a*) D_3, yellow... ...	587·45	Very strong. Sharp.
(*b*) Yellowish green ...	568·05	Faint. Sharp.
(*c*) Yellowish green ...	566·41	Very faint. Sharp.
(*d*) Green	516·12	Faint. Sharp.
(*e*) Greenish blue ...	500·81	Faint. Sharp.
(*f*) Blue	480·63	Faint. Sharp.

I have taken photographs of the spectrum given by the Helium tube. At first glance the ultra-violet part of the spectrum looks like the band spectrum of nitrogen, but closer examination shows considerable differences. Some of the lines and bands in the nitrogen spectrum are absent in that from the Helium tube, whilst there are many fine lines in the latter which are absent in nitrogen. Accurate measurements of these lines are being taken.

ISOLATION OF FREE HYDRAZINE, N_2H_4.

M. LOBRY DE BRUYN contributes a memoir of special interest to the current issue of the *Recueil des Travaux Chimiques des Pays-Bas.* It is not long since the distinguished Amsterdam chemist succeeded in preparing for the first time free anhydrous hydroxylamine, and now he announces that he has likewise been successful in isolating free hydrazine by a similar method. Eight years ago the important discovery of hydrazine was made by Prof. Curtius, and since that time the amount of knowledge which has been accumulated concerning the base and its compounds by Prof. Curtius and his assistants is so large that a separate volume might well be devoted to it. Nevertheless, the free anhydrous base itself has not hitherto been satisfactorily prepared; indeed it would now appear, in the light of M. de Bruyn's remarkable work, that it has not hitherto been in any way isolated. The hydrate of the base has been obtained in the pure state and fully described by Prof. Curtius, but in his later communications he has expressed the view that the free base is so unstable that most probably it is incapable of separate existence. The hydrate only is produced when the salts are decomposed by a caustic alkali, and even digestion in a sealed tube at 170° with anhydrous baryta, has failed to detach the water molecule from its combination with hydrazine. It appeared, however, to M. de Bruyn that the nature of the salts and other compounds of hydrazine rendered it scarcely probable that the base was less stable than hydroxylamine, and he considered it not unreasonable to hope that it might therefore be isolated in an analogous manner to the latter base, namely, by reacting upon the chloride with sodium methylate in methyl alcohol solution. The experiments made in this direction are only preliminary, but their result is so interesting that an account of them is at once published.

The salt employed was the chloride $N_2H_4.HCl$, prepared as described by Prof. Curtius. Ten grams of this salt in powder were added to 200 c.c. of pure methyl alcohol, and a solution of the calculated quantity of sodium methylate CH_3ONa in methyl alcohol were subsequently added. Common salt was immediately precipitated without any perceptible rise of temperature. The mixture was consequently boiled for half an hour in a flask fitted with an upright condenser. After cooling the sodium chloride was removed by filtration, and the solution submitted to distillation. At first mainly methyl alcohol passed over, but after a time the distillate began to contain augmenting quantities of hydrazine; the pressure was then reduced, and four further quantities separately collected. The temperature of ebullition rose to 55°, although the pressure was materially reduced. The last 20 c.c. contained the greater portion of the base. This last fraction was then again distilled at the ordinary pressure, until a residue was left which contained 73 per cent. of hydrazine. The hydrate of hydrazine only contains 64 per cent. of the base, hence it was evident that some free hydrazine had been obtained, and that hydrazine is a comparatively stable substance boiling at a temperature higher than that of methyl alcohol.

In a second experiment 42 grams of chloride of hydrazine were treated in a similar manner with methyl alcohol and sodium methylate. This larger quantity evinced some rise of temperature after the admixture, and the heat caused by the reaction of the hydrazine chloride, which at first had not all dissolved, was just sufficient to keep the liquid boiling for several minutes, when once it had been brought to the boiling point by extraneous heating. After the conclusion of the reaction the contents were cooled, avoiding the access of moisture and carbon dioxide, the sodium chloride filtered off as before, and distillation proceeded with, at first in an ordinary distillation apparatus and afterwards with the aid of a Le Bel-Henninger apparatus. A residual 40 c.c. was again fractionated under reduced pressure and six portions collected. The sixth friction contained no less than 82·6 per cent. of N_2H_4. A smaller quantity passing over after removing the sixth fraction contained over 84 per cent. The fifth and sixth portions solidified when cooled by a freezing mixture of ice and salt. The crystals melted about 4°. Although the crystals when exposed to the air exhaled dense white fumes, owing to the attraction of moisture, a number of them were quickly pressed between cooled blotting paper, weighed, and volumetrically analysed. The analytical numbers corresponded to 92 per cent. of N_2H_4, a result which, considering the extremely hygroscopic nature of the crystals, would appear to indicate that they consisted of practically pure N_2H_4. The dried crystals melted at $-1°$ to $-2°$.

A drop of the liquid obtained by fusion of the crystals did not explode when heated with a naked flame; a yellow flame was produced, however, accompanied by a hissing noise. The liquid base is heavier than water and considerable heat is evolved upon mixing it with a small quantity of the latter liquid. Dry oxygen slowly oxidises it. When paper is moistened with a drop of hydrazine and exposed to the air, it becomes hot spontaneously and fumes strongly. Crystals of sulphur dissolve promptly in the liquid base with considerable rise of temperature and formation of a reddish-brown liquid whose odour reminds one of ammonium sulphide; upon the addition of water to this liquid, sulphur is precipitated. The halogens react very violently with hydrazine, producing their acids, and liberating nitrogen. Iodine disappears instantly, and a quantitative experiment showed that the reaction proceeded in accordance with the equation $N_2H_4 + 2I_2 = N_2 + 4HI$. Potassium permanganate or bichromate act with great violence upon the liquid base, but the reaction is unaccompanied by either incandescence or explosion. The liquid appears to possess the further property of readily dissolving many salts, such as the potassium salts of the halogen acids, and nitre.

It would thus appear that, instead of being a gas, as at first supposed by Prof. Curtius, free hydrazine is at the ordinary temperature a liquid, which, however, solidifies at a temperature in the neighbourhood of that of the freezing-point of water, to colourless crystals. The base is, moreover, endowed with a very much higher degree of stability than was supposed. M. de Bruyn is now engaged in preparing it upon a very much larger scale, in order more completely to study its properties.

A. E. TUTTON.

SCIENCE IN THE MAGAZINES.

MR. CHAS. DIXON has discovered a new law of geographical dispersal of species, and he expounds its capabilities in the *Fortnightly*. Here is a statement of his conclusions:—"Species in the northern hemisphere never increase their range in a southern direction; they may do so north, north-east, or north-west, east or west. Species in the southern hemisphere never increase their range in a northern direction; they may do so south, south-east, or south-west, east or west. The tendency of life is to spread in the direction of the poles. Among the six corollaries which I have drawn from this law, mention may be made of the following. By the fourth corollary, species never retreat from adverse conditions. If overtaken by such they perish, or such portion of the species that may be exposed to them. By the fifth corollary, extension of range is only undertaken to increase breeding area. By the sixth corollary, contraction of range is only produced by extermination among sedentary species, and probably also by extermination (through inability to rear offspring) among migratory species that are neither inter-polar nor inter-hemisphere. . . . If this law of geographical distribution be true, polar dispersal of species—in other words, from the direction of the poles towards the equator—is a myth." Mr. Dixon brings forward a number of facts in support of his theory, which will no doubt be given the consideration it deserves.

An address by Mr. Leslie Stephen, on the choice of books, appears in the *National*; but, to prevent misconception, it is just as well to state at once that scientific literature is altogether ignored. Yet it is difficult to understand why this should be, for writings of men of science are apparently included in the definition stated by Mr. Stephen himself. "Literature, in short," he writes, "is one utterance of Matthew Arnold's *Zeitgeist*—the vague but real entity which is a summary of all the sympathies and modes of thought and feeling characteristic of the best minds at a given stage of human progress." A few natural history notes will be found in the *National*, in an account, by Miss Balfour, of a journey through the British South Africa Company's territory, in 1894.

Among other popular articles on natural history in the magazines received by us, we notice "Nestlings," by the Rev. Theodore Wood, in the *Sunday Magazine*, and "Snake-Taming" in *Chambers's Journal*. This periodical also contains a very readable elementary description of the great Indian Trigonometrical Survey. Mr. L. N. Badenoch describes a number of species of Plasmidæ in *Good Words*. In the same magazine Sir Robert Ball writes on the life and works of Copernicus. Under the title, "Tesla's Oscillator and other Inventions," a good account of some of Mr. Tesla's recent electrical work is given in the *Century*, by Mr. T. C. Martin. The article "discloses a few of the more important results he has attained, some of the methods and apparatus which he employs, and one or two of the theories to which he resorts for an explanation of what is accomplished." It is illustrated with fifteen figures, all of which possess points of interest. Mention must be made here of a short biographical sketch of Helmholtz, contributed by Mr. Martin to the March number of the *Century*, but overlooked at the time. The sketch is illustrated bv a fine engraving from a photograph of Helmholtz, taken in 1893. A brief note in *Cassell's Family Magazine* describes some curious tubular dwellings constructed against the side of a small aquarium by the species *Amphithœ littorina*. The tubes are semicircular, and composed of sand and small pieces of seaweed, cemented together with a glutinous matter secreted by these shrimps.

The practicability of constructing a railway from the Mediterranean to India is discussed by Mr. C. E. D. Black in the *Contemporary*. Over India proper there are 18,500 miles of lines open to traffic. But westward these lines break off at Peshawur, Chaman, and Kurrachee. It is proposed that a line should be constructed from Port Said, through Northern Arabia, along the edge of the Persian Gulf, to Kurrachee—a distance estimated at 2400 miles.

In addition to the magazines mentioned in the foregoing, the *Humanitarian*, *Scribner*, and *Longman's Magazine* have been received. A portrait of Prof. Bonney accompanies an article on "Science and Faith" in the first of these magazines.

PRECIOUS STONES, AND HOW TO DISTINGUISH THEM.[1]

AMONG the duties which fall to the lot of an official in the Mineral Department of the British Museum, in his otherwise unromantic and sternly studious life, is one which is not altogether devoid of human interest. It may happen, for example, that a lady having inherited a priceless heirloom in the shape of a large emerald, travels from the Antipodes in order to sell it in England for its true value, and desiring to display its charms brings it to the Museum. To inform such a person that the stone is but green bottle glass cannot be a pleasant task.

Only within the last few months came an Afghan prince who had sold his worldly goods, travelled to the coast of India, and worked his passage to England, having secreted about his person a stone which he supposed to be of enormous value. His story was that as he slept upon the hillside, Mahomet had appeared to him and told him that he would find a rare jewel under his hand. The poor man could not be convinced that a stone with this celestial guarantee could be anything common; for, as he said, "Mahomet cannot lie." Be this as it may, the stone was quartz, and its princely owner could only be advised to repair his fallen fortunes in some Oriental fashion at Constantinople—Kensington.

It is curious that the stones brought by such people are always, in the opinion of their owners, gems of the greatest value and rarity. Could they but have consulted some competent expert nearer home, they would have been saved time and money and bitter disappointment.

But after such interviews, I have always been very forcibly impressed by the fact that even the experts do not seem in the least aware of the simple and certain methods which have been placed at their disposal by recent mineralogical research. There is, perhaps, no subject in which experts have been so slow to take advantage of practical methods supplied by science as in the manipulation and discrimination of precious stones.

The stones brought by these chance visitors have often been bought and sold over and over again under totally false names. There is, I suspect, scarcely a collection, public or private, in which some of the jewels are not wrongly described.

Mistakes are constantly made; and these are sometimes of considerable commercial importance. It may be remembered, for example, that a few years ago much excitement was caused by the discovery of rubies in the Macdonell Range in Southern Australia. Much time and money was wasted in their extraction before it was discovered that, like the so-called Cape rubies, they were merely garnets.

I should be the last person to underrate the great value of that knowledge which results from long experience, or to deny that in ninety-nine cases out of a hundred an expert may be absolutely right. Every one must admire the confidence with which a practised eye can even pick out from several packets of diamonds those which came from a certain mine.

Such a professional expert may in five seconds pronounce a judgment which it might require half an hour to establish by scientific methods, and one which may be equally correct.

But there is a vast difference between "may be" and "is," and scientific men are not satisfied with that sort of judgment, but require actual proof.

One ought to distinguish between two sorts of expert knowledge—that which results from long experience and the training of eye and hand, and that which results from familiarity with scientific methods. To have confidence in the non-scientific expert, one must place reliance upon his personal character and the soundness of his senses, and be sure that his actual experience has included problems similar to the one submitted to him, and even then he may fail in that hundredth case.

But the scientific tests cannot err; moreover, they furnish a proof which carries conviction to all who see it. The opinion of the expert need *convince* none but himself.

An exact parallel is to be found in medical practice. It is no doubt often possible for a doctor of experience to diagnose diphtheria and phthisis by their symptoms. But in recent years new methods have been made available by the discoveries relating to bacteria, and at the present time no diagnosis of diphtheria or of the early stages of consumption would be con-

[1] A lecture delivered at the Imperial Institute, by Mr. H. A. Miers.

sidered complete which did not include the bacteriological evidence; that is to say, the isolation and microscopic examination in each case of the specific bacillus. What is more, such evidence is proof positive of the existence of the disease.

Now the only characters at all generally employed by persons connected with the trade in precious stones are two—namely, the hardness and the specific gravity or weightiness.

If a stone scratches quartz, and is scratched by topaz, it is said to have a hardness between that of quartz and that of topaz; if it scratches topaz, but is scratched by sapphire, it is said to have a hardness between that of topaz and that of sapphire. All minerals, including the gem-stones, have been tabulated according to their hardness with reference to ten standard stones, of which the diamond, the hardest of all known substances, heads the list. If, for example, a red stone, supposed to be a ruby, is found to be only about as hard as topaz, it cannot be a true ruby, but must be a spinel ruby, which is quite a different thing; or if it is sufficiently soft to be scratched by rock-crystal, it is probably a red garnet.

This test is obviously a very rude one in more senses than one. Not only does everything depend upon the nature of the scratching part, whether it is a sharp corner or a curved surface, and upon the direction in which the scratch is made; but, to say the least, the surface of a gem is certainly not improved by scratching.

The second test—that of the weightiness—is a really accurate and scientific one, provided that it be made by means of a delicate chemical balance. A stone which is, bulk for bulk, three times as heavy as water, is said to have a specific gravity of 3; one such as topaz, which is three and a half times as heavy as water, is said to have a specific gravity of 3·5. The ordinary method is to weigh the stone, suspended by a thread, first in air, and then immersed in water. The difference is exactly the weight of the water displaced by the stone, and so the specific gravity is easily found.

The objections to this method are, firstly, that it is too laborious; and secondly, that it is not applicable when the stone is very small, because it is then impossible to weigh it with accuracy under water. I should not rely upon the specific gravity of a stone under two carats in weight as determined by this method. A method which I shall presently describe is perfectly free from both these objections.

Incredible as it may seem, the estimation of hardness and the specific gravity are the only attempts at anything like scientific measurement ever made in the ordinary course of business applied to stones; and even then the weightiness is usually estimated merely by poising the stone in the hand. For the rest they are identified by their colour, their fire or sparkle, their lustre and their general appearance.

In a lecture delivered to the Society of Arts in 1881, Prof. Church drew attention to the necessity of scientific methods for this purpose, and has more than once, on subsequent occasions, reiterated his plea. I propose to dwell more particularly on improvements which have been introduced since the date of his lecture, and to indicate how one may, by simple practical tests, which require little special knowledge, distinguish with certainty all gem-stones without in any way injuring them.

Chemical analysis is, by the very nature of the problem, out of the question, for in order to make an analysis, or to apply the simplest chemical test, it is necessary to destroy a part of the material; and this cannot be done, at any rate in the case of a cut stone.

We can begin by dismissing the hardness as a character which it is really unnecessary to determine, except to identify diamond or to distinguish a real stone from paste; here, I know, I shall earn a rebuke from the orthodox mineralogist who, in order to pursue the study of what should be a peaceful science, arms himself with a knife, and proceeds to scratch everything which he comes across.

The weapons which I would recommend are of a milder nature: the microscope, the spectroscope, the goniometer, and the dichroscope.

Among the available characters of gems, first and foremost are the optical properties; that is to say, the appearances seen when we look at them, or through them, in various ways.

The extent to which a ray of light is refracted on entering and leaving a transparent stone, is a characteristic property most useful for determination. As everyone knows, a stick half immersed in water appears bent owing to the refraction of light on passing out of the water; if it is immersed in a more highly refractive liquid, it appears more bent.

To ascertain the refractive power of any transparent substance like glass, a prism-shaped piece is cut from it, and the extent to which a ray of light is refracted on passing through the prism is measured by the goniometer, an instrument found in every physical laboratory.

I have not seen this recommended as a method to be practically used, because it is commonly supposed that a special prism must be cut from the stone for the purpose. For the benefit of those who possess a goniometer, I may say that it is a method which I constantly apply, and find most useful for unmounted cut stones. It is always possible to find two of the facets which form a convenient angle, and, after inking over the remainder of the stone, to trace the ray passing through these two facets, and so to measure with absolute accuracy not only the refraction but the double refraction of the stone; moreover, this method is applicable to any stone, however great its refractive power.

Another simple plan which can be used by any one, but unfortunately only for stones of comparatively low refractive power, has been invented during the last few years. This delightfully simple little instrument, known as the reflectometer, consists of a hemispherical glass lens viewed by an eye-piece containing a graduated scale; it need only be pressed against the plane surface of a cut stone previously touched with a drop of liquid of higher refractive power than the stone itself. On looking into the eye-piece a shade is seen over half the field of view, and its edge crosses the scale at a point which gives the exact refractive index of the stone. The best available liquid is monobromo-naphthalene, which has a refractive power higher than that of topaz, and enables one at a glance to distinguish a cut topaz or any less brilliant gem-stone.

Most useful, again, are the so-called interference figures—the appearances seen on looking through a transparent stone by means of a polarising microscope, such as is used by every geologist. There is, of course, nothing new in these figures; they are now employed by geologists in the study of rocks, and even sometimes by those whose business it is to distinguish precious stones.

Without endeavouring to explain the nature of these figures, except to say that they are due to the double refraction of the crystal, it is easy to show that by looking at a stone through a microscope, one may see something very characteristic.

(The interference figures of several minerals were thrown upon the screen by means of a projection apparatus lent by Prof. Ayrton; sapphire, tourmaline, and emerald were shown to give coloured circular rings intersected by a black cross; sphene and chrysoberyl, coloured oval-rings intersected by a hyperbola; and quartz, coloured circular rings with a black cross having a tinted centre.)

This beautiful method is not employed nearly so largely as it deserves, because most people find it difficult. In order to see the figure it is necessary to look through any given crystal in one certain direction. (The stones used for projection were plates appropriately cut for the purpose). Now it may happen that a facetted stone is so cut that to look along the required direction would be to look through an angular corner; and every one knows that it is not possible to look through a pointed corner, owing to the refraction of the light. For this reason when an unmounted cut jewel is held under the polarising microscope, and yields no interference figure when turned about into various positions, it is usually given up as hopeless. But obviously we have only to immerse the stone in some liquid having nearly the same refractive power as itself, in order to eliminate the difficulty due to refraction. I find that if the stone be placed in a small tube filled with oil or glycerine, and held in various positions, the interference figure can always be seen. Little more than a year ago, a small facetted stone of peculiar appearance was sent to me, which had deceived the experts to whom it had been shown, although agreeing in some respects with quartz, and was supposed to be a new stone. But by immersing it in oil in a hollow glass sphere, I was able to see the characteristic interference figure of quartz. When a stone has the refraction, the double refraction, the specific gravity, and the characteristic interference figure of quartz—it is quartz and nothing else.

Other optical characters of great value are those resulting from the absorption of the light in its passage through a crystal;

some of the colours contained in ordinary daylight are more absorbed than others, and the light emerges more or less coloured; in consequence of differences of absorption, some gem-stones appear differently coloured according to the direction in which one looks through them. I need not dwell upon this curious property because the instrument used to observe it is the one piece of scientific apparatus sometimes, but by no means generally, used by gem experts—I mean the instrument known as the dichroscope. (A diagram, kindly lent by Prof. Judd, illustrated the appearance seen with this instrument.) Far less familiar is the method of studying the absorption by means of the spectroscope, although the value of this extremely simple method was pointed out many years ago by Prof. Church. Every one knows the colours of the spectrum seen by daylight through a glass prism, and it is also well known that if light transmitted through various vapours be appropriately observed through such a prism by means of the spectroscope, certain black lines are seen in the spectrum, indicating that the vapour has absorbed light of a certain colour; in this way astronomers are able, by merely looking at the sun and stars, to ascertain many of the elements which they contain.

But it is not commonly known that a precisely similar effect is produced by many transparent minerals. It is only necessary to look through a pocket spectroscope in a bright light at any transparent mineral containing the rare element didymium, and certain black bands characteristic of that element are at once seen in the spectrum.

(A diagram of the spectrum of the phosphorescent light emitted by ruby when made to glow in the electric discharge in a vacuum tube, lent by Prof. Crookes, though not a picture exactly of what is here described, served to illustrate the appearance of the black bands in the spectrum of a red mineral.)

Now, there are two gem-stones which give very characteristic black bands when looked at through a spectroscope, namely, the jargoon or jacynth, and the variety of garnet known as almandine, commonly called carbuncle. When a stone, say one set in a ring, is looked at in this way, and gives the characteristic spectrum of zircon, it is at once known to be a jargoon without further trouble.

When one remembers how many pocket spectroscopes are bought by people who wish to see the rain-band and predict the weather, it is surprising that it has not also come into use for the examination of gems.

To pass from optical to other characters, there is a very remarkable property possessed pre-eminently by one mineral which has not, so far as I know, been previously recommended as a practical test.

A crystal of tourmaline while being warmed or cooled becomes electrified; one end becomes charged with positive, the other end with negative electricity. The fact has long been known. But a few years ago an extremely pretty and ingenious way of showing the electrification was devised by Prof. Kundt. If a mixture of powdered red lead and sulphur be shaken or blown through a sieve, the particles become electrified by mutual friction, and if it then be dusted upon a crystal of tourmaline which is being warmed or cooled, the positively electrified end of the crystal attracts the negatively electrified yellow sulphur, and the other end attracts the positively electrified red lead; one end of the crystal becomes red, and the other end yellow; and so the difference of electrification is made visible. Now every crystal of tourmaline behaves in this way, and I find it perfectly easy to show the property in an ordinary small jewel, even when mounted in a setting. All that is necessary is to warm the stone, and then, while it is cooling, to dust it with the mixture; at once one part of the stone becomes red, and another part yellow.

(A facetted stone treated in this way was shown upon the screen by reflected light.)

The last character which I have to mention is the one to which I alluded at the beginning, namely, the heaviness or specific gravity. The use of the balance is, as I said, too laborious; but within the last few years an entirely different method has been introduced.

Cork and wood float in water because, bulk for bulk, they are lighter; stone and iron sink because, bulk for bulk, they are heavier than water. But find some substance whose density is exactly that of water, and it will neither rise nor sink, but will remain poised in the water like a balloon in mid-air.

Several liquids have been discovered which are more than three and a half times as dense as water, in which, therefore, amethyst, beryl, and other light stones will actually float. Prof. Church strongly recommended mercuric and potassium iodide; but a still more convenient liquid is now available, namely, methylene iodide. This liquid has a specific gravity of 3·3, so that tourmaline readily floats in it; further, it is not corrosive or in any way dangerous, which is more than can be said for several of the other liquids which have been recommended.

Now it is scarcely possible to prepare a number of liquids, each having the specific gravity of one gem-stone, in order to identify each stone, but methylene iodide is easily diluted by adding benzene to it; each drop of benzene added makes the liquid less dense, and so it may be used to separate tourmaline and all the lighter gem-stones from each other. Nothing can be easier or more satisfactory than this method; no matter how minute the stone may be, it can be identified by its density in a few moments. Suppose it be doubtful whether a certain gem is aquamarine or chrysoberyl, all that is necessary is to place it in a tube of the liquid, together with a small fragment of true aquamarine to serve as an index; if it be a chrysoberyl, which has a specific gravity of 3·6, it will sink like lead; if it be an aquamarine, which has a specific gravity of 2·7, it will float; and if the liquid be then stirred and diluted until the index fragment is exactly suspended, the gem also will neither float nor sink, but will remain poised beside it.

The delicacy and simplicity of the method is marvellous; the only reason why it has not been more generally adopted is that, unfortunately, the greater number of gem-stones are heavier than methylene iodide. What is the use of employing such liquids when they cannot float jargoon, carbuncle, sapphire, ruby, chrysoberyl, spinel, topaz, peridote, and diamond, to mention only those stones whose names are familiar?

But this objection is now entirely removed, thanks to a discovery made quite recently by the distinguished Dutch mineralogist, Retgers. He has found a colourless solid compound which melts, at a temperature far below that of boiling water, to a clear liquid five times as dense as water; and therefore sufficiently dense to float any known precious stone.

This compound is the double nitrate of silver and thallium, and it further possesses a most remarkable property; it will mix in any desired proportion with warm water, so that by dilution the specific gravity may be easily reduced. The fused mass may be reduced in density by adding water drop by drop so as to suspend in succession jargoon, carbuncle, sapphire and ruby, chrysoberyl, and spinel.

This wonderful compound should certainly be employed by all who wish to distinguish gems with ease and certainty.

Let me now remind you how one could apply the methods which I have been describing, to identify with absolute certainty some gem-stone. Take, for example, a cut tourmaline. Dropped into methylene iodide it would just float, and, when the liquid is diluted, it would remain suspended beside an index fragment of tourmaline, and no other gem-stone. Examined with the dichroscope it would show two coloured images, indicating remarkable differences of absorption characteristic of tourmaline, and no other mineral; the absence of absorption bands, when it is viewed through the spectroscope, would show that it is neither garnet nor jargoon; in the polarising microscope it would show the interference figure of tourmaline.

Even if the stone were mounted in a setting so that these tests could not be applied, it could be examined with the reflectometer, the boundary of the shade would cross the scale at a point exactly corresponding to the refractive power of tourmaline; and lastly, it could be warmed and dusted with red lead and sulphur, when the two coloured patches would betray the electrical properties of tourmaline. There is enough evidence here to satisfy any one but an English jury hearing expert witnesses, and everything can be done without inflicting even a scratch upon the stone.

Another mineral character of great value in distinguishing gem-stones in the rough I have not alluded to, because it can only be made use of when they are more or less well crystallised; I mean the shape of the crystals. (This feature was illustrated by some very beautiful photographs of gem-stones and other minerals in their natural state, which were taken from specimens in the British Museum by the distinguished photographic expert, Mr. Hepworth.)

It might be asked, with some show of reason, why should we require all these scientific tests which I have described, when the varieties of precious stones are so few in number? In reality, however, gem-stones are far more numerous than is commonly supposed, although they often pass muster under erroneous names. Tourmaline is sold as ruby, cinnamon stone as jacynth, white jargoon and phenacite as diamond, while green garnets are universally known in the trade as olivine or peridote.

That the varieties of available gem-stones are not far more numerous, is due mainly to the prejudice of purchasers, who ring the changes on diamonds, rubies, sapphires, and emeralds, and have heard of nothing else; estimating the stones, as the public estimates popular actors or authors, not by their real excellence, but by their names.

In the mineral gallery of the British Museum are many examples of cut stones which have rarely or never been employed in jewellery, but should certainly win favour on their own merits.

One very curious example is a little gem cut from a crystal of the ordinary tin-stone, the same ore which is worked for tin in the Cornish mines. This is a stone which, when cut from a sufficiently transparent crystal, possesses a most beautiful lustre and colour.

As another example, I may mention a stone which, I suspect from its appearance, would make a very beautiful gem. It was sent with some other fragments from the ruby mines of Burmah; it is only a single rough fragment, and has completely puzzled every one to whom I have shown it. By means of the very tests which I have been describing, and without sacrificing more than a pin's point of the stone, I have been able to identify it as the boro-silicate of lime known as Danburite. This mineral, if it has ever been used in jewellery. which is most unlikely, has certainly never been rightly named.

(A number of facetted stones lent by Mr. Gregory, who has made many interesting experiments in this direction, were thrown upon the screen by reflected light; among these were several of the less familiar gems, such as tourmaline, chrysoberyl, phenacite, felspar, andalusite, axinite, spodumene, sphene, and idocrase.)

I do not know whether the final impression produced by what I have said, is that the determination of stones is an easy or a difficult thing. The impression which I wished to convey, is that where these scientific tests can be applied, it is an absolutely certain thing; and where they cannot be applied, there is no such certainty.

The crystals from which these gems are cut are changeless and imperishable, their beauty has been enhanced by the art of man, but they have lost none of their wonderful properties in the process; in fact, it is only by utilising these very properties that the lapidary converts them from dull stones to flashing jewels, and it is by these properties that we have to recognise them.

The ruby formed countless ages ago in the heart of Burmah, is the same thing in all essentials as the ruby formed to-day in a Paris laboratory.

It is curious to reflect that the diamond which to-day glitters in a London ball-room, may have adorned the crown of some Oriental monarch centuries ago—may have been picked from the shores of an Indian stream in the dawn of civilisation—may have been the silent witness of the growth and decay of empires—but by its own unchanging existence has always borne steadfast evidence to the everlasting laws of nature.

H. A. Miers.

THE OBSERVATION OF EARTH-WAVES AND VIBRATIONS.

THE object of this communication is to call attention to the apparently high velocity with which motion is transmitted from an earthquake centre to places distant from it a quarter of the earth's circumference, and to the importance of instituting an extended systematic observation of these movements.

During the last few years Dr. E. von Rebeur-Paschwitz and other observers in Europe have recorded earth movements which had their origin in Japan or in other distant countries. Beyond a radius of a few hundred miles from their origin these disturbances are often too feeble to be sensible or to be recorded by ordinary seismographs. Their presence is, however, made known by the use of specially contrived nearly horizontal pendulums, and by these and other instruments we find that they usually have a duration of from ten to thirty minutes, though now and then they last one or two hours. On June 3, 1893, the writer obtained a record lasting 5 hrs. 24 min. In Europe what was probably the same disturbance indicated a movement which continued for about fifteen hours. From observations hitherto made, it seems extremely likely, as Dr. E. von Rebeur-Paschwitz has suggested, that these earth-waves could be recorded at almost any point upon the surface of our globe, while the phenomena they present are such that it is probable that their extended study would throw light, not only upon the manner in which motion is transmitted through the superficial portions of the earth, but also across its interior.

As illustrative of the results to which these records lead, I take those derived from diagrams of several seismographs in Tokyo, and from that of a long pendulum seismograph at Rocca di Papa in Italy, which on March 22, 1894, together with many other instruments in Europe, exhibited considerable motion. The origin of the disturbance was off the N.E. coast of Yezo (Lat. 42° N., Long. 146° E.).

From observations made in Tokyo, distant about 600 miles from the epicentrum, not only upon the initial disturbance, but also four after-shocks, it seems that motion was propagated at an average rate of about 2·3 km. per second. Inasmuch as the instruments from which these records were obtained, are not capable of recording movements of small amplitude, probably this velocity was that of the pronounced vibrations of the quasi-elastic nature characteristic of most earthquakes. There are reasons for believing that such waves outside an epifocal area are practically confined to the surface of the earth. A movement which from the manner in which it slowly affected ordinary or horizontal pendulum seismographs, had probably a similar character, travelled from Japan to Italy with a velocity of from 2·7 to 3 km. per second, the larger waves travelling at the slower rate.

Preceding these decided motions, minute tremors were observed, which, if they originated at the epicentrum and travelled on the surface of the earth, must have done so at a rate of 11·5 km. per second, while if they were created by the transformation of the energy of the partially elastic undulations as they passed from medium to medium, then their velocity of propagation must have been still more abnormal. If it is assumed that they reached Italy by direct radiation through the earth, or that in consequence of refraction they followed curvilinear paths, the observations indicate a velocity of 9 or 10 km. per second.

Considering the influence of gravity upon the propagation of surface undulations, the observed velocities may possibly be a little lower than what might have been expected. The minute tremors, however, seem to have a velocity which is roughly twice that for a condensational rarefactional wave in glass.

Observations upon other earthquakes, although none of them can claim any great degree of accuracy, point to the same general results.

At present, the diversity of instruments employed in Europe, and the various degrees of sensibility given to the few instruments which are approximately similar, apparently results in the recording of different phases of motion, and it is not likely that our knowledge will be increased or made more accurate until there is greater uniformity in the methods of observation.

Now to determine whether the disturbances created by large earthquakes are propagated to distant localities in the manner suggested, much might be learned by establishing twelve or fourteen similar instruments at an equal number of selected stations round the northern hemisphere. It is yet premature to indicate the class of instruments to be employed, but if their chief function is to record the time of arrival and the different phases of these wide-spreading movements, it is the writer's experience that many difficulties may be avoided in installation, adjustment and management, by using a type that is not too sensitive to extremely minute changes of level, such as accompany fluctuations in temperature and changes in atmospheric conditions. All of them should admit of adjustment to a similar degree of sensibility, and so far as possible be attached to similar foundations in localities or places where the effects of tremor storms, which often eclipse the effects due to earthquakes, are not likely to be pronounced. Photographic surfaces on which records are received, should move at a rate of *not less* than two inches per hour, which will enable an observer to determine time intervals to within 30 seconds.

It would seem advisable that the first attempt to make a seismic survey of the world should be tentative. Having obtained the co-operation of observers in selected localities, each of these should be furnished with a similar instrument, and if possible receive personal instruction as to its installation and working. If this is done, then an inexpensive type of apparatus may be employed, which in an ordinary foundation will yield results not much inferior to those obtained from more elaborate arrangements, which subsequently it may be thought desirable to establish.

Although it may only be possible to minimise the effects of tremors, the records of these over extended areas may perhaps present new features. Other movements which are likely to be noted, but which will not influence the recording of movements resulting from distant earthquakes, will be diurnal and other periodic displacements of the pendulums. The records of these, together with those of local earthquakes, could hardly fail in adding to the knowledge we possess about earth movements.

The principal object of the proposal made in the foregoing remarks, is to determine the velocity with which earthquake motion is propagated over the surface of the earth, and possibly through its interior. If it is established that vibratory motion is transmitted with a measurable velocity *through* the earth, it will be difficult to over-estimate the value of the knowledge we shall have gained. The rigid scrutiny of the records bearing on this latter point have to be left to European observers.

At present the writer is engaged in drawing up a report upon the state of our knowledge respecting the velocity with which earth vibrations and waves are transmitted through rock and earth, and in making experiments to determine a form of simple instrument which shall be not only sensible to slight changes of level, but which is also capable of recording vibrations of small amplitude.

Since writing the foregoing, which was printed for circulation amongst a few of my friends interested in this branch of earth physics, I have received Nature of December 27, 1894, in which, on p. 208, Dr. E. von Rebeur-Paschwitz gives a description of the remarkable disturbance of June 3, 1893, to which I have already briefly referred. In July of that year I sent photographs of this record to various acquaintances in Europe. One of these, together with a description of the same, because it was illustrative of a great number of unfelt earthquakes which I had recorded, was sent with the fourteenth report to the British Association on seismological work in Japan during 1893–1894. This report is, I believe, now in the press. The object in calling attention to this matter is to show that this disturbance, wherever it originated, was also pronounced at places far distant from Strassburg, Nicolaiew and Birmingham.

Mr. C. Davison, who writes the introduction to the description of the European records of this earthquake, makes a brief reference to the desirability of having a few well-chosen stations in various parts of the world where earth pulsations might be recorded—a matter on which I have had considerable correspondence with my friend Dr. E. von Rebeur-Paschwitz. At present Mr. Davison considers that Europe is fairly well provided with instruments. Instruments are certainly fairly numerous, but at the same time in many instances they vary in their sensibilities and also in their objects. Judging from the report of the Committee on Earth Tremors to the British Association in 1893, p. 294, it would seem that the instruments in Birmingham and Edinburgh are arranged to be unaffected by rapid tremors, and register "slow earth tilts only," while the tromometers of Italy are, I presume, constructed to record what this name implies. Whether they are able to record "elastic" tremors is a debatable matter. A very good illustration of what the heterogeneity of the instruments at present employed in Europe leads to, is given by Mr. Davison in the records of two earthquakes, contained in the report of the above-mentioned Committee for 1894, which may have had velocities of propagation varying between 1 and 12 km. per second, according to the type of instrument from which records were obtained. The apparent explanation of these anomalies is that different instruments have recorded different phases of motion, and for this reason I have been led to say that it is not likely that our present knowledge will be increased until there is greater uniformity in the methods of observation.

Mr. Davison's remark that "in Japan Prof. Milne's tromometer (as described in British Association Report, 1892, pp. 207–209) leaves little to be desired," requires qualification. As a "tremor" recorder it is excellent, but even as such I have improved it by reducing its length to 30 mm. and its total weight to 0·39 grms. Unfortunately however, because it is a tremor recorder, its movements are such that even on a photographic film only one metre distant, it may during a severe "tremor storm" give a trace which appears as a band two inches in breadth, which eclipses any effects due to distant earthquakes, for the recording of which it is therefore useless. At various times I have experimented with at least a dozen of such contrivances, which from the nature of their construction have necessarily short periods of vibration, and are therefore not sensible to slight tilting. Although I condemn these instruments for the recording of distant earthquakes, I must admit that I am indebted to a pair of them for having first made visible to me the diurnal wave.

In the *Seismological Journal*, vol. iii. p. 60, a sketch is given of a horizontal pendulum, such as I have used to record the daily wave and unfelt earthquakes since November 1893. One of these, which has a boom 5 feet in length, has usually a period of about 50 or 55 seconds. Altogether I have six sets of such apparatus with photographic recording surfaces, together with one or two others, which are read once per day.

These have been installed at and given records from eighteen localities—in caves, in the solid rock, in an underground chamber, and on substantial columns rising from the natural soil.

Although these instruments are exceedingly bad forms for tromometers, by these experiments—each of which continued over several months, during which time continuous records were obtained—much was learned about the localities where "tremor" effects might be avoided.

To solve the problem under consideration it does not seem necessary to have an instrument sensible to less tilting than 1″, and it is certainly undesirable to have one sensible to the phenomena called earth tremors or microseismic disturbances, which appear to have the character of earth pulsations. What is required is an instrument which is susceptible to the tilting produced by the undulatory slow travelling quasi-elastic disturbances of an earthquake, and at the same time is sensible to the minute, and possibly truly elastic vibrations which, both in Japan and Europe, outrace the more pronounced movements. The first object, and to some extent the second, is certainly attained by many instruments in Europe. From the records given by the long pendulum of Dr. Agamennone, of which I have not had an opportunity to see a full description or drawings, I take it that for the preliminary vibrations, the pendulum acts as a steady point, relatively to which the movements are magnified by means of a pointer arranged like that of a seismograph. The larger movements, which have periods of about 16 seconds, may be due to the slow heeling over of the pendulum following the motion of the supporting tower. About these latter movements we already know a great deal, and their velocities of propagation, as determined by the most accurate methods in Japan, do not materially differ from the rate at which the same disturbances continue on their journey to Europe.

What we most require is an investigation of the velocities of propagation of the elastic movements which apparently go from Japan to Europe in 15 or 20 minutes.

If such phenomena exist, and if the European records are correct, their existence is a reality, the instruments to record their repetition must be sensible to small but rapid vibrations; and for the results to be comparable, these instruments must not only be similar in construction, but they must be similarly adjusted and similarly installed.

Within a few days the writer will have completed two instruments differing only in their size, which may be described as conical pendulum seismographs in which the multiplication relatively to their centres of oscillation will be adjustable from about 20 to 40. The registration will as usual be photographic. It is hoped that because the multiplication is large, and because everything is as light as possible, the preliminary tremors (elastic vibrations) may be recorded; while because the booms are long, it is not unlikely that the sensitiveness to tilting will be sufficient to record the slower waves. They will be tested upon a foundation the diurnal tilting of which is known, and where it is also known that tremors (earth pulsations) are seldom met with.

John Milne.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 21.—"A possible Explanation of the two fold Spectra of Oxygen and Nitrogen." By E. C. C. Baly.

The two spectra of oxygen are shown to be of a different nature. They behave differently, and reasons are given for their being in all probability the spectra of different gases. They may either be two spectra produced by different vibrations of the oxygen molecule, or they may be the spectra of two different modifications of oxygen, or the spectra of two distinct gases resulting from a dissociation of oxygen, a combination of which is called oxygen.

It appeared worth while to undertake experiments with a view of testing the last of these. Oxygen was sparked in an apparatus similar to that used by Prof. J. J. Thomson in his experiments on the electrolysis of steam. Hollow platinum electrodes were used, each one of which was connected with a Sprengel mercury pump. In the first experiments, the distance between the electrodes was 35 mm., and the highest pressure compatible with the appearance of the two spectra was made the starting point of the experiments. In these first experiments it was 380 mm. The density of the oxygen before sparking was determined, and taken as a test of its purity. The fractions obtained from the anode and cathode were weighed, and the results are given. They follow the lines of J. J. Thomson's results, inasmuch as with long sparks a lighter fraction was obtained at the cathode, and with short sparks a heavier fraction. The fractions from the anode were not so definite as from the cathode, though the difference was in the right direction. The probable maximum error of weighing was 0·0001 gram. This meant exactly one in the second decimal place of the density obtained. The general accuracy of the results may be gauged from the densities of unsparked oxygen obtained.

Density of cathode fraction with long sparks.		Density of oxygen unsparked.		Density of cathode fraction with short sparks.

15·79	...	15·88	...	16·04
		15·88	...	16·06
				16·05

Mean of results of other observers = 15·887.

Density of cathode fraction from oxygen, previously for three days fractionated with short sparks, 15·75.

The experiments are still in progress.

Physical Society, March 22.—Mr. R. T. Glazebrook, F.R.S., in the chair.—On the objective reality of combination tones, by Prof. A. W. Rücker and Mr. E. Edser. The question as to the objective or subjective nature of combination tones has excited much keen controversy, and the authors have devised some experiments to elucidate this point. These experiments, some of which were exhibited before the Society, show that under certain conditions difference and summation tones are produced which are capable of disturbing resonating bodies. As resonator they have, in the first instance, employed a tuning-fork. A piece of thin wood, about 5 in. square, is attached to one of the prongs of this fork, while a silvered glass mirror is attached to the other, and the pitch of the fork is very accurately adjusted to sixty-four complete vibrations per second. In order to detect any movement due to resonance set up in this fork, the mirror carried by the prong forms part of a system of mirrors for producing Michelson's interference bands. By this means a movement of the prongs of the fork of 1/80,000 of an inch (half a wave-length of light) is shown by the disappearance of the interference bands. As a source of sound a siren was employed, this being one of the instruments which Helmholtz recommends as giving the best results. The pitch of the notes given by the siren was adjusted by noting the disappearance of the beats produced by one of the notes with a bowed fork, or by a stroboscopic method. A large wooden cone, placed between the siren and the resonating fork, served to concentrate the sound on the wooden disc attached to this latter. The sensitiveness of the arrangement is such, that when a large Köenig standard fork, giving sixty-four vibrations per second, is struck so lightly that an observer, with his ear close to the fork, cannot detect the fundamental note, the bands instantly disappear. The apparatus, however, is unaffected by any other note, except one of sixty-four vibrations per second. A number of experiments have been made, using various rows of holes on the siren, and in every case when the summation or difference tone corresponded to sixty-four vibrations per second, the interference bands vanished, showing that under the conditions of the experiment these tones have an objective existence. An experiment has also been made to determine whether Köenig's lower beat tone when the interval is greater than an octave is objective. In this case, however, the authors entirely failed to get any evidence of such an objective existence. A number of experiments have been made with a view to elucidating the cause of the production of the summation tone, which tend to show that it is not the difference tone of the partials of the fundamental notes. In addition to using a tuning-fork to detect the combination tones, the authors have made use of an instrument originally devised by Lord Rayleigh. A light mirror is suspended by means of a fine quartz fibre, and hangs in the neck of a resonator, tuned to the given note, and when at rest is inclined at 45° to the axis of the resonator. Under these circumstances, when the resonator responds the mirror tends to turn and set itself at right angles to the direction of motion of the air in the resonator. The results obtained with this instrument are in complete accord with those obtained by the first method. Up to the present the authors have failed to obtain any evidence of the objective reality of the combination tones produced by organ-pipes and tuning-forks (see p. 474). The discussion on this paper was postponed till after the reading of the next paper.—Some acoustical experiments, by Dr. C. V. Burton. (1) On the subjective lowering of pitch of a note. The author has noticed that if a tuning-fork, mounted on a resonator, is strongly bowed, then if the ear is placed near the opening of the resonator the pitch of the note heard appears lower than when the fork is bowed very gently or is held at some distance. This subjective lowering of pitch is most marked with forks of low pitch; and in the case of a fork giving a note of 128 complete vibrations per second, amounts to about a minor third. The author suggests an explanation depending on the supposition that the basilar membrane of the ear behaves as if it consisted of a number of stretched strings of various lengths, each resounding to a given note; and that the appreciation of the pitch of a note depends on the localisation of the part of the basilar membrane which resounds most strongly. Further, he shows that in the case of a stretched string, for finite displacements, the string which most strongly resounds to any note will have a "natural" period longer than the period of the disturbance; the greater the disturbance the longer will be the natural period of the strings most strongly affected. Hence when the intensity of a note increases, the tract of the basilar membrane most strongly affected is displaced in the direction which corresponds to the perception of lower notes. (2) Objective demonstration of combination tones. Where two organ-pipes are sounded and alternately separated and brought close together, an observer, at some distance, hears the difference tone much more clearly when the pipes are close together than he does when they are separate. As the position of the pipes with reference to his ear does not appreciably change, the change in the intensity of the combination tone indicates that it has a real objective existence. The author mentioned that he had sounded his two pipes, which give a difference tone of 64 vibrations per second, before the collector of Prof. Rücker and Mr. Edser's apparatus, but without obtaining any motion of the interference bands, and that he was therefore less confident of the correctness of his deductions than he had been before. Mr. Edser mentioned that Dr. Burton had suggested an explanation of the production of objective tones in the case of the siren, which depends on the production of the tones in the wind-chest of the instrument itself when two rows of holes are simultaneously opened. They had made an experiment which seemed to show that the above explanation was incorrect, for on connecting together the wind-chests of two sirens, fixed on the same spindle, by means of a short length of wide metal tubing, no effect was observed on the bands when the two notes were produced on different instruments having what was practically a common wind-chest.—Prof. Everett (communicated) said he considered the experiments described in the paper proved conclusively the objective existence of the summation tones as distinguished from supposed beat tones. He had lately been investigating the pitch of the loudest combination tone obtained when two notes having frequencies as 3 to 5 are sounded. Is the frequency of this tone 2, *i.e.* the first difference tone, or is it 1, which corresponds to the first term of the Fourier series for the periodic disturbance? In the chords 2 to 3, 3 to 4, 4 to 5, &c., the difference of the integers being unity, the first difference tone is identical with the first Fourier tone. When the difference of the two integers which express the chord is not unity, then the writer considers that experiments he has made with strings and pipes, show that the first Fourier term is usually the only combination tone that is audible. Prof. S. P. Thompson considered that care should be taken to define what we mean by the subjective or objective existence of a note. There are two very delicate methods which have already been employed for detecting the existence of a given note in the air. (1) The formation of ripples on a soap-film stretched over the opening of a resonator tuned to the required pitch (Sedley Taylor); (2) the sounds produced in a telephone connected to a microphone placed on a thin elastic membrane stretched over the neck of the resonator (Lummer). It was very important to limit our acceptance of the demonstration of the objectivity of combination tones, given by the authors of the paper, to the case actually proved, *i.e.* to tones produced by the polyphonic siren. It did not necessarily follow that if pure tones produced by tuning-forks were used, the same results would be obtained. A number of experiments had been made by Zantedeschi in 1857, in which two notes were sounded, and skilled musicians were asked to record their impression of the third tone present. In 75 per cent. of the cases the note recorded was the difference tone; in the remaining 25 per cent. it corresponded to Köenig's beat tone. Köenig himself had never heard the summation tone in the case of lightly-bowed forks. Voigt in a theoretical paper has shown that if there are two disturbances whose mean kinetic energy differ, the Helmholtz tones will be produced; but that if the mean kinetic energy of the two disturbances are equal, the Helmholtz effects soon die out, and you get beat tones or beats. He (Prof. Thompson) considered that Dr. Burton had allowed his perception of tone to be governed by the quality of the note, and that the apparent lowering of pitch was due to the variation in the intensity of the overtones present. In reply to Prof. Thompson, Dr. Burton said he did not merely perceive a lowering of pitch, but he was able to estimate the change in pitch, and say at what instant, as the vibrations of the fork died out, the lowering amounted to a tone or half a tone, &c. Mr. Boys said he found that by careful attention he could apparently persuade himself that the note in Dr. Burton's experiment was lowered or raised in pitch, or that it remained unaltered. A similar effect in the case of the eye could be obtained with a stereoscopic picture. The Chairman considered that, while Helmholtz' explanation of the production of combination tones might be real, it did not follow that this explanation gave the sole cause of their formation. In particular, Helmholtz does not explain why the tones should only be produced by some sources of sound. Prof. Rücker, in his reply, said he did not deny the existence of Köenig's beat tones; in fact, he had heard them. They did not lay much stress on the negative result of the experiment they had made to test the objective existence of these beat tones.

Zoological Society, March 19.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Lt.-Col. H. H. Godwin-Austen, F.R.S., presented a paper on behalf of Mr. Walter E. Collinge, and himself, "On the Structure and Affinities of some new Species of Molluscs from Borneo." Three new species were described, viz. *Damayantia smithi*, *Microparmarion pollonerai*, and *M. simrothi*. Details were given of their structure and comparisons instituted with other members of the genera and allied Indian genera. One of the most interesting features, perhaps, was the similarity they show anatomically to shell-bearing molluscs of Borneo. That these slug-like forms of Borneo have the same close relationship to the shell-bearing mollusca among whom they are now found living, as the Indian forms bear to *Macrochlamys* and allied shell-bearing genera, there can be little doubt, and any true attempt at classification must be based on these lines, and would place a wide gulf between *Girasia* and *Austenia* on the one side, and *Parmarion* and *Microparmarion* on the other.—Mr. F. E. Beddard, F.R.S., read a preliminary account of new species of earthworms belonging to the Hamburg Museum. These worms belong chiefly to the genera *Acanthodrilus* and *Microscolex*, and had been collected in South America.—Prof. F. Jeffrey Bell communicated, on behalf of Prof. Alphonse Milne-Edwards, Jardin des Plantes, Paris, the description of a new species of crab of the genus *Hyastenus*, obtained near the Straits of Magellan during the *Challenger* Expedition, and proposed to be described as *H. consobrinus*.—Dr. A. G. Butler gave an account of two collections of Lepidoptera received by the British Museum. One from Zomba, made by Mr. J. McClounie, remarkable for the number of specimens of the fine Butterfly genus *Charaxes* it contained. The other made at Fwambo, Lake Tanganyika, by Mr. Alexander Carson, interesting as including not only rare species previously only received from Zomba and Lake Mweru, but several novelties, the finest of which was *Junonia pavonina*, a new form allied to *J. artaxia*.—Mr. P. Chalmers Mitchell read a paper in which he gave a description of the proventricular crypts he had found in a specimen of the African Tantalus (*Pseudotantalus ibis*) recently living in the Society's Gardens.

Entomological Society, March 20.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. H. St. John Donisthorpe exhibited a living female of *Dytiscus marginalis*, with elytra resembling those of the male insect. Dr. Sharp, F.R.S., said he had seen this form before, but that it was very rare in this country, though abundant in some other parts of the palæarctic region. Prof. Stewart asked if the genitalia had been examined. Mr. Champion stated that Mr. J. J. Walker had collected several females of an allied species (*Dytiscus circumflexus*) at Gibraltar with elytra resembling those of the male.—Dr. Sharp exhibited specimens of *Brenthus anchorago*, from Mexico, showing extreme variation in size. He remarked that the males varied from $10\frac{1}{2}$ mill. in length to 51 mill.; the female from $9\frac{1}{2}$ mill. to 27 mill. In the male the width varied from $1\frac{1}{3}$ mill. to 4 mill. The length therefore varied from about 5 to 1, and the width from 3 to 1 in the male.—Mr. Blandford commented on the difficulty of mounting minute Lepidoptera, Diptera, Neuroptera, &c., and exhibited samples of strips of material which he had found most suitable for the purpose of staging minute insects. He said his attention had been called to this method of mounting by the receipt of specimens from Dr. Frič, of Prague. On examination of the material he found it to be a fungus, *Polyporus betulinus*. He stated that Lord Walsingham had expressed his satisfaction with this material, and had sent him specimens, similarly mounted, from Zeller's collection. Mr. McLachlan, F.R.S., remarked that he thought the material exhibited preferable to artichoke pith, which had been used for a similar purpose.—Mr. Goss exhibited a species of a Mantid, *Pseudocreobotra Wahlbergi*, Stål, received from Captain Montgomery, J.P., of Mid-Illovo, Natal.—Mr. Frederick A. A. Skuse communicated a paper, entitled "On a colour variety of *Heteronympha merope*, Fab., from New South Wales," and sent coloured drawings of the typical form and the variety for exhibition.—Mr. Oswald H. Latter read a paper, entitled "Further notes on the secretion of potassium hydroxide by *Dicranura vinula* (imago) and similar phenomena in other Lepidoptera." The paper was illustrated by the oxy-hydrogen lantern. Prof. Meldola congratulated Mr. Latter on the thorough way in which he had worked out his experiments, and said that in view of the small quantity of material at his disposal, the concordance in the results was remarkable. He added that Mr. Latter had, for the first time, proved the secretion of free potassium hydroxide in the animal kingdom. Mr. Blandford, Mr. Merrifield, and Dr. Dixey continued the discussion.—Mr. Merrifield read a paper, entitled "The results of experiments made last season on *Vanessa C-album* and *Limenitis sibylla*." This was illustrated by an exhibition of specimens of *L. sibylla*, and a long series of *V. C-album*, to show the effects of temperature in producing abnormal forms. Dr. Dixey said that many of the forms of *V. C-album* exhibited reminded him of *V. C-aureum*, a Chinese species, which he believed to be one of the oldest forms of the genus. He thought that much of the variation shown in this series of specimens was due to atavism, and was not directly attributable to the effect of temperature. Mr. Barrett said he was interested to find that one of the forced forms of *L. sibylla* was similar to a specimen he had seen which had emerged from the pupa during a thunderstorm. In connection with Mr. Merrifield's paper, Mr. F. W. Frohawk exhibited a series of 200 specimens of *V. C-album*, bred from one female taken in Herefordshire, in April 1894. The series consisted of 105 males and 95 females, and included 41 specimens of the light form, and 159 of the dark form. Prof. Meldola, in proposing a vote of thanks to Mr. Merrifield, Dr. Dixey, and Mr. Frohawk, said that he was glad to think that the subject of seasonal dimorphism, which had been first investigated systematically by Weismann, was receiving so much attention in this country. He was of opinion that the results hitherto arrived at were quite in harmony with Weismann's theory of reversion to the glacial form, and all the evidence recently accumulated by the excellent observations of Mr. Merrifield and others went to confirm this view as opposed to that of the direct action of temperature as a modifying influence.

Mathematical Society, March 14.—Major P. A. MacMahon, R.A., F.R.S., President, in the chair.—The President announced that he had written letters of condolence to Lady Cockle and Mrs. Cayley, and had received their acknowledgments of receipt of the same, which he communicated to the meeting.—Prof. Hill, F.R.S., communicated a paper, by Mr. F. H. Jackson, entitled "Certain Π Functions," and the President (Mr. A. B. Kempe, F.R.S., in the chair) read a paper on the perpetuant invariants of binary quantics.—Lieut.-Col. Allan Cunningham, R.E., gave a proof that $2^{197}-1$ is divisible by 7487.—The President read a letter from the Rev. T. C. Simmons, announcing what the writer believed to be a "new theorem in Probability."

PARIS.

Academy of Sciences, March 25.—M. Marey in the chair.—On the theory of surfaces and of algebraical groups, by M. Émile Picard.—New researches by Prof. Ramsay on argon and on Helium, communicated by M. Berthelot. A letter from Prof. Ramsay was read describing the spectrum of argon obtained from clèveite and the discovery of Helium.—Remarks on the spectra of argon and of the aurora borealis, by M. Berthelot. During the author's recent experiments on the condensation of argon with benzene vapour under the influence of the silent discharge, a magnificent greenish-yellow fluorescence was observed. Its spectrum consisted of a series of lines and remarkable bands. So far as the experimental conditions allowed of comparison, this spectrum recalled that of the aurora borealis. It is suggested that this phenomenon may possibly be due to the formation of some fluorescent combination of argon in the upper regions of the atmosphere under electrical influence.—Researches on the metals of Cerite, by M. P. Schützenberger. The preparation of cerium sulphate in a state of such purity as to admit of accurate determinations of the atomic weight of cerium is described. The value 139·45 is obtained for this constant by a special process of estimating the sulphuric acid in this sulphate. It is shown that other methods of obtaining the atomic weight give unreliable results. Taking various fractions of the sulphate on recrystallisation, the later fractions give a much less value for the atomic weight of cerium than the earlier ones.—Observations of Charlois' planet BU, made at Toulouse observatory, by MM. B. Bailland and Rossard.—Observations of Wolf's planet BT (March 16, 1895), made at Besançon observatory, by M. H. Petit.—A general property of axoids, by M. A. Mannheim.—On lines of curvature, by M. Thomas Craig.—On the theory of equations to the derived partials, by M. Wladimir de Tannenberg.—On linear equations to the derived partials, by M. Emile Borel.—On the movement of projectiles in the air, by M. Chapel. A series of four equations are given which supply a complete solution to the ballistic problem for speeds ranging between 300 m. and 1100 m.—On the extension to magnesia of a method of synthesising fluorides and silicates, by M. A. Duboin. The compounds $MgF_2 . KF$, $MgF2 . 2KF$, and $MgO . K_2O . 3SiO_2$ are described and their optical and chemical properties given.—On a new method for the preparation of chloroplatinous acid and its salts, by M. Léon Pigeon. Reduction of chloroplatinic acid in accordance with the equation,

$$BaPtCl_6 + BaS_2O_6 + 2H_2O = H_2PtCl_4 + 2HCl + 2BaSO_4,$$

is employed. Following the method given in detail, the yield is almost theoretical—Heat of formation of calcium acetylide, by M. de Forcrand. The heat of formation of solid C_2Ca from diamond and solid Ca is −7·25 Cal., substituting amorphous carbon it is −0·65 Cal., for gaseous carbon it is +76 95 Cal.—Action of ortho-amidobenzoic acid on benzoquinone, by MM. J. Ville and Ch. Astre.—Alterations in saccharine matters during the germination of barley, by M. P. Petit. The conclusions are drawn: (1) There is a relation between the quantities of reducing sugars and of saccharose existing in barley during its germination. (2) The formation of saccharose commences even during the damping, whereas reducing sugars remain nearly constant during the same period. (3) The variation of reducing power represents the activity of respiration.—Chemical process for the purification of water, by MM. F. Bordas and Ch. Girard. Calcium permanganate is employed to oxidise the organic matters, and the excess of this salt is removed by treatment with lower oxides of manganese. The treatment recommended removes organic matter also by physically precipitating it from the water, which, after treatment, contains no micro-organisms, and very little calcium carbonate.—On the wheat produced on a saliferous soil in Algeria, by MM. Berthault and Crochetelle.—On the abnormal fronds of ferns, by M. Ernest Olivier.—Origin and division of granular nuclei in large sarcomatous cells, by MM. O Van der Stricht and P. Walton.—A note, by M. Delaurier, concerning an easy method of obtaining a perfect vacuum without mechanism, deals with the production of a vacuum by absorption, as with oxygen and iron at a red heat.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Birds, Beasts, and Fishes of the Norfolk Broadland: P. H. Emerson (Nutt).—Balistique des Nouvelles Poudres: E. Vallier (Paris, Gauthier-Villars).—La Théorie des Procédés Photographiques: A. de la Baume Pluvinel (Paris, Gauthier-Villars).—La Distillation: E. Sorel (Paris, Gauthier-Villars).—Dissections Illustrated: C. G. Brodie, Part 4 (Whittaker).—Methodisches Lehrbuch der Elementar Mathematik: Dr. G. Holzmüller, Dritter Teil (Leipzig, Teubner).—A Primer of Evolution: E. Clodd (Longmans).—Geometrical Conics: F. S. Macaulay (Cambridge University Press).—Standard Dictionary, Vol. 2 (Funk and Wagnalls).—Outlines of Zoology: J. A. Thomson, 2nd edition (Pentland).—The Book of the Dead. The Papyrus of Ani in the British Museum: Dr. E. A. W. Budge (British Museum).

PAMPHLETS.—Report of the Meteorological Council to the Royal Society for the Year ending March 31, 1894 (Eyre and Spottiswoode).—Stonyhurst College Observatory. Results of Meteorological and Magnetical Observations, 1894: Rev. W. PHYSIOLOGY OF THE EXCITABLE TISSUES.

Electrophysiologie. Von W. Biedermann, Professor der Physiologie in Jena. (Jena: Fischer, 1895.)

PROF. BIEDERMANN, who was not many years ago promoted to the chair of Physiology at Jena, is well known as having co-operated with Prof. Hering in a very extended series of researches on the "general physiology of muscle and nerve," of which the results have been communicated to the Vienna Academy from time to time during the last twenty years. The present work will be welcomed by physiologists in the hope that it will not only place at their disposal the rich harvest of the author's persevering labours in this field of inquiry, but that it will afford to him the opportunity of dealing more completely than has hitherto been possible with one of the most fundamental characteristics of the animal organism—its power of responding in a specific way to stimulation. This being, as we learn from the introduction, the purpose of the book, the title "Electrophysiologie" may seem scarcely suitable, for however intimate and essential may be the relation between vital processes and the electrical phenomena which accompany them, these, after all, are only concomitants, and must be thought of apart from the process itself. However this may be, the author makes it quite clear that his scope is not electrical, but purely physiological. Referring to the "Muskel-physik" and the "Nerven-physiologie" of Prof. Hermann, published in 1880, he declares it to be his purpose to bring the subjects therein treated up to date, and in doing so to follow the true physiological method.

"In morphology it is obvious that we must proceed from the simple to the more complicated, but in physiology . . . the opposite is in a certain sense the case. Under the apparent simplicity of an amœba manifold physiological functions are latent." "The most various duties are performed by the same protoplasm, whereas in the higher animals each particular cell is devoted to a specific function, and consequently affords a better subject of study than the protozoon, when the nature of that function is to be determined." It is for this reason that "our knowledge of contraction and of the processes which are associated with it have been advanced infinitely more by muscle physiology than it ever could have been by the microscopical examination of the lower organisms." (p. 1.)

The volume before us is the first part of a work which is to include the whole of the physiology of the "excitable tissues." Its 440 pages relate directly to muscle, but also comprise the electromotive properties of epithelial and gland cells. In accordance with the general principle that the study of structure must precede that of function, the book opens with a very useful chapter of anatomical prolegomena, in which, beginning with a section on the contractile fibres of the stem of vorticella, the author proceeds to the epithelial nerve-muscle cells of the cœlenterates, and so on to those of the worms. Then come in order the muscular elements of Mollusca (Lamellibranchs and Gasteropods), of interest as showing the striking relation of structure to physiological endowment. Next we have before us the simplest forms of muscle-cells in vertebrates, and finally the structure of striped muscle, with reference to which we again find that the relations between anatomical characteristics and functions receive more attention than the endless questions of histological detail which, in the minds of most students, are associated with this subject.

Of the 340 pages given to the physiology of muscle, scarcely a third relate to its electrical properties. These comprise four sections. The first and second deal with the electromotive phenomena of muscle at rest and in action; the third relates to the so-called "positive variation"; the fourth to secondary electromotive actions. Throughout it is felt that Biedermann writes as a physiologist, not as a physicist, availing himself of the best physical methods to investigate phenomena, but regarding them not as the thing itself, but merely as indications, by the aid of which the time and place relations of vital processes become known to us. In this tendency to take things as they are, postponing theoretical speculations, until the results of the more exact methods of observation which we are now only beginning to know how to use, have been systematised, Biedermann is happily at one with all the leaders of thought and work in this field of inquiry.

Among the most interesting of the observations by which Prof. Biedermann has contributed to the advance of what may, in the truest sense, be called *elementary* physiology, are those by which, in co-operation with his master, and, it may be added, in language not unfamiliar to English students, he has sought to work out that notion of *ana* and *cata*, or of A and D, as Hering puts it, in accordance with which the influences exercised by one part of the organism on another through the nervous system, are regarded as manifestations of two antagonistic tendencies, the one quelling, the other exciting in its nature. This principle, which Prof. Hering first invoked to explain certain antagonisms relating to the perception of colour, has served Biedermann as a guide in the study of similar antagonisms in the behaviour of muscles, and he has furnished us with several instances showing that in the responses of muscles to the stimulation of their nerves, we may have to do not with spur only, but with a mixture of spur and bridle, a co-operation of quelling and exciting influences conveyed to the responding muscle by the same channel—its motor nerve.

In Biedermann's very interesting third section, the reader will find this subject fully discussed. The gist of what he has observed is as follows:—The change of form by which a muscle responds to stimulation of its nerve is not always, as is ordinarily the case, of the nature of shortening or contraction. Under certain well-ascertained conditions the "normal" effect is reversed: the muscle relaxes. By comparison of the instances in which this happens, we learn that the anomaly (if we are to call it so) depends on the terminal organ, not on the nature of the stimulus, or on the channel by which it is conducted. For it is found that muscles which normally exhibit no tendency to respond by relaxation, acquire that tendency when they have undergone "modification," either by the persistent action of

 B B

certain external causes or under exceptional physiological conditions; and, moreover, that in certain invertebrates the constant condition of the muscles corresponds rather to the modified than to the ordinary state of the muscles of the higher animals. If we proceeded to inquire in what this modification consists, Biedermann's answer would be that it may be distinguished in all cases by its electrical concomitants—all "modified" parts being relatively negative to similar parts which are unmodified. Thus when the adductor muscle of the nipper of the crayfish, which is normally in a state which resembles the "modified" state of an ordinary muscle, passes into a condition corresponding to that which is normally present in the muscles of the frog, a change takes place in the electrical relations of the structure of such a character that the sign of the electrical response to stimulation is reversed; it becomes negative instead of positive. Comparing these facts with others relating to vision, with the processes of secretion, and with other processes under the immediate control of the nervous system, one is encouraged in the hope that the relations between *ana* and *cata*, between rest and activity, between restoration and exhaustion, between integrity and hurt, will eventually be linked together by their electrical concomitants, and that by these characters it may be possible to ascertain with exactitude and certainty in how far these various antagonisms may be referred to a common principle.

Space will not allow us to give an account of the last chapter in Prof. Biedermann's book, which contains much that is new and important relating to the electromotive phenomena of secreting cells. Enough has been said to satisfy the physiological reader that the book is one which will have permanent value. It is, moreover, readable. The author tells us in his preface that he has done his best to get rid of "lehrbuchmässige Trockenheit." We think that he has fairly succeeded.

J. Burdon Sanderson.

THE PHYSIOLOGY OF PLANTS.

A Popular Treatise on the Physiology of Plants, for the use of Gardeners, or for Students of Horticulture and of Agriculture. By Dr. Paul Sorauer, Director of the Experimental Station at the Royal Pomological Institute in Proskau (Silesia). Translated by F. E. Weiss, B.Sc., F.L.S., Professor of Botany at the Owens College, Manchester. (London: Longmans, 1895.)

Of all the sections into which the teacher of botany must divide his subject, perhaps the most difficult for him to deal with is that of vegetable physiology. No adequate elementary text-book has hitherto existed in English, the classical works of Sachs and Vines being, by their very completeness, too bulky and too full of detail for the student who is beginning the study of the subject. The work of Dr. Sorauer is intended to supply this deficiency. It is written especially for those whose interest in the matter is a practical one, and it deals, consequently, mainly with those questions which are of interest to the horticulturist as bearing on the problems of cultivation. Approaching the matter, however, from this side only, the book, as a work on physiology, to a certain extent comes short of what is needed, as many important sections of the subject are left untouched.

The author deals almost entirely with the problems of nutrition and their bearings on the details of horticultural practice. At the outset he strikes a rather heavy blow at what has hitherto been, unfortunately, the prominent idea of most agriculturists and horticulturists as to what constitutes the scientific side of agriculture. The latter has been held to embrace little or nothing beyond the chemistry of the soil, and everything not directly connected with this has been pushed into a secondary position, the metabolism of the plant and the chemical changes of its constituents being generally very superficially treated and held of not very great interest. It certainly seems strange that those who have been engaged especially in the cultivation of sensitive organisms under very varied and rapidly changing conditions should have given so little attention to the physiological peculiarities which these organisms present, and to their power of availing themselves of the various advantages that their environment offers to them. Dr. Sorauer, at the outset, strikes the right line when he points out that the chemistry of the soil, important as it is, plays only a secondary part in the development of the various plants which that soil supports, and directs his readers' thoughts chiefly to the problems of nutrition which the plant itself offers for consideration, showing that it is the business of the cultivator to endeavour to guide the natural development of the plant towards the special ends which are the needs of horticulture.

This idea, put prominently forward in the opening chapters, runs throughout the whole of the book. In developing it, the interactions between the soil and the plant, or between the plant and the atmosphere, are kept in the foreground, so that the gardener may realise that he is face to face with an actual struggle that is going on continuously between the organism and its environment, and that he is working to secure that in this contest those conditions of the latter may be secured which are most favourable to the success of the organism, and hence to its most complete development.

In the earlier chapters of the book, the author treats successively of the several members of the plant, the root, stem, leaf, flower, and fruit. Without going very deeply into their anatomical structure, he explains it sufficiently for the student to get an adequate comprehension of the duties or functions which are especially discharged by each. Again his mode of procedure is sound, as it is only function that gives the clue to the right interpretation of structure. The method, as carried out by Dr. Sorauer, is, however, open to a little objection, as it has led him rather to push too far the idea of the several members of the plant living for themselves, and to relegate a little to the background that of the plant being an organic whole, differentiated in different directions for the carrying out of different functions. Thus the leaf is spoken of as passing off into the vascular bundles of the axis only such materials as it cannot at once employ for its own growth, leading the student probably to the conception that the latter problem is for the leaf the primary one, and that the nutrition of the whole organism is only subsidiary when the relation of leaves to the rest of the plant is considered.

The chapters on the general processes of horticulture; the correlation of stems and roots, and their separate treatment; the principles of manuring; the theories of the proper supply of water to the plant, the aëration of its roots, &c., will be read with much attention, and will be found very useful in actual practice. The deposition of nutritive material in various parts of the plant, and the ways in which this can be influenced by different modes of treatment of the shoot at different ages, deserve careful study. The relation of such questions to the operations of pruning, grafting, &c., is discussed at some length, and the development of vegetative or fruiting branches respectively, is shown to be capable of great modification in the hands of the skilled horticulturist.

The book, however, though a valuable one for practical gardeners, leaves something to be desired as a contribution to the literature of vegetable physiology. Indeed some of the fundamental facts of the metabolism of the cell are, if not inaccurately, at any rate not clearly stated. The absorption of water is certainly one of the most important processes which it carries out. As described on p. 127, the early changes in the young cell connected with this process are stated as follows:—

"Very soon there arise within the protoplasmic mass which fills up the cells, very small quantities of liquid substance (cell-sap) which collect together to form small vesicles (vacuoles), and these give to the protoplasm a foam-like structure. Now, as the protoplasm becomes used up during the elongation of the cells, the vacuoles increase in number, run together, and force the remainder of the protoplasm outwards towards the cell wall."

Put in this way, the student would get the idea that the elongation of the cells takes place apart from the entry of water, and that the formation of the vacuole, that is, the increase of the cell-sap, is rather the result than the cause of the extension of the cell. No statement is made as to the cause of the entry of the water, the osmotic activity of the cell-contents, which really underlies all cell-growth.

Another strange statement is that the main cause of the growth in length of a young stem is the longitudinal tension in the pith, which "drags the young ring of wood with it, as long as the latter is still soft and thin-walled." This will be a new view to most physiologists.

Dealing with the absorption of nitrogen by certain leguminous plants, and the recently established fact that the atmosphere is a source of supply of this constituent, the author commits himself to the view that this absorption is carried out by means of their leaves.

In section 23, which treats of the substances formed by the leaves, we find several statements to which exception must be taken. The classification of the vegetable proteids is inaccurate, the latter being said to consist of albumins, caseins, and fibrins. Albumins are extremely rare in plants, and fibrin resembling animal fibrin is unknown. Globulins, which are numerous and varied, and albumoses, which have comparatively recently been investigated, are not even mentioned. The formation of starch grains in the leaves is thus described—

"When the light shines on the leaf its transpiration is exactly increased, and its cells lose some of their water; then we may imagine the starchy substance to be forced out of the thickened (concentrated) cell-sap, and the latter will become more liquid."

The nutrition of the cell is summed up in the remarkable sentence:

"The nutrition consists in this, that the raw materials which enter the cell are attracted, now by one, now by another of the constituents of the cell, and adopt its specific movements, and are thus transformed with the same substance (assimilated)."

These drawbacks to an otherwise valuable work make one regret that Prof. Weiss has confined himself to translating Dr. Sorauer's text. Had he rather edited than translated it, no doubt we should have found the English edition free from these defects.

MINES AND MINERALS.

Traité des Gîtes Minéraux et Métallifères. Cours de Géologie appliquée de l'École Supérieure des Mines. By E. Fuchs and L. de Launay. (Paris: Baudry, 1893.)

Étude industrielle des Gîtes Métallifères. By George Moreau. (Paris: Baudry, 1894.)

IN these days, when memoirs and papers follow in rapid succession, the geologist and the miner are justly grateful to any careful compiler who will aid them to keep pace with the ever-widening flood of technical literature. The debt of gratitude is increased when the task is undertaken by a writer like Prof. de Launay, who brings together into one colossal work the results of the labours of his master, the late Prof. Fuchs, and of his own personal researches.

The book is a treatise upon applied geology, which Fuchs defined as the application of geological knowledge to seeking and working mineral deposits. Very rightly Fuchs took a wider basis for his course of lectures at the Paris School of Mines than mere ore deposits. He recognised the fact that the mining engineer of to-day must be a man of wide attainments, capable of giving an opinion upon all sorts of mineral workings, reporting upon gold mines in one journey, upon gem-diggings in the next, and a little later being asked to determine the value of deposits of phosphate of lime or other earthy minerals. For work of this description Prof. Fuchs' lectures formed an admirable kind of training, which has too often been neglected in the past; in fact, until this treatise appeared, many geologists may have failed to realise the vast importance of the subject.

While admitting that various systems of classification may be adopted, Prof. de Launay says that he felt bound to arrange his minerals according to the metalloid or the metal, and he chooses the so-called chemical order. In a huge book of this description, alphabetical order would have been more convenient, and would have prevented some of the anomalies which cannot help striking the reader. The chloride, carbonate, and sulphate of sodium appear under the head of that metal, whilst the borate and nitrate are classed respectively under boron and nitrogen; again, chalk and gypsum are brought under calcium, whilst apatite is placed under phosphorus, no doubt for the reason that the non-metallic element is the one to which the mineral more especially owes its commercial importance. While slate is sandwiched in between the gems, under the heading "Silica and Silicates," clay is relegated to "Aluminium."

In a general treatise upon mineral deposits, exception may fairly be taken to the absence of any mention of coal; the author excuses himself on the ground that fuel forms a special subject too vast to be included within the compass of his book. The overwhelming importance of coal seems, on the other hand, an additional reason for finding it a place in a work which is practically an encyclopædia of applied geology; besides, if fuel is to be omitted, why are natural gas and petroleum inserted?

In a gigantic work of this description, it is impossible for an author to avoid some errors. Five mistakes in spelling Welsh words in the first three lines of p. lxxviii. will not be looked upon as a heinous crime by the average Englishman, who himself feels that he is skating upon thin ice when he is dealing with the orthography of names of places in the Principality; however, these are not the only cases of misprints which might be noticed.

The geographical tables, occupying forty-five pages, form a useful feature in the book; an alphabetical list is given of the principal minerals worked in each country, together with references to the pages where they are described. These tables and the index of localities take the place of a general index, which is not supplied. Small maps inserted in the text are of much assistance in enabling the reader to follow the author's descriptions; the total number of woodcuts, 390, may seem large, but, scattered as they are through more than 1800 pages, they are not as numerous as one would like. Great pains have been taken with the bibliography, and Prof. de Launay's lists will often bring into notice original papers which would otherwise have passed unnoticed.

Though too expensive for the pockets of ordinary students, the book will find a place in the libraries of all mining schools and geological and engineering societies, and it is sure to be frequently consulted with profit by geologists and mining engineers.

Moreau's work has a totally different object to that of de Launay; the latter is a record of observed facts, whilst the former, dealing solely with metallic ores, is mainly devoted to general principles. After describing briefly the classifications of ore deposits proposed by von Groddeck, de Lapparent, Phillips, Whitney and Raymond, the author suggests one of his own, viz.:—

(A) Stratified deposits.
(B) Eruptive deposits.
(C) Deposits in pre-existing cavities.
(D) Substitution deposits.

Mineral veins are classed under the head (C), and apparently Moreau does not admit that they may sometimes be substitution deposits.

Two chapters are devoted to disquisitions upon the origin of mineral veins, and are based upon the works of Daubrée, Lyell, Elie de Beaumont, De la Beche, Henwood, Moissenet, Geikie, and others; Vogt's recent researches and theories remain unnoticed.

Chapter v., which treats of the chemical and physical characteristics of ores, and the earthy minerals which accompany them, should have been omitted; and the same remark applies to the chapters upon qualitative testing, quantitative assaying, dressing and smelting. These subjects cannot be taught in a few pages, and are better studied in the ordinary text-books.

Chapter vi., largely borrowed from von Groddeck, Phillips, Fuchs and de Launay, contains descriptions of well-known characteristic ore deposits. The important iron ores of the Secondary rocks are dismissed in a very cavalier fashion, for, strange to say, no mention is made of the great iron-field of the Department of Meurthe and Moselle, Lorraine and Luxemburg.

The most valuable part of the book for mining men will be found in two of the concluding chapters, which deal with the study of ore deposits from a purely commercial point of view. They are full of useful hints and warnings, not only to the engineer who is examining mining properties offered for sale, but also to the capitalist who is meditating their purchase. M. Moreau is evidently imbued with many of the ideas which were running through the brain of Mr. J. H. Collins when he delivered his recent presidential address to the Institute of Mining and Metallurgy. The more deeply counsel of this kind is taken to heart, the better will it be for investors in mining enterprises.

A few errors in the names of well-known geologists are inexcusable. It is strange that any one should write "Sir *Richard* Lyell"; "Sir Logan Foster, Whitney," is evidently meant for "Sir William Logan, Foster and Whitney"; even Elie de Beaumont's name is not always spelled correctly. "Gossan" is a Cornish and not a Welsh term, as supposed by the author.

OUR BOOK SHELF.

Elementary Text-book of Metallurgy. By A. Humboldt Sexton, F.I.C., &c. (London: Griffin and Co., 1895.)

THIS book is intended, for those who are commencing the study of metallurgy, as a kind of preparatory course to that of Prof. Roberts-Austen, as given in his "Introduction to the Study of Metallurgy," which the student is advised to read after digesting the contents of Prof. Sexton's manual. The work is got up in good style by the publishers, and printed in a clear and distinct manner. With the general arrangement there is very little to complain of; but the same by no means can be said of the subject-matter, which contains many errors, and the definitions are often expressed in such crude language that a student might be easily misled in taking *his first* lessons in metallurgy from its pages. The following examples may be cited:—P. 3: Malleability. This is the property of being expanded into sheets. Ductility: This is the property of being drawn into wire. A small quantity of antimony in lead is said to make it quite brittle. P. 4: Lead may be drawn into wire if means be taken to prevent the metal being subject to stress. P. 5: With regard to tensile testing, the author *says* that elongation takes place mostly near the point of fracture. P. 46: There are but two neutral substances in general use, graphite and chrome iron ore. P. 89: Fluor spar is said to be used to increase the quantity of slag. On pp. 92 and 121: C below ·5 is termed wrought iron, and steel when C is between ·5 and 1·5; while on

p. 110, it is stated that, in puddling, the carbon is reduced to ·1 per cent.; and also that during the melting-down stage there is little chemical action. P. 111: Puddled bloom is chemically wrought iron with intermingled slag. P. 123: Steel is made by *carbonising* malleable iron. P. 128: Mild steel, not more than ·5 per cent. carbon, does not harden when heated and quenched in water. P. 134: The slags from the acid Bessemer process are *very basic silicates* of iron and manganese. P. 138: In Open Hearth process it is stated that the iron ore should be as free as possible from silica, whereas the Spanish hematite usually employed is very siliceous. P. 143: The strength increases as the diameter of the wire decreases. Also cake or tough copper may contain any amount of impurities. P. 223: An alloy of 80 per cent. copper and 20 per cent. zinc is called *red brass*. P. 229: Electro refining of copper; the anode is a thin sheet of copper; the cathode is a bar of blister copper. P. 230: The passage of the electric arc through the carbons produces a very high temperature. It is a great pity that a work which has been so judiciously compiled as the present one should be marred by so many mistakes, when by a more careful supervision of the proof sheets they might have been easily detected and corrected.

Annals of British Geology, 1893. A Digest of the Books and Papers published during the Year. By J. F. Blake, M.A., F.G.S. (London: Dulau and Co., 1895.)

ONCE more has Prof. Blake overcome all the obstacles of prolonged research among publications that are many of them difficult of access. Once more has he braved the disappointment of inadequate support, and following his own independent course in the selection and arrangement of his material, he has now given us the fourth volume of his "Annals of British Geology." Every addition to the series renders the whole of greater value, and we sincerely hope that the present volume will be self-supporting, as he ventures to anticipate. To all geologists, and to the provincial worker especially, these "Annals" must be of the greatest service, for the author contrives to give so much of the substance of each paper, that the reader will gain a very fair notion of the additions made to our knowledge during each year. Except in the student's special department of work, there will be no occasion to consult the originals.

Altogether 730 papers and books are noticed, being an increase of 180 over those recorded in the previous volume. The author's introductory review, occupying twenty-four pages, gives a summary of the chief geological news of the year. Although not essential to the Annals, this review acts as a safety-valve for the escape of some few of the critical remarks which arose while the author was perusing the 730 works. New forms of Ammonites and Corals come in for critical observations, so also do the "hemeræ" of the Inferior Oolite, and various glacial theories.

In Palæontology the place of honour is rightly given to the Elgin Reptiles described by Mr. E. T. Newton, and an excellent illustration of *Elginia mirabilis* forms the frontispiece of the book.

The Origins of Invention. By Otis T. Mason, A.M. Ph.D. Pp. 419. (London: Walter Scott, Limited, 1895.)

To trace our modern industries to their origins, to show how they have evolved, and to point out the changes from naturalism to artificialism that mark the course of civilisation, is a difficult task, but an attractive one; and few ethnologists are better equipped with facts relating to this development than the Curator of the Department of Ethnology in the United States National Museum, who is the author of this book.

Dr. Mason lays down the following as the order in which kinetic energy has been commanded: (1) man-power in every pursuit; (2) fire as an agent in cooking, pottery, metallurgy, &c.; (3) the power of a spring, as in a bow or trap; (4) beast-power, for burden and traction; (5) wind-power, on sails and mills, and in draught; (6) water-power, as a conveyance and a motor, and gravity or weight generally; (7) steam-power, utilisation of an expanding gas; (8) chemical power, in the arts of the civilised; (9) electric power, motors, message-bearers, in mechanics and illumination; (10) light as a mechanical servant, only beginning to be domesticated.

Prominent among inventions are tools and mechanical devices—objects employed as means to ends. Many of these have come down from remote antiquity. Following M. Adrien de Mortillet's classification, Dr. Mason describes the tools and appliances used by primitive peoples for cutting; abrasion and smoothing; fracturing, crushing, pounding; perforating, grasping, and jointing. At the basis of tool-using, lie the systems of counting and weighing and measuring, all of which receive attention.

The invention and uses of fire, forms the subject of a very interesting chapter. Other matters treated in separate sections are stone-working, pottery, primitive uses of plants, the textile industry, inventions belonging to the chase, methods used for the capture and domestication of animals, means of travel and transportation, and instruments of warfare.

The work is readable throughout; it is a valuable history of the development of the inventive faculty, and has, therefore, an important relation to the history of humanity. The ethnologist will find in the volume much that is interesting in regard to the relationship between man's activities in different regions.

Short Studies in Nature Knowledge. By William Gee. Pp. 313. (London: Macmillan and Co., 1895.)

FOR boys in the upper standards of our elementary schools, this forms an ideal reading-book. It is simply worded, is not too full of details, contains numerous illustrations, and is likely to create and foster a love of natural knowledge. The book is intended to be used as an introduction to physiography, and it covers the ground usually understood to belong to that science. Copious extracts from the poetical and prose writings of standard authors are introduced into the text wherever possible, and serve to lighten it. The author appears to have spent a deal of care upon the work, and we think he has succeeded in producing a volume which will be welcome to teachers, as well as readable to all who find pleasure in the study of inanimate nature.

Organic Chemistry: The Fatty Compounds. By R. Lloyd Whiteley, F.I.C., F.C.S. Pp. 291. (London: Longmans, Green, and Co., 1895).

THIS is another elementary science manual "written specially to meet the requirements of the elementary stage of science subjects as laid down in the syllabus of the Directory of the Science and Art Department." It is hardly a book that we could recommend to followers of departmental organic chemistry, and certainly not one to be adopted by other students of the science. It is most unequal in structure, and very deficient in parts: Chapter iv., on percentage composition and empirical formulæ, consists of less than one and a half pages. As well-known standard works have been "freely employed" in the preparation of the volume, it is difficult to recognise the sections for which the author is responsible, and therefore undesirable to impeach the accuracy of some of the information.

LETTERS TO THE EDITOR.

The Age of the Earth.

I am surprised to observe, in the article which Prof. Sollas has written on this subject in your issue of the 4th inst., p. 533, that he speaks with approval of Dr. A. R. Wallace's method of calculating the earth's age. About two years ago, I have only this week's number of Nature at hand, I wrote to you on this subject, and was under the impression that I had proved the complete fallacy of Dr. Wallace's method of calculation.

To put Dr. Wallace's view briefly, he assumes that deposition within a limited area of, if I remember rightly, 3,000,000 square miles, goes on 19 times as fast as denudation over the whole land area, which is 19 times as great, and then argues that the whole maximum thickness of the stratified rocks and hence the earth's age could be deposited in 1/19 of the time required to carry away from an equal area of land an equal bulk of material.

The fallacy consists in assuming that a great rapidity of deposit over a limited area can in some way allow of the deposit or formation of sedimentary rocks at a greater rate than that of denudation.

It is obvious that, in a given time, no greater volume of deposits can be formed than the volume of material denuded in the same time. If, therefore, as Prof. Sollas assumes, 1/2400 of a foot of sediment per annum is denuded from the land area, by no arrangement can a land area of equal extent, consisting of sedimentary rocks of the same composition and thickness as those which actually constitute the land area, have been formed as a whole more rapidly than 1 foot thickness over 57,000,000 square miles area in 2400 years. Taking the estimate of Prof. Sollas, viz. 164,000 feet, as the maximum thickness of the sedimentary rocks, and taking the existing land area to be accounted for as 57,000,000 square miles, the time required to form an area of 57,000,000 square miles of rock 164,000 feet thick, at 1/2400 of a foot per annum, is 393,600,000 years, unless the area undergoing denudation was greater or less than it is at present; and it could not be four times as great as at present. No concentration of the deposit over a small area would shorten the time required by a single moment.

Bernard Hobson.

If, in the compass of a short article, I did not allude to the controversy which followed the attack made by Dr. Hobson (Nature, vol. xlvii. p. 175, 226) on Dr. Wallace's method of estimating the age of the stratified series, it was because I thought, as I do still, that the honours of that controversy rested entirely on the side of Dr. Wallace.

There is no fallacy in Dr. Wallace's argument, but a strange misconception on the part of Dr. Hobson, which arises from his consistent disregard of the word *maximum* as prefixed to the estimated total thickness of stratified rocks. It is obvious that stratified systems cannot have a maximum thickness everywhere over the whole 57 million square miles of the land surface. As a matter of observation, a system attains its maximum thickness over a very limited area, and over a large part of the 57 millions of square miles of land surface it has no thickness at all, or, in other words, is entirely absent. If "maximum" could be made to mean the same as "average," no doubt Dr. Hobson's contention would hold; but those who have made use of a maximum in estimating the age of the stratified series have observed a strict distinction in the application of the two terms.

Kingstown, April 5.

W. J. Sollas.

Polyembryony.

In connection with the note in the last number of Nature on the above, I think it should be known that the phenomenon was incidentally observed some two years ago in the red beet (*Beta vulgaris*) by the late Mr. Romanes and myself. We found that a single seed might produce as many as four distinct plants, and as far as our observations went, polyembryony was quite the normal condition. It seems to be more characteristic of the Gymnosperms than the Angiosperms, and has of course been investigated in the former, and in the latter among the Monocotyledons (Treub and Dicotyledons (e.g. Citrus-Strasburger). The fact of its occurring in such a common type as *B. vulgaris* should, I think, be taken advantage of by some botanist, as the results could not fail to be both interesting and important. Treub's discovery that the supernumerary embryos in Monocotyledons may be produced by the antipodal cells, certainly suggests his comparison between such embryos and those produced by "parthenogenetic" apogamy on the prothallia of the lower plants.

Frank J. Cole.

IMPROVEMENTS IN PHOTOMETRY.

Nearly sixty years have passed since it first occurred to the philosophic mind of Sir John Herschel to attempt an arrangement of the relative brilliancy of the stars, upon a method that should be more secure than the eye estimations that had done duty for many centuries. It is not necessary to enter into any description of his method, which may be regarded now as entirely superseded. Doubtless, had he been surrounded by skilled workmen, furnished with better tools, the cumbrous method employed would have been simplified, but the establishment of an observatory remote from the assistance and contrivances of the workshop is not without drawbacks, as he and others since have discovered and regretted. About the same time, Seidel, in Germany, was at work on the same problem, and the fact that two astronomers, independently of each other, undertook the solution of the same problem, is a proof that it was ripe for mature consideration, while the series of astronomers who have laboured in the same path confirms the suspicion that this kind of investigation too long neglected offered a field having a rich prospect of reward.

But a photometer at once convenient and capable of general application to the stars remained to be invented, and this want was effectually supplied by Zöllner, who proposed a form of construction which has certainly obtained the most general use of any of the suggestions that have been from time to time put forward by astronomers, who have recognised its deficiencies and tried to remedy them. The distinguishing characteristics of the Zöllner photometer are the introduction of an artificial star formed from a lamp shining through a small aperture, and the controlling of the light of that star by means of polarisation. This principle is now of such general use that no lengthened description is necessary. But to explain the reason for the introduction of other forms of photometer, it is necessary to point out what are, or what were, considered to be its defects by those who first used the instrument, defects which it is believed care and experience have since done much to diminish, if not entirely to remove. A source of error might be anticipated in the varying brilliancy of the lamp employed to form the artificial star, and in the early days of the instrument this was a fruitful source of annoyance. Next, the light of the lamp had to strike no less than twenty-eight surfaces, and apart from the difficulty of getting so many surfaces true, and ensuring the parallelism of the Nicol prisms by which the diminution of the artificial star is effected, there is also to be considered the inevitable loss of light at so many surfaces. One consequence of this is that the brightest stars of the heavens are apt to be brighter than the artificial star, and since the observation is made by reducing this light to match that of the real star, it is necessary to have recourse to some such expedient as reducing the aperture of the telescope. And then a difficulty is encountered which has not yet met with a complete explanation. The light deducted from the star, as seen with a reduced aperture, does not coincide with that which would be predicted from theory. In some of the recent series of observations the differences between observation and theory are as great as they are perplexing. "There can be no doubt," wrote Mr. C. S. Peirce, of Harvard, twenty years ago, "that the errors introduced by the use of these diaphragms are by far the most serious of those by which my observations are affected." Dr. Wolff met with similar difficulties, and doubtless anomalies such as these have encouraged the production of other photometers which should be free from the suspicion of error. Having regard to the photometric work actually accomplished, we may confine attention to two forms of apparatus known as the Pickering Meridian Photometer and the Pritchard Wedge

Photometer. In the first of these the principle of polarisation is still used, but the artificial star is discarded. This is apparently an advantage, but it is a question if it does not introduce an error as large as that which it seeks to eliminate. An image of a star, as Polaris, is used as the constant of comparison, and this image can be reduced by polarisation till it equals that of the star of which the magnitude is sought. A lack of resemblance between the stars under consideration is removed, but the removal is effected by the introduction of a second object-glass with evidently different optical capacity, requiring a fresh constant to be determined. Prof. Pickering's photometer consists practically of two telescopes, placed at right angles to the meridian, and over each of the object-glasses is placed a right-angled prism. By means of the northern prism the image of Polaris is reflected, and by suitable adjustment can be made to occupy any convenient position in the field of view, while the prism on the other object-glass can be set to any declination so as to bring the image of any other star, when on or near the meridian, into juxtaposition with that of Polaris. Ingenious arrangements are introduced to ensure the coincidence of the pencils forming the images to be compared, and a control over the accuracy and efficiency of the whole is secured by contrasting the brilliancy of Polaris with itself—that is, by comparing the images formed by either object-glass. This is effected in all cases by rotating a Nicol prism in the eye-piece of the telescope through a measurable angle, and thus equalising the lights of the stars by means of varying the planes of polarisation. How effective this instrument has proved itself in the hands of Prof. Pickering, we shall presently see.

But either of these forms of photometer is necessarily a special production, and therefore the object-glasses are small and the light-gathering powers limited. In Prof. Pickering's first photometer, the aperture was only 4 c.m., with a magnifying power of only fifteen diameters. Prof. Pritchard, considering this limitation a defect, directed his attention to the construction of a photometer which should be readily available on any instrument, and be applicable to stars of very varying degrees of brightness. For this purpose he had recourse to the principle of extinction of the light of a star, by means of a wedge of neutral-tinted glass, which could be moved over the image of a star till its rays were lost by the gradual increasing thickness of the medium through which they had to penetrate. This principle had been used by the late Mr. Dawes, and also by Capt. Abney, but the long-continued use of such an apparatus by the late Savilian Professor is likely to connect his name with this form of photometer. The main defects in its construction arise from the difficulty of obtaining an absorbing medium equally operative throughout the entire length of the spectrum, and also that of determining with certainty the coefficient of absorption—in other words, how much light is lost by the difference of thickness corresponding to one inch in length of the wedge. Recent and more exact methods than those employed by Prof. Pritchard seem to show that the constant used in his work is in error, and that a correction to his magnitudes so obtained is necessary. But it is a peculiarity of the form of construction and method of observation adopted that such a correction can be very easily applied.

These forms of photometers, the Zöllner, the Pickering, and the Wedge, are the three instruments which have been most generally in use, and with which the modern work has been accomplished. The rapidity and the progress of this class of observation can easily be shown by a few statistics. Previous to their introduction, exact photometry was limited practically to two catalogues. Exact photometry is, of course, a relative term; it is meant to include observations other than eye estimations, and therefore Herschel and Seidel, the one with 69 stars, the other with 208, are the only two observers to whom it is necessary to refer. Since the introduction of the more rapid methods, and possibly from a better appreciation of the importance of the inquiry, we have had many extensive catalogues. Leaving out Zöllner himself, who did not attempt to condense his observations into catalogue form, we have—

Peirce's Harvard Catalogue of	494	stars.
Wolff's First Bonn Catalogue of	475	,,
Wolff's Second Catalogue of	923	,,
Potsdam Photometric Catalogue of	3522	,,

All these catalogues have been made by means of a Zöllner photometer, but the list in no way exhausts the photometric work that has been done by this instrument. For instance, Lindemann, at Pulkova, has carried out a long series of observations with the view of determining the scale that has been unintentionally adopted in the record of eye estimations in various catalogues. Ceraski and others have been at work on variable stars, while interesting inquiries into the extinction of light by the atmosphere and other physical investigations have been made by its aid. A debt of gratitude, therefore, of no common kind is due to the ingenuity of Dr. Zöllner. Confining our attention, however, solely to the compilation of catalogues, we have with the Pickering meridian photometer a collection of the relative magnitudes of 4260 stars, followed by a photometric revision of the Durchmusterung of Argelander, in which are given the magnitudes of some 17,000 stars. This leaves out of the summary a quantity of miscellaneous work on the Pleiades, on the Asteroids, on double stars, standard stars, &c. In fact, Prof. Pickering has placed it on record, that the number of measures made with the Nicol prism was up to 1890 slightly under half a million. Finally we have the more modest catalogue of Prof. Pritchard, embracing 2647 stars, and, to complete the record with this particular instrument, we must add a small item of some 45,000 extinctions made at Harvard under Prof. Pickering's direction. Of course, many stars are common to all the catalogues, but the record shows that in the last few years instrumental photometry has been applied to something like 30,000 stars. It is not easy to form an adequate conception of so much activity.

But if the numbers have increased in such welcome proportions, it may be asked is there an equally gratifying advance in the accuracy of the observations? This question is not so easily answered. Doubtless there is a much greater accord among the observations found in the same catalogue, and made by the same observer, employing the same instrumental means. But when these catalogues are compared with one another, large and provoking differences are sometimes encountered, and not a small portion of time has been given by various astronomers to the investigation of these differences, and the attempt to systematise the various recorded values of lustre. But when all has been done, there still remain individual differences which baffle explanation. They seem to point either to irregular variations of brilliancy in the stars themselves, or to baffling meteorological influences, which it is impossible entirely to eliminate. The suggestion has been made by others, and it is intended here to give it the fullest support, that a far larger number of stars exhibit variations of lustre than are included in our variable star catalogues. It must be remembered that these catalogues have been formed, and the variations detected, by the eye alone—that is to say, without the advantages of a photometer. Consequently it is only the larger variations that have attracted attention. It is not easy to establish the fact of an alteration in brilliancy, if it be small, either with or without a photometer; but it seems not unlikely that as star magnitudes gain in trustworthiness, a larger addition will be made to the stars recognised as variable. To come, however, to actual facts, it is recorded in the latest published catalogue of magnitudes, that of Potsdam, that the probable error of the concluded magnitude is 0·04 mag. This amounts to the same thing, practically, as deciding between the illuminating power of 25 and 26-candle gas. It is not known whether such a problem would offer any difficulty to gas experts, but even they sometimes fail to gain full credence from the public.

But the record of photometric research is by no means exhausted by this catalogue of work, limited to the application of specially devised photometers to the stars directly. Another and entirely different method of investigation has been actively prosecuted in the last few years, and apparently with the greatest success. This method avails itself of the refinements and the results of photography. Every one knows the appearance of a photographic plate on developing it after it has been exposed in the focal plane of a telescope for a longer or shorter time. It is seen that the circular images of the stars impressed differ greatly in size, and it may be in depth of deposit, according to the magnitude of the stars impinging on the plate. Consequently, by appropriate means of discussion we are able to determine the relative magnitudes of the stars themselves. And since we have here to contemplate the measurement of a sensible area, it may not be unwise to recall the fact that the term "magnitude" of a star is strictly limited to its brilliancy. Magnitude, therefore, in its accurate astronomical sense, is not easy of definition; difference of magnitude, involving as it does difference of brilliancy, is, however, easily apprehended, and it is a difference of magnitude that is sought to be determined by measurement of the blackened area corresponding to the star images on the sensitised film.

The problem here offered for solution is not precisely the same as that in the direct application of a photometer to the light of the stars. The eye ceases to be the actual photometer employed. For the impression on the retina we have substituted the impression recorded on the photographic film. This film may be more or less sensitive to some of the rays that go to make up the whole of the light of a star than is the ordinary retina, and consequently the record will differ in individual cases from that obtained by photometric means in the more ordinary sense of the word. Leaving out of the question orthochromatic plates, which are not usually employed in recording the positions of stars, the films are prepared so as to be most sensitive for the violet light of a star, whereas the eye is generally most sensitive to the yellow. If object-glasses are employed, this difference is usually aggravated again, for the optician seeks to make this coloured light most operative, according to the direction in which the telescope is to be employed. In the case of a photographic telescope, the rays about G in the spectrum are most important; in the visual telescope, those rays about D. In whatever way the photographic observations are discussed, with the view of ensuring a general agreement with photometric results, it must be anticipated that exceptional cases will differ, especially when the star light is rich in violet rays. Speaking generally, while a photometer, as usually employed, seeks to arrange the stars according to their appearance to a normal eye, a photographic determination of relative brilliancy exhibits the stars as they would appear to an eye most keenly sensitive to chemical rays.

The method of deriving the photographic magnitude will differ according to the manner in which the observations have been made. In the first place the ordinary plate, whether it be taken with the view of producing a general chart of the heavens, or the accurate representation of any small selected area on the sky, will contain implicitly the magnitudes of the stars impressed. Consequently, if we measure the diameter of the circular images produced by the stars of known magnitude, we have a relation between diameter and stellar magnitude. Such attempts end in the derivation of a convenient formula of interpolation. We may find that an expression of the form $m = a - bd$ or $m = a - b \log d$ (where m and d are respectively magnitude and diameter and a and b constants applicable only to that plate, and available only through a small range of magnitudes) is serviceable practically, but has no physical meaning. The determination of the constants a and b is troublesome, and demands a previous knowledge of the photometric magnitudes of some of the stars on the plate—information not always at hand. For these reasons attempts, more or less successful, have been made to assign the magnitude of a star from a knowledge of the diameter of the image and the duration of exposure. To be completely successful such an inquiry demands an acquaintance with the manner in which the image grows on the sensitised film, and this inquiry has progressed but slowly, and is still incomplete. In the early days of photography, it was supposed that the diameter varied as the square root of the time of exposure; later, with the modern dry plate, the fourth root of the time was thought by some to more nearly express the rate of growth; but Prof. Turner and the Astronomer Royal have both shown that neither of the suggestions is satisfactory. The character of the plate, the steadiness of the image, and the accuracy of "driving" (that is, the successful removal of the effects of the earth rotation), all enter as perplexing variables in a research of this character. The Astronomer Royal has suggested that the square root of the diameter of the photographic image increases as the logarithm of the time of exposure. This may be applicable to a particular telescope and through a definite range of magnitudes, but is scarcely likely to express a physical law. But, accepting such a result as a working hypothesis, we cannot pass directly to the magnitude of stars without making another assumption with regard to the diameters. This is usually summed up in the expression that for equal diameters--

$$\text{Exposure} \times \text{brightness} = \text{constant.}$$

That is to say, in order to get equal diameters of the images of two stars, one of which has four times the light of the other, we must expose the plate to the fainter star four times as long as to the brighter. This sounds almost axiomatic, and was for a long time accepted as a demonstrated fact. So much so, that at the Paris Conference in 1889 it was decided that the proper time of exposure to photograph eleventh magnitude stars was six and a quarter times that required for a ninth magnitude star. This decision of six and a quarter was adopted because this number expresses the ratio of the light in a ninth magnitude star to that in the eleventh. Probably no great harm will come from the adoption of such a resolution, but Captain Abney has given good reasons for doubting the assumption that length of exposure and intrinsic brightness are equally operative in producing the same photographic effect. All this goes to show that the determination of magnitude from an examination of the small circular dots on a "star plate" is not at all a simple problem. There is, too, another fact which should be borne in mind. All the discs are small, and yet in a range of five magnitudes, one hundred times more light has gone to make up the larger than the smaller of the two discs. This means that the scale is much contracted, and will probably interfere with final accuracy, quite as much as a want of definiteness at the edge of the disc, or distortion from a circular shape by being photographed at a distance from the optical axis, or other causes which make the measurement of the exact size of the blackened area, uncertain.

It is a question if the problem be materially simplified when the plates are photographed with the direct purpose of determining magnitude. We should then probably adopt a plan which has been extensively employed by Prof. Pickering, but so far has had few imitators. This consists in photographing the trail of a star. If we leave a phototelescope at rest with a plate exposed, the stars describe circular arcs on the plate having the pole as a centre, and having a length of 15° for each hour of exposure. The linear length will vary according as the star is near or remote from the equator, and since the energy is distributed over this varying length, polar stars will produce more intense trails than those stars of equal brightness near the equator. Effectively if two stars are found giving trails of equal density, the brightness of the two stars varies as the cosine of the declination. But if it be found that the stars near the equator travel, by reason of the earth's rotation, so rapidly across the plate that the fainter among them leave no trail, it is possible to give such a rate to the driving clock that the trail may be of any definite length, and the energy concentrated for a longer or shorter time over this space.

The method of deriving the stellar magnitude from an examination or measurement of these trails will be best understood by considering the case of the polar stars. A plate was exposed to the pole for ten minutes, and the telescope left stationary. The aperture was then reduced by successive amounts, so that theoretically any star would appear one magnitude fainter. In the case of a selected star, therefore, we have the thickness of the trail corresponding to known magnitudes, which could at once be compared with the trails formed on other plates. Actually these trails, corresponding, it is presumed, to stars of known magnitudes, were brought into juxtaposition with the trails of stars whose magnitude was sought, and the brilliancy was decided by equality of appearance. Of course similar practices could be and have been pursued when the stars are represented on the plate by means of circular discs. By varying the length of exposure in the photograph of a star of known magnitude, we can approximate to the appearance that stars of any magnitude would present for known durations of exposure. But here difficulties connected with the sensitiveness of the plate, and the meteorological circumstances of the night affecting the transparency of the atmosphere, have to be taken into the account, and the effects eliminated from the observation as carefully as possible, so that it is doubtful if a higher degree of precision results than in the case of photometric observation. There is, however, the obvious advantage that the photographs remain, and greater leisure and further experiment may suggest improved methods of observation and reduction, that shall ultimately give us all the accuracy needed in investigations of this character. The process as at present employed by Prof. Pickering appears to be fairly rapid. Three or four years ago he could report that he had applied his method to over 60,000 images, and the accuracy appears to be about as great as in the case of photometric observations. The chances of systematic error are probably greater.

NOTES.

AT Marlborough House, on Tuesday, in the presence of the Council of the Society of Arts, the Prince of Wales presented to Sir Joseph Lister, Bart., the Albert Medal accorded to him by the Society for "The discovery and establishment of the antiseptic method of treating wounds and injuries, by which not only has the art of surgery been greatly promoted and human life saved in all parts of the world, but extensive industries have also been created for the supply of materials required for carrying the treatment into effect."

PROF. CHRISTOPHER HEATH has been elected President of the Royal College of Surgeons, in the place of the late Mr. J. Whitaker Hulke, F.R.S.

DR. G. S. BUCHANAN has been appointed to the office of Medical Inspector of the Local Government Board.

THE Croonian Lectures at the Royal College of Physicians will be delivered by Dr. W. Marcet, F.R.S., on June 18, 20, 25, and 27, the subject being the "Respiration of Man."

THE grants lately made by the United States Congress, for the Geological Survey during the fiscal year 1895-96, amount to 515,000 dollars, or £103,000. This sum includes all field and office expenses and salaries.

LAST week, the colleagues and former pupils of Sir William Turner, Professor of Anatomy in the University of Edinburgh, presented him with his portrait, as a mark of appreciation of his services in the cause of science and to the University.

IN connection with the Goldsmiths' Company's grant for researches on the anti-toxin treatment, a Committee of the Royal College of Surgeons of England have recommended a grant of one hundred pounds to Dr. Sidney Martin, for the purpose of working out the action of the anti-toxic serum, when used to counteract the effects of various poisons separated by him from the membrane, and from the spleen, in cases of diphtheria.

WE have already noted that the London Chamber of Commerce are promoting a Bill for legalising the use of metric weights and measures for export trade purposes. In connection with this, the London County Council has just resolved to do all in its power to secure the passing of the Bill during the present Session. In the meantime the Council's inspectors will not interfere with the use of metric weights and measures in the execution of foreign orders.

AMONG the men of science who have died during the past week is Theodor Brorsen, whose name is so well known to astronomers. He was born in 1819, and was the discoverer of five comets, as well as the author of a number of writings on astronomical subjects. Since 1879, he lived in retirement at Norburg, his native place. Mr. J. H. Greener, the constructor of several early lines for telegraphic communication, and one of the most able of practical telegraph engineers, died on Sunday, in his sixty-sixth year.

THE President of the German Meteorological Society has issued invitations for a general meeting of the Society, to be held at Bremen on the 17th, 18th, and 19th inst., when various matters of interest to meteorologists will be discussed. The time of meeting has been fixed so as to fall in with the geographical conference, which will be held at the same place during Easter week, and in which oceanography and maritime meteorology form a prominent part. The subject of south polar investigation is also included in the geographical programme, so that it is anticipated that a large number of scientific men will take part in the proceedings.

THE spring meeting of the Iron and Steel Institute will be held in London on Thursday and Friday, May 9 and 10 next, in the rooms of the Society of Arts. The presidential address will be delivered by Mr. David Dale, and the Bessemer gold medal will be awarded to Mr. H. M. Howe, who will contribute a paper on "The Hardening of Steel." Mr. Stead, of Middlesbrough, will contribute a paper on "The Effect of Arsenic on Steel"; Mr. Sergius Kern, Metallurgist to the Russian Admiralty, will discuss the manufacture of armour-piercing projectiles in that country; Mr. Herbert Scott will communicate a paper on the iron ore mines of Elba; and Mr. W. J. Keep, of Detroit, will contribute a paper on "Tests of Cast Iron."

PROF. DR. G. SCHWEINFURTH, the distinguished African traveller and botanist, has passed the winter at Hélouan, near Cairo, where he is engaged in mapping and describing the adjacent mountains and "wadis," for a memoir to be communicated to the Institut Egyptien. Dr. Schweinfurth has just published the text of an interesting lecture on Erythræa—the Italian colony on the Red Sea—delivered before the Geographical Society of Berlin in July last year. This paper gives an account of a four-months' expedition which he made to Erythræa in the early spring of 1894, in company with Dr. Max Schoeller. It gives a most favourable report of the progress of the new Italian colony and of its future prospects.

A CORRESPONDENT has sent us particulars of an explosion which occurred at Providence, Rhode Island, U.S.A., on March 8, in connection with the electric light mains of that city. The explosion resembles those recently investigated by Major Cardew (see p. 539). Through a leak in the gas mains, the conduits became full of an explosive mixture, which suddenly exploded with great violence. The street was blown up for some thirty feet, all the glass in neighbouring houses wrecked, and missiles of wood and iron thrown to some distance. The noise and shock are said to have been felt all over the city.

THE circumstances connected with the formation of the dangerous alkaline deposits found by Major Cardew on the mains of the St. Pancras electric light supply, and the presence in this deposit in some cases of the alkaline metals in an unoxidised condition, have been inquired into by a Committee of the Royal Society and the Institution of Electrical Engineers, and the results have been issued in a report, which states that "the Committee are of opinion that the explosions which have occurred were caused by the firing of an explosive mixture of coal-gas and air by sparks caused by means of the abovementioned incrustation. It has been proved that sparks may be caused either by the incrustation itself acting as an imperfect electrical conductor, or by moisture coming into contact with metallic sodium or potassium, both of which metals have been found to exist within the incrustation. These metals have been produced by the electrolytic decomposition of alkaline salts, chiefly derived from the soil and conveyed by moisture along the fibres of the wooden bearers towards the negative conductor. To avoid a repetition of these accidents, the bearers of the insulators at present in use should be replaced by other devices through which moisture is prevented from travelling, and it is recommended that the pattern of insulator in use should be changed, and a pattern adopted in which a longer insulating surface is interposed between the conductors and the bearer. The Committee are also of opinion that it is desirable that means should be provided by which the conduits can be inspected throughout their length, so far as is necessary to detect incrustations on the insulators. The Committee have not thought it within their province to investigate the causes of the presence of coal-gas within the electric lighting conduits, but it is obvious that this is the primary source of danger."

DR. DUPRE's report with reference to the recent explosion of a cylinder filled with compressed oxygen, at Fenchurch Street Station, was read at the coroner's inquiry last Thursday. An examination showed that the inner surface of the cylinder was fairly clean, but at the end on which the valve was, the surface was incrusted with magnetic oxide of iron, which was easily removable, and which under the microscope showed in many places the globular form assumed by the magnetic oxide produced by the burning of iron or steel. The lower end of the brass screw, by means of which the valve fittings were screwed into the bottle, was also incrusted with magnetic oxide of iron, much of which was in the form of small globules produced by fusion at very high temperature. They were evidently fused to the material of the screw, and it in some cases even slightly pitted the metal. These facts lead Dr. Dupré to conclude, first, that the bottle at the time of the accident contained an explosive gaseous mixture; and that, secondly, this mixture was fired by some portions of finely-divided iron, or perhaps grease, igniting in the compressed gas. That some iron had actually been on fire in the cylinder the condition of the screw sufficiently proved. The coroner, in summing up, spoke strongly in favour of a Government test being imposed with regard to the cylinders; and the jury included in their verdict the recommendation that all compressed gases of an explosive nature should be scheduled under the Explosives Act, that all cylinders should be tested by the Government periodically, that no cylinder should be allowed to be used or conveyed about unless bearing the Government stamp, that all manufacturers should be licensed by the Board of Trade in the future, and that separate hydraulic pumps should be used in the apparatus in filling the cylinders, and also recommended a Board of Trade and railway inquiry.

AT the Institution of Civil Engineers, on April 2, Mr. J. I. Thornycroft, F.R.S., and Mr. S. W. Barnaby, in a joint paper, expressed the belief that the speed of vessels had now approached within measurable distance of that at which propulsion by screws became inefficient. For a given pitch-ratio and slip, the thrust per unit of area varies as the square of the speed. Certain conditions of pressure on the screw-blades cause the formation of cavities, filled with air and vapour driven off from the water, behind the blades. Experiments carried out by the authors, with screw-blades of elliptical form, show that this "cavitation" does not commence suddenly, but appears to become detrimental when the mean negative pressure on the forward side of the blades exceeds about 6¾ lbs. per square inch, or when the whole thrust exceeds 11¼ lbs. per square inch. Cavitation can only be avoided at very high speed by increasing either the immersion of the screw or its blade-area. Immersion is limited by considerations of draught. Increased area, the authors remarked, can be obtained in three ways: (1) by increasing the ratio of surface to disc-area, (2) by employing a larger diameter than that theoretically best for the given conditions, (3) by increasing the pitch-ratio, which involves a larger diameter with a reduced rate of revolution. Either tends to a waste of power if pursued beyond somewhat narrow limits, and it appears inevitable that reduced efficiency must be submitted to as the speed of vessels is increased.

A FEW noteworthy points were brought out last week in evidence before the Select Committee of the House of Commons appointed to consider the advisability of adopting the metrical system of weights and measures. Captain H. R. Sankey, R.E., director of the engineering firm of Willans and Robinson, Thames Ditton, said that the metric system of measurement had been adopted by his firm for the last two years. The reason of the change was the advantage of working interchangeably with manufacturing engineers on the continent. His firm's trade was mainly British, but no objection had been made to metrical measurements by British customers. The workmen were agreed that the metric system was much more easy to work with than the English measures, and was much less liable to error. The inconvenience of the change to the metric system was only felt by the workmen for a few days. In his evidence, Dr. Gladstone estimated that in the elementary schools about 350 hours were occupied in teaching our cumbrous system of weights and measures. As the children had to learn decimals, very little more time would be needed by them for learning the metric system. A chart explaining the metric system was now to be found in nearly all the London schools, and lately it had been decided to supply actual examples of the metre and litre to such schools as asked for them. The metric system was but partially taught in the schools, for the teaching involved additional labour, and was not insisted on by the inspectors. The introduction of the metric system would be much facilitated if the system were compulsory in the elementary schools.

IN a paper read before a recent meeting of the Académie des Sciences (*Comptes rendus*, cxx. p. 611), M. Lucien Poincaré described some experiments on secondary batteries he has been performing. With a view of reducing the losses that take place in the ordinary lead accumulator, the author has tried to obtain a battery with *liquid* metallic electrodes. For this purpose mercury has been employed, and as it would not do to employ an acid as the electrolyte, since the hydrogen would be liberated and thus cause a waste of energy, a solution of a salt is used. Under these circumstances an amalgam is formed at the cathode, which, together with the mercury of the anode, forms a secondary cell. Of all the different salts tried, the most interesting results have been obtained with the haloid salts of the alkaline metals. With these salts the electromotive force of the secondary battery is about two volts, but in the case of the chlorides and bromides, the chlorine or bromine combines with the positive mercury, forming a badly-conducting layer, so that the output of the cells is not satisfactory. With a solution of iodide of sodium, however, very satisfactory results are obtained, for as long as the solution is kept sufficiently concentrated, the current density during the charging is not too great, and the positive electrode has a larger surface than the negative electrode, no deposit is formed on the anode. Hence by this arrangement a secondary cell is obtained in which the two electrodes remain, after the charge, entirely metallic, so that the internal resistance does not increase as the cell is charged. The efficiency of these cells amounts to very nearly 90 per cent., the electromotive force, when fully charged, being 1·85 volts. The capacity per kilogram does not differ much from that obtained with ordinary lead accumulators, being about 10 ampere-hours. A very important point about this form of cell is that the density of the *discharge* current is immaterial, and they may be completely discharged without in any way deteriorating.

WE have received from Prof. G. Hellmann an interesting pamphlet entitled "Contribution to the Bibliography of Meteorology and Terrestrial Magnetism in the Fifteenth, Sixteenth, and Seventeenth Centuries." The work was prepared for the Report of the Chicago Meteorological Congress, and contains a list and brief bibliographical notes of 272 old books in Dr. Hellmann's library, arranged under the authors' names, with cross references under subjects and dates. This pamphlet is of considerable value to meteorologists, as the early literature of this subject is as yet little known, and no meteorological institute is as rich in the older literature as the library in question. Arranging the books according to the language in which they were written, Dr. Hellmann shows that the authors comparatively seldom employed their native language, as 157 of the works are in Latin. There is also a preponderance of Italian works, as in the seventeenth century Italy probably contributed more to meteorology than all the other nations of Europe. Many of the works described are exceedingly scarce.

SINCE the great Japanese earthquake of 1855, the strongest shock felt in Tokyo was that of last June 24. No house was absolutely destroyed, but in the lower parts of the city many brick buildings were damaged and chimneys thrown down. The total land-area disturbed was 42,000 square miles. The diagram of the earthquake, taken by a large-motion seismograph at Tokyo, is given by Messrs. Sekiya and Omori in a short but valuable paper (*Journ. of the Coll. of Science*, Imp. Univ., Tokyo, Japan, vol. vii. part v. 1894). This diagram being on the natural scale, the preliminary tremors are not shown, and during the first two seconds of the record the motion was already strong. It then became suddenly violent, the ground moving 37 mm., followed by a counter movement of 73 mm., the maximum horizontal displacement during the earthquake. At about the same time, the maximum vertical motion of 10 mm. occurred. The movement, which lasted altogether 4½ minutes, soon became comparatively weak, and it is no doubt to the small number of violent oscillations that the slight amount of damage is due. As usual, the direction of motion changed during the earthquake, but the maximum horizontal motion was directed towards S. 70° W., and this is identical with the mean direction of overturning of 245 stone lanterns in different parts of Tokyo.

THE Natural History Society of Queensland, established in the beginning of 1892, has progressed so well that it is able to issue a volume of *Transactions*. The volume should prove to be a useful contribution to the literature on the natural history of the colony.

THE fifteenth volume of observations of "Rainfall in the East Indian Archipelago," published by the Government of Netherlands, India, has been received. The volume is edited by Mr. Van der Stok, the director of the observatory at Batavia, and it comprises observations made at 194 stations, of which 104 are in Java and Madoera, and ninety in Sumatra and the different islands of the Eastern Archipelago.

IN the *Geological Magazine* for April appears a translation of a Swedish paper by Prof. Lindström, on the discovery of *Cyathaspis* in the Silurian formation of Gotland. In the cutting of canals for the drainage of marshy tracts of the island, many good exposures have been made of the fossiliferous marl-shales that underlie the famous limestones with the operculate coral *Rhizophyllum*. Among the fossils obtained from these shales were a pair of dorsal shields of a Pteraspidian fish. Hitherto the oldest known indubitable fish-remains date from the Ludlow epoch, but the Gotland beds are of Wenlock age. It is pointed out that since the vertebrate character of the Cambrian conodonts has been disproved, and the supposed Ordovician fish-remains of North America are very doubtfully of that age, these Gotland fossils are, for the present, the oldest known Vertebrates.

FIRST among the new editions received within the past few days is Prof. James Dana's "Manual of Geology," published by the American Book Company. The appearance of this fourth edition of Prof. Dana's classical work, makes us marvel at the energy of the eminent author who, though now eighty-three years of age, could rewrite the whole of the matter in such a ponderous volume as the "Manual," and add one hundred and fifty pages to what was published in the third edition. It is hardly necessary to say that a multitude of new principles, new theories, and new facts, in all branches of geology, have been included in the new edition. "The Partition of Africa" (Stanford), by Mr. J. Scott Keltie, has reached a second edition, after two years of life. The many events that have taken place in Africa during this time are all given consideration. Another volume which has attained the eminence of a second edition is "Outlines of Zoology," by Mr. J. A. Thomson, published by Mr. Y. J. Pentland. The book has evidently been appreciated by students of zoology as a manual for use in the lecture-room, museum, and laboratory. Messrs. W. H. Allen and Co. have published a third and revised edition of "Practical Microscopy," by Mr. G. E. Davis.

THE lower sulphide of carbon, CS, appears to have been obtained by Dr. Deninger, of the Dresden Laboratory, in considerable quantities. Anhydrous sodium sulphide and excess of chloroform were heated in sealed tubes, from which the air had previously been removed, to a temperature about 180°. Upon opening the tubes after cooling a large volume of gas was discharged, which consisted of sulphuretted hydrogen, a small quantity of hydrogen chloride, and a new gas, which was practically unaffected by passage through a solution of caustic soda. This gas was combustible, burning with production of sulphur dioxide, and would appear to be carbon monosulphide, produced in accordance with the following equation:

$$3Na_2S + 2CHCl_3 = H_2S + 6NaCl + 2CS.$$

The same gas is obtained, less admixed with impurity, by heating in sealed tubes a mixture of silver sulphide and iodoform, and subsequently allowing the product, consisting of carbon monosulphide and sulphuretted hydrogen, to bubble through caustic soda solution, whereby the latter gas is absorbed.

$$3Ag_2S + 2CHI_3 = H_2S + 6AgI + 2CS.$$

An analysis was made of the gas thus obtained, and the result agreed with the formula CS. The gas explodes violently in the eudiometer, so that analysis is not readily carried out volumetrically; the explosion pipette was destroyed in a second attempt. The action of sodium upon carbon disulphide was next studied. When the metal is placed in the liquid disulphide it becomes coated with a greyish substance, which prevents further action. It was found, however, that aniline dissolves this coating, leaving the metal clean; when carbon disulphide is then added, a continuous evolution of gas occurs, but the greater portion of the gas does not escape, being energetically absorbed by aniline, unless the sodium is maintained at the surface of the liquid. After purification of the gas by passage through caustic soda, and through triethyl phosphine to remove carbon disulphide, it is found to burn with a blue flame, with production of sulphur dioxide and water. The latter is owing to admixture of free hydrogen, which can readily be isolated by absorption of the carbon monosulphide in aniline in a Hempel burette. Carbon monosulphide is also rapidly absorbed by alcohol. Upon allowing the mixture of hydrogen and carbon monosulphide to stream through tubes immersed in a freezing mixture, the latter gas condensed to a clear colourless liquid, which rapidly evaporated upon removal from the freezing mixture. It would thus appear that carbon monosulphide is a gaseous substance at the ordinary temperature, but which readily condenses to a liquid in an ordinary freezing mixture, is combustible, and is energetically absorbed by alcohol and aniline.

THE additions to the Zoological Society's Gardens during the past week include a Feline Douracouli (*Nyctipithecus vociferans*) from South Brazil, a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, presented by Mr. Augusto Lewy; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Lady Aitchison; two Hybrid Widgeon (between *Mareca penelope*, ♂, and *M. chilœnsis*, ♀), bred in England, presented by Mr. J. Charlton Parr; seven Common Skinks (*Scincus officinalis*) from the Sahara Desert, presented by Major Sullivan; a Haast's Apteryx (*Apteryx haasti*), an Auckland Island Duck (*Nesonetta aucklandica*) from New Zealand, nine Hamadryads (*Ophiophagus elaps*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

THE LYRID METEORS.—Mr. Denning draws attention to the fact that this year the Lyrid shower may be observed practically in the absence of the moon. Though rarely forming a striking shower, the stream is astronomically important for the reason that it is probably the only one, besides the Perseids, which has its radiant displaced on successive nights of observation. The duration of the shower is from April 16 to 23, with a maximum on the 20th, and the displacement of the radiant is comparatively small. On April 20, the radiant is situated in R.A. 270°, Decl. + 33°, that is, about 1° N. of 104 Herculis, a star of the 5th magnitude. Like the Perseids of August, the Lyrids never fail to show themselves, though they are rarely to be compared with the Perseids in point of richness (*Observatory*, April). The orbit of the swarm is probably identical with that of Comet I, 1861.

A NEW FORM OF ZENITH TELESCOPE.—The determination of the zenith distances of stars near the zenith appears likely to be greatly simplified by an arrangement recently devised by M. Louis Fabry (*Bulletin Astronomique*, April). The main idea is to materialise the zenith point so that micrometric measurements can be made directly in the field of view. A horizontal telescope is fixed in the meridian, and in front of it is a thin sheet of glass inclined at 45°; beneath this is a basin of mercury. When adjusted so that the reflected image of the cross-wires is coincident with the wires themselves, the wires mark the zenith point, and stars of sufficient brightness will also be seen in the field of view after transmission through the glass and subsequent reflection from the mercury and glass. The great objection to this simple plan is the reduction of brightness of the star images, and there is also an objection to observing stars after reflection from mercury. To overcome these difficulties, a second telescope is directed towards the first, so that the cross-wires can be seen at the centre of the field, and the sheet of glass is coated with silver to a thickness that will just allow the strongly illuminated cross-wires of the first telescope to be seen in the second. The first telescope thus serves the purpose of marking the zenith point, and this is utilised in the second telescope for the measurement of distances.

As compared with the zenith telescopes in common use, the new instrument has the advantage of greater simplicity and rigidity, and it is unnecessary to make differential measures of stars north and south of the zenith. It should especially be of use in such an investigation as that of the variation of latitude.

THE ORION NEBULA.—An exhaustive discussion of the photographs of this nebula, and of the stars in its vicinity, taken at Harvard and elsewhere, has been recently completed by Prof. W. H. Pickering (*Annals of the Harvard College Observatory*, vol. xxxii. part 1.) 146 stars have been catalogued, in addition to those given by Bond for the same area, and a comparison of magnitudes suggests that a few of the stars are either variable or have increased in brightness. No clear indications of change in the nebula, either of shape, position, or brilliancy, have been detected in the photographs taken during the last ten years. By the ingenious arrangement of photographing the nebula through a thin perforated sheet of brass placed in contact with the sensitive film, Prof. Pickering has constructed a chart of the nebula showing isophotal contours, or lines of equal photographic intensity, which will be very valuable in subsequent searching for evidence of change. A photograph of the spectrum of the nebula taken with the objective prism shows at a glance which regions shine with light of any particular wave length. The image corresponding to the hydrogen line $H\gamma$ is seen to resemble most closely the ordinary photographs, while the ultra-violet line at λ 372 is found particularly strong along the south-east border of the Huyghenian region. Among the photographs reproduced, that showing the vast nebulosity which nearly surrounds the whole constellation of Orion is, perhaps, of the greatest interest. This was taken with a portrait lens of about $2\frac{1}{2}$ inches aperture, and shows the nebulous stream, about 15 degrees in diameter, which has since been photographed by Prof. Barnard (NATURE, vol. li. p. 253). Prof. Pickering gives reasons for supposing that the parallax of this remarkable nebula is not greater than 0″·003, corresponding to a distance of 1000 light-years. A useful account of the fundamental principles and processes of astronomical photography, including the determination of photographic stellar magnitudes, is given in the same volume of the *Annals*.

THE SUN'S PLACE IN NATURE.[1]

III.

THE next question that we have now to consider has to do with the connection between nebulæ and stars, and I shall show that the more the facts are studied the closer does this connection prove to be. You remember that that was the idea which lay at the bottom of the hypotheses both of Kant and of Laplace. In the last lecture I referred to some of the earliest observations which had been made of the nebulæ by means of the spectroscope, and it so happened that Dr. Huggins, to whom we owe this work, came to the conclusion that the result of his inquiries was rather to show that this connection, which had been asserted both by Kant and Laplace, and which had been accepted by everybody up to then, really did not exist. In a paper which detailed these spectroscopic observations, published in 1865, Dr. Huggins stated his conclusion that the nebulæ, instead of having anything whatever to do with any evolutionary line along which both nebulæ and stars might be traced, possessed a structure and a purpose in relation to the universe altogether distinct and of another order. So that you see the first apparent teaching which we got from the spectroscope practically put us in a very considerable difficulty; if it had to be accepted, of course the views of Kant and Laplace would have to be rejected.

When I commenced my general survey in 1887, this view held the field, and further, it was imagined that the observations of Dr. Huggins justified the idea that the nebulæ were masses of gas; what particular gas will concern us a little later on, but for the moment I need only say that these statements announcing the nebulæ to consist of one or two gases, at once led to several most remarkable views of the general constitution of the heavens.

Near the end of this nineteenth century chemists claim to know something of the materials which have built up the planet on which we dwell, and if you consult any of the books which have been written about spectrum analysis, giving the results of the work during the last thirty years or so, you will find it stated over and over again that the spectroscope has put it for ever beyond doubt that the chemistry of the skies, *i.e.* the chemistry of the various bodies which people space, and which are at a sufficiently high temperature to enable us to examine them spectroscopically, exactly resembles the chemistry of the earth. So that, if this were true, we should have a common chemistry of the earth, of the stars, and among the stars of course our own sun. On the other hand, we should have, according to Dr. Huggins, absolutely and completely distinct from these bodies another class, the nebulæ, in which the chemistry is absolutely and completely unique. This was so clearly the idea suggested to philosophical students of these questions, that Dr. Wolf, a famous French astronomer, who has written an all-important book for those who are interested in these inquiries, "Les hypotheses cosmogoniques," published in 1886, writes: "If we admit the data of spectrum analysis as to the gaseous state of these singular bodies, the nebulæ, and the simplicity of their composition, one is led to see in them only the residuum of the primitive matter after condensation into suns and into planets has extracted the greater part of the simple elements which we find on the earth and chemically in some of the stars."

It was perfectly clear then to Dr. Wolf that, if the constitution of the nebulæ was anything like what was supposed to have been revealed by early spectroscopic observation, we were dealing with a residuum. There was one kind of action in space, bringing together one class of elements with which we are familiar here, and forming them into stars, suns, and planets; but there was another kind of matter which declined to form part of these aggregations, which remained by itself, and finally put on the appearance of the so called nebulæ.

The first thing I have to say concerning this view is, that the discussion of the spectroscopic observations which I told you, in the last lecture, had been undertaken with a view of seeing what really could be determined in relation to this question, showed, beyond all question, that there was no ground whatever for it; that there was no real ground for supposing that there was this enormous difference between the nebulæ and the stars. In the year 1887, the year following the course of lectures to which I have already referred, after testing the views on this question by an appeal to all the available observations, I stated that the facts taken in all their generality showed that the nebulæ simply represent early stages of evolution; that is to say, that we have a continuous and orderly progression from the nebulæ to the oldest star, and that the nebulæ represent the first stage, and the oldest star or planet represents the last. It seemed to be perfectly clear from the discussion that we were justified in stating that every nebula which is visible now will some time or other, owing to the condensation of its various parts, become a star of some order or another; and that it is equally true to say that every star which we see now in the heavens, knowing it to be a star, has really been a nebula at some time or another.

I told you that the first suggestion of a possible condition which would enable an evolution to take place from nebulæ to stars had been made by Prof. Tait, when he thought that probably cool meteoritic particles might have something to do with it. The complete inquiry shows that these meteoritic particles might account equally well both for the luminosity of comets and of nebulæ. This association is important because it is generally conceded that comets are swarms of meteorites.

It seemed so obvious that there was this close connection that in 1888 I predicted that, if the nebulæ were carefully observed, we should find in them sooner or later indications of that same substance which makes the comet's spectrum so very distinct and special. In almost every comet which has been observed, the spectrum of carbon, or of some compound of carbon, is the strongest and most obvious feature which is presented to us. In 1889, *i.e.* only the next year, matters were made very much clearer by the discovery, by Mr. Fowler and Mr. Taylor, of the spectrum of carbon in the nebula of Andromeda (Fig. 12), so that there, you see, was a prediction verified, and such verification is always a very precious

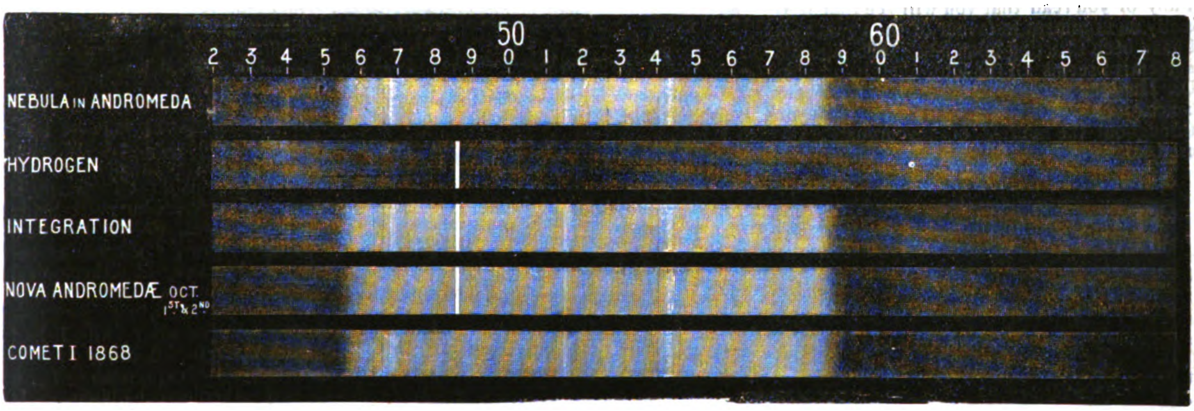

FIG. 12.—Spectrum of the nebula in Andromeda compared with Nova Andromedæ and comet. The flutings common to all are those of carbon.

[1] Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December, 1894. (Continued from page 397.)

test, since it helps us to know whether one is going right or wrong, and it seemed to strengthen very much the view under consideration. Further, not only do we find carbon both in comets and nebulæ but it is recognised by everybody that in some stars the same substance exists in enormous quantities. Here, then, we are in the presence of the fact that the statement that there is an enormous chemical difference in structure between nebulæ and stars is shown spectroscopically to be unfounded, while the evidence also goes to show that there is a close connection between nebulæ and comets. By this, of course, the argument is very much strengthened all round, because, as we have seen, nearly everybody agrees that comets most probably consist of meteoritic stones or particles.

I am glad to say that among the first to accept the new evidence proving that nebulæ are really early stages of evolution of stars was Dr. Huggins himself, the observer whose statement which I have quoted I had been fighting for years. That you see was a great victory. He says now not only that these bodies may represent early forms; places them in the line of evolution where I had placed them, but he even adduces the same evidence which I had brought forward in several of the arguments which I had employed. Dr. Huggins made a reference to this question as President of the British Association in the year 1891, and if any of you read that you will see that it is really an argument in favour of the views that I have been insisting upon since 1886, and his agreement seems all the more important since Dr. Huggins appears to have arrived at these conclusions quite independently. Not one word is said throughout the address of any arguments which I may have used, or of any line of thought or observation on which I had founded the various statements which I had made; and therefore it would be charitable to suppose that he was unacquainted with my work when that address was given to the world. Of course. you will acknowledge that that was a very extraordinary change of opinion, so extraordinary indeed that it is clear that Dr. Huggins felt that it was of importance to himself that the change should be explained; and he confesses in the address, to which I refer, that the communication he made to the Royal Society in 1864 was not entirely founded on scientific evidence, but partly made under, to use his own words, "the undue influence of theological opinions then widely prevalent."

FIG. 13.—The nebula near 52 Cygni, from a photograph by Dr. Roberts.

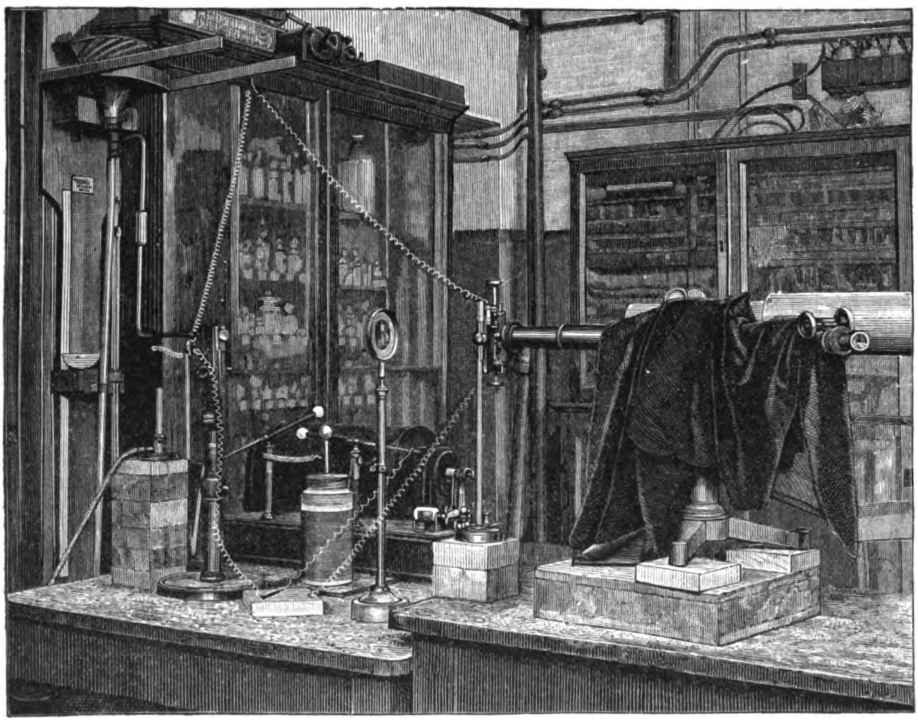

FIG 14.—Observation of a meteoritic glow.

So after all I had been fighting partly an expression of a theological opinion. If we had known that before, probably some trouble might have been saved.

It is a very important thing to know that now, from east to west, those who dwell upon this planet are all perfectly convinced that nebulæ are early forms in the evolution of the heavenly bodies. The more one knows of the history of human thought, especially during the last two centuries, the more important does it seem that that result should be acknowledged as one of the most important truths established during the present century.

Before I go further, let me refer to two or three typical examples of these strange bodies, as I can do by the kindness of Dr. Roberts, whose method of work I described in the last lecture.

First of all we have a representation of a form of nebulæ which is not very common, but the study of which is all important for our present purpose. It is called a spiral nebula, it is one of the nebulæ in the constellation of the Great Bear. I wish to point out that in the centre we have a condensation, and from the centre of the condensation the luminosity gradually gets less and less until at last we have no luminosity greater than that of the surrounding sky. In the nebula itself we find exquisite spirals, starting apparently from different points, and gradually coming towards the centre, and if you look along these spirals you will see that the star-like masses, which may not be stars, are in many cases located on the spirals, representing apparently minor condensations, each spiral itself being probably brighter than the other parts because it is more disturbed.

Next we have an absolutely untouched photograph of the famous Dumb-bell Nebula. I am certain that many here have studied the drawings of this nebula given in encyclopædias and in books of astronomy during the last forty years, and that it is a great comfort to you to see, as it is to me to be able to show you, the autobiographical account that it gives of itself, because if you refer to those drawings it will be very difficult to find any two alike, even if it is distinctly stated that one has been copied from the other. In this again we find a central condensation, and associated with it arcs in which the luminosity is greater than in the adjacent regions.

The other nebula that I have to exhibit is one remarkable for its difference from the other two, inasmuch as no condensation is suggested. This nebula, which you see stretching across the screen like a sort of celestial river (Fig. 13), seems to be careering through space, and I call your attention specially to this because it is well to remember that, if we have meteoritic swarms in space, *i.e.* swarms which are condensing, it is quite possible that we may have meteoritic streams. I think you will consider that it is not any misuse of words to say that we have there a possibility of a meteoritic *stream*.

So much then for some typical representations of some of the different forms of nebulæ.

While, however, Dr. Huggins in his presidential address, apparently from quite independent inquiry, announced my main contention, viz. that nebulæ and stars *do* belong to the same order of celestial bodies, and withdrew his unfortunate statement as having been made on theological grounds, I am compelled to say, but wish to say it with the utmost courtesy, that a complete study of the literature shows that he was quite familiar with my work all the time, and that while he thought fit to republish my main contention as his own on the one hand, on the other he was engaged in attempting to throw discredit on my work, and to conceal his retreat after the manner of the sepia by a

1

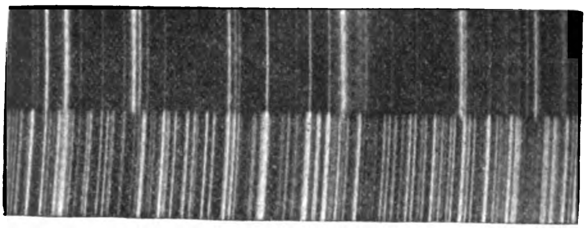

FIG. 15.—Line-spectra of barium and iron. 1, Barium. 2, Iron.

great cloud of ink—printer's ink, referring to a minor point. He endeavoured to suggest to anybody who was not really completely acquainted with my work, that the methods employed by my assistants and myself for something like three years were inaccurate, and that the conclusion reached, which must have been right because he had come to agree with it, had been got at in the wrong way. Although the charges of inaccuracy which Dr. Huggins thought fit to make were general, in his printed papers the chief stress has been laid upon a statement I had made with regard to a matter of secondary importance in the general discussion, I refer to the possible origin of the chief line in the nebular spectrum.

I propose to go into this matter in some detail, because it will enable me to indicate the closeness with which the skill of trained observers and the magnificent instruments of modern research that I have already referred to, enable us now to deal with facts, and to replace the imperfect observations of the past with others of which the accuracy may be relied upon.

Among the many lines of evidence which had been brought forward, it was stated by myself that in following up the suggestion of Prof. Tait and experimenting upon meteoritic dust, a line had been seen very near the position of the chief line which Dr. Huggins had discovered in the year 1864 in the spectrum of the nebulæ. In fact, after accumulating all the spectroscopic

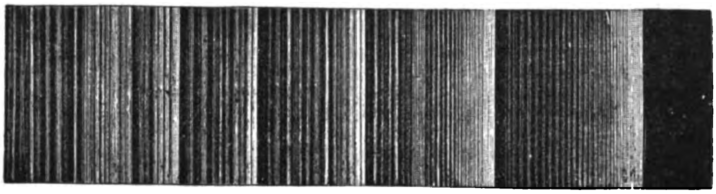

FIG. 16.—Flutings of carbon.

observations which I could lay my hands on, I went on to experiment myself, and I have here some apparatus which will give you an idea of the kind of experiment which was undertaken (Fig. 14.) Meteoritic dust is placed in a horizontal spectrum tube connected with a Sprengel air-pump, so that an electric spark can be passed through the dust; an image is formed on the slit of the spectroscope, and an arrangement for an ordinary electric spark in air serves for a comparison spectrum. The point was to see whether there was any probability that Prof. Tait's suggestion was right, by examining the spectrum of meteoritic dust. For this purpose some dust was placed in a tube resembling the one now on the table, and an electric current was sent through it. Now it had long been known that when one heats meteoritic dust, it gives out compounds of carbon, and also hydrogen gas; what I did was to observe the change in the spectrum of that tube under different conditions. For instance, if it were wished to expose the dust to a higher temperature, a Bunsen burner was placed underneath it.

You will be able to see that, in a little time, the heat will make a considerable difference in the phenomenon observed in the region which comes under its influence, and I think you will also see that in some parts we get a distinct indication of green colour. Now what I found was that in the spectrum of dust from several meteorites so examined, there was a line very near the position which had been stated by Dr. Huggins to represent the actual position of the chief line seen in the spectrum of the nebulæ. That line I was able to trace home by comparative work to olivine, a substance which occurs in almost all meteorites, even in iron meteorites. and not only to olivine, but to one of the constituents of it, which is magnesium. I have here a diagram of some of the results obtained in the green part of the spectrum, and it will be seen that we get in the nebula of Orion, and in the comets of 1866 and 1886, a bright line apparently in the same position. When I say line I should correct myself, this luminosity given out by magnesium does not take the form of a line as ordinarily so called. I will throw on the screen photographs of two spectra of the vapours of two metallic substances, barium and iron (Fig. 15), and you will then see what is meant by men of science when they talk about a line spectrum.

But besides what we call line spectra, there is another thoroughly well-recognised class, which we call fluted spectra, because it reminds one of the flutings of a column. Here, for instance, is a fluting of carbon (Fig. 16). In these flutings, instead of the lines being distributed irregularly, as in the case of iron and barium, we get a beautiful rhythm from one part where the light rapidly degrades to another where there is an enhancement of the light, followed by another degradation, and so on. Indeed, we not only get main flutings, but we get subsidiary flutings.

J. NORMAN LOCKYER.

(*To be continued.*)

THE INSTITUTION OF NAVAL ARCHITECTS.

THE annual spring meeting of the Institution of Naval Architects was held on Wednesday, Thursday, and Friday of last week, in the theatre of the Society of Arts. There was a long list of papers set down for reading and discussion as follows:—

"Notes on further Experience with first-class Battle-ships," by Sir William White, Director of Naval Construction.

"The Elements of Force in a Warship," by Vice-Admiral P. H. Colomb.

"On Steam Pipes," by J. T. Milton, Chief Engineer Surveyor, Lloyds' Registry of Shipping.

"Light Draught River Steamers," by George Rickard.

"On solid Stream Forms and the Depth of Water necessary to avoid abnormal Resistance of Ships," by D. W. Taylor, Senior Assistant to Chief Constructor of U.S. Navy.

"On the Method of initial Condensation and Heat Waste in Steam Engine Cylinders," by Prof. R. H. Thurston, Sibley College, Cornell University, New York.

"Description of an Aluminium Torpedo Boat built for the French Government," by A. F. Yarrow.

"On Vibrations of Higher Order in Steamers, and on Torsional Vibrations," by Otto Schlick.

"On the Vibrations of Ships and Engines," by W. Mallock.

"On a Method of Extinguishing Vibrations in Marine Engines," by Mark Robinson and H. Riall Sankey, Captain (retired) R.E.

"On the Transverse Stability of Floating Vessels containing Liquids, with special Reference to Ships carrying Oil in Bulk," by W. Hök.

"Induced Draught as a Means for developing the Power of Marine Boilers," by W. A. Martin.

After the usual formal proceedings had been transacted, and the President, Lord Brassey, had given a brief address, Sir William White's paper was read by his colleague at the Admiralty, Mr. W. E. Smith, the author being absent owing to serious illness; from which, every one will be glad to hear, he appears in a fair way of recovery. This contribution dealt chiefly, indeed almost wholly, with the question of steadiness in the large battle-ships of the *Royal Sovereign* class, and the effect of fitting them with bilge keels. This paper may be said to be the complement of another memoir by the same author, read before the Institution last year, in which the experience gained with the big line of battle-ships was recorded. When the *Royal Sovereign* was designed, it was thought that the period of oscillation would approximate to that of the *Inconstant*, *Hercules*, and *Sultan*, which were all remarkably steady ships. The *Hercules* and *Sultan* had only shallow side keels from 9 to 10 inches deep. It was thought that the great inertia due to the large dimensions of the new ships would render them so steady that these small bilge keels might be omitted. That the expectations formed in this respect have not been fulfilled, shows that even the best-informed naval architects, even when supported by the best scientific evidence at their command, may be wrong at times. The performance of the ships of the *Royal Sovereign* class at sea led to the fitting of bilge keels to one of them—the *Repulse*. These keels are each about 200 feet long and 3 feet deep. Four of the class were at sea off the west coast of Scotland in company. There was a long low swell, 300 to 400 feet from crest to crest, and with a period of about ten to twelve seconds. The *Resolution*, without bilge keels, rolled 23, and the *Repulse* 10. The sea was on the quarter, and the speed such as to produce heavy rolling. The records of angle of roll were obtained by the pendulum, an instrument notoriously untrustworthy, but in the present case the results quoted were probably fairly accurate. At any rate, there was no doubt that the behaviour of the ship was immensely improved by the bilge keels, and it was decided to fit all other ships of the class in a similar manner to the *Repulse*. The consensus of opinion of naval officers is that rolling has been greatly reduced. Sir William White very frankly admits that the steadying effect of bilge keels has greatly exceeded that which was anticipated; and, indeed, the opinion of naval architects at large will now have to be readjusted, and the data upon which ship designers work will require to be modified. For scientific purposes more exact information was required than could be obtained by trials at sea, on which, as is well known, it is generally impossible to obtain accurate records. It was therefore arranged that still-water rolling experiments should be made with the sister ships *Revenge* and *Resolution*. Mr. R. E. Froude, whose father's work is so well known in this field, had charge of these trials. One series of experiments was made before bilge keels were fitted, and another after the keels had been attached. Each series was divided into two sections, the ships having a metacentric height of 3½ feet in one case, and a little under 4 feet in the other. The conditions approximate to those of maximum and minimum stability on service. The oscillation of the ships was produced by training the heavy guns and running men across the deck in the usual way. The results of these trials were shown by means of diagrams hung on the walls of the theatre. Curves for the older ships *Sultan* and *Inconstant* were also placed on the diagram. Starting from an angle of inclination of 12° from the vertical, it was seen that in order to reduce the corresponding inclination of 6°, the *Revenge*, without bilge keels, required to make 18 to 20 swings, and the *Sultan* about 17; there being a remarkable similarity between the curves of declining angles of the two ships. The *Sultan*, as already stated, has always been considered a satisfactory vessel in regard to steadiness. Starting from an angle of inclination of 6° from the vertical, it required 45 swings in the *Revenge* without bilge keels to reduce the corresponding angle of inclination to 2°. After bilge keels were fitted, an equal reduction was obtained by only 8 swings. For the *Sultan* and *Inconstant*, 32 to 20 swings respectively would be required to produce the same reduction. The *Revenge*, before the bilge keels were fitted, could be rolled up to an angle of inclination of 13° to the vertical by moving her barbette guns. After the keels were in place it was difficult to exceed an inclination to the vertical of 6° to 8°, even with 300 to 400 men running across the deck, and acting in conjunction with the movement of the guns.

The variation in the periods of swing (from out to out) brought to light by these trials are instructive. Without bilge keels, the author continues, the rolling was practically isochronous at large as well as small angles. The period for a single swing was 7·6 seconds for maximum stiffness, and 8 seconds for minimum stiffness, for large as well as small arcs of oscillation. With bilge keels, within the range of experiment up to a swing of about 12° (6° each side), the period of a single swing decreased as the angle of inclination became smaller; the reduction being about 2½ per cent. in going from a mean inclination to the vertical of 5° to one of 1°. When the metacentric heights and radii of gyration of the ship were appreciably unchanged, there was an increase of about 5 per cent. in the period due to the action of the bilge keels.

A study of the action of bilge keels on a ship's performance not only involves questions of the greatest practical importance to the ship designer, but also problems of high scientific interest. From whichever point of view we consider Sir William White's paper, it is one of exceptional value. It is seldom that the naval architect has the opportunity of making trials or experiments on so grand a scale as that afforded by the big battle-ships of the *Royal Sovereign* class, and for this reason we are giving unusual space to this paper. Nevertheless, we are unable to follow the author in his comparison of the experiments under consideration with those previously made both by French and English engineers. For these we must refer our readers to the original memoir, confining ourselves to the main results, from which a comprehensive view of the scope of the paper may be formed. One of the most important of these results is the increased extinctive effect shown by the experiments to be produced by bilge keels when the ship has headway, compared to the effect when she is not progressing. The experiments under way were limited in number, and, as the author points out, are perhaps not so definite as those with the ship not having headway. "Still they are very suggestive," to once more quote the author's words, "and confirmatory of the conclusion from previous experience that the rate of extinction is sensibly increased by headway, the ship entering undisturbed water while oscillating, and the inertia of that undisturbed water having to be overcome." We can only quote the broad results. Starting at 5° from the vertical the angles of inclination reached, after a certain number of swings, were as follows:—After 4 swings, no headway 2·95°, at 10 knots 2·35°, at 12 knots 2·2°. After 16 swings, no headway 1·15°, 10 knots ·20°, 12 knots ·25°.

It will be remembered by students of this subject that the late Mr. Froude assigned a coefficient of resistance of 1·6 lbs.

per square foot for deadwood and keels moving at 1 foot per second, and this was confirmed by the behaviour of the *Sultan*. Accepting Mr. Froude's formula, the extinctive effect due to bilge keels, such as have been added to the *Revenge*, was calculated, with the result that, in an extreme case, supposing the ship to be rolling to 20° on each side of the vertical, the extinction value due to the bilge keels would appear to be not quite 2°. This, it will be seen, is far short of the observed results obtained from the vessels themselves. Working on the data that have been obtained in this way, new coefficients have been calculated for bilge keel resistance, it being assumed that the whole increase of work were credited to the bilge keel area. For an angle of swing of about 10° instead of the coefficient being 1·6 lbs., it would be about 11 lbs. for a swing of 4° the coefficient would reach as high a value as 15 or 16. It must be remembered that these coefficients are not put forward as truly representative, they only hold good if the assumptions stated are accurate.

In any case the difference is very great. Mr. R. E. Froude, who contributed a most interesting speech to the discussion, confessed that the results took him, when he first had them put before him, entirely by surprise, and, indeed, he did not credit the statements made as to the improved behaviour of the ships; or, rather, he could not attribute this improvement to the presence of the bilge keels. We judged, however, from his remarks that he now accepts the observed data and the truth of the recorded experimental conditions, but still considers the phenomenon one for which he can offer no adequate explanation. He himself had made tank experiments which agreed fairly well with the results obtained by his father, and was quite at a loss to account for the great difference between these experiments and the results of the trials now recorded. The only explanation he could suggest was that bilge keels, on a rolling ship, meet on the return roll with water set in motion by the previous roll; but this, he thought, was quite insufficient to account for an increase in resistance of as much as, say, ten times that which would be calculated on the 1·6 coefficient. Naval architects will be glad to hear that the whole question is to be madethe subject of exhaustive inquiry at Haslar. The principal reasons that bilge keels are not fitted—putting aside expense and difficulties as to docking—are that they add to the immersed surface, and are thus likely to decrease speed. It is, therefore, satisfactory to learn that "the practical tests of actual service prove there is no sensible reduction in speed for power." As it is also stated that the keels have not sensibly reduced diameter of circles made by the vessels, and, further, that additional steadiness in steering has been obtained, it is not hazarding much to say that in future ships of this class in the Royal Navy will all be fitted with bilge keels, unless exigencies of docking forbid their application.

The space which we have devoted to Sir William White's paper will compel us to dismiss most of the other contributions briefly. Mr. Milton's paper on steam-pipes was an excellent practical contribution, and was followed by a no less excellent discussion. The general conclusion arrived at appeared to be that, with high pressure, steel steam-pipes are likely to take the place of those of copper. Mr. Taylor's paper was read in brief abstract, and as it was not in the hands of members until a few minutes before the meeting, we must pass it by. The same thing may be said of Prof. Thurston's paper. It is very gratifying to the members of an English institution to receive papers from foreign members of such eminence as the two American gentlemen just mentioned. We regret we have not yet been able to devote the time to their contributions which their merits doubtless demand. Mr. Yarrow's paper on the aluminium torpedo boat he had built for the French Government, was a very interesting contribution. The boat appears to have been thoroughly successful, so much so that she is to be the prototype of a class. The discussion turned largely on the form of test pieces for copper alloys, it being generally conceded that there is a want of standard conditions for tests. The micro-sections of various alloys thrown on the screen were also very interesting.

The last day of the meeting (Friday) was devoted chiefly to the vibration question, the sitting proving one of the most instructive of the series. As will be seen, three papers were contributed on this important and interesting subject.

These three papers on vibration of steamers formed, with Sir William White's paper on steadiness, the two distinctive features of the meeting. It is hardly necessary to insist on the importance of these two features in steamship performance, both of which affect alike the comfort of the passenger in mercantile vessels, and fighting efficiency in a war vessel. Since engine power has increased so greatly and speeds have been raised, the vibration question has become one of extreme importance in passenger steamers. Two of the most recent largest and costliest of our ocean liners were almost unfitted for carrying passengers—at any rate, they were fast acquiring an uneviable reputation—on account of excessive vibration. By the application of scientific principles the cause of this defect was traced, and the evil cured; a circumstance, if measured by money value, now worth many thousands of pounds to the owners. The extremely interesting paper and series of experiments performed two or three years ago by Mr. Yarrow, at a meeting of this Institution, will be remembered by our readers; and since then Herr Schlick has read two papers on the subject. Records of these will be found in previous volumes of NATURE. The seriousness of vibration in steam vessels is largely dependent upon the period of the hull as a structure synchronising with the beats of the engines, and thus it is that a vessel may vibrate excessively at speeds less than the highest speed she can attain. That is the elementary fact upon which a study of the problem is based. Herr Schlick, in his previous papers, has already considered the case of vibrations of the first order—that is to say, such oscillations of the longitudinal axis of a ship in a vertical direction as have two nodular points. Vibrations of this order claim most attention because they are most common, and are more violent than those of higher orders. It is in vessels with engines running at high speeds that vibrations of a higher order are sometimes observed. It would, as the author of the paper points out, be very advantageous if the naval architect could ascertain beforehand the position of the nodular points of a ship in getting out the design; but this, he is of opinion, cannot be done directly in a satisfactory manner. Mr. Mallock also enters into this question, as will be seen when we deal with his paper later on. As the question cannot be treated directly in a satisfactory manner in the case of a ship, Herr Schlick has recourse to the mathematical investigations of the vibrations of an elastic, prismatical rod. Such investigations have been made by several authorities, and the author quotes at some length the formulæ that have been constructed for vibrations of the first and higher orders. These it is not necessary to repeat.

It is evident that in a complex structure like the hull of a vessel, the vibrations will be of a very different nature to those of a prismatical rod. Treating only of vibrations of the first order—for the author has not yet succeeded in correctly ascertaining coefficients for the second order—Herr Schlick finds that in a ship they are at a greater distance from the ends than in a vibrating prismatic rod; a circumstance which is explained by the fact that a ship is less weighted in the ends than in the middle. For ships of very fine lines, the only class investigated, for vibrations of the first order the distance of the after nodular point from the after perpendicular is 0·231 to 0·253 times the length of the ship. The distance of the fore modular point from the fore perpendicular varies from 0·310 to 0·365 times the length. The author had already shown that an ordinary engine with three cylinders cannot produce vibrations of the first order when the moving weights (pistons, &c.) of each cylinder are in such proportions to each other that the products obtained by multiplying these weights by the distance between the axis of the cylinder and the next nodular point are the same for all three cylinders. The same engine, therefore, will produce vibrations of the second order when the number of the revolutions increases accordingly. The new nodular point, moving away from the engine, causes the moments of the moving weights to be no longer equal to each other. The author considers, therefore, that as the nodular points can only be determined after the ship is completed, it is necessary to alter the moving weights of the engines in such a manner that their moments respecting the nodular point are made equal to each other. The vibrations will thus be considerably reduced, if not entirely avoided. The influence of the screw in producing vibration, owing to the impulses it imparts at the extreme end, is also discussed in this part of the paper; and the author then proceeds to deal with the so-called "horizontal vibrations," which he considers really consist of a twisting action on the ship's axis, due to the turning-moment of the engines, acting on a screw, in the case of a single propeller. An apparatus, constructed for the purpose, illustrated this fact by showing that the horizontal oscillations at the deck and bottom of the ship respectively are in opposite directions at the same instant of time. At a certain height above the keel there is no horizontal oscillation, this being therefore the *locus* of the axis of torsion. Maxima and minima of the turning moment at each revolution depend on the number of cranks, the amplitude of the oscillations being mostly dependent on steam distribution. These oscillations are periodic, and likewise have their nodular points. The author next proceeds to treat the points mentioned mathematically in the case of a prismatic rod. He shows that the number of vibrations is proportional to the speed of progress of vibration. Substituting a ship's body, he finds that this speed of progress remains constant for similar ships, and also that the number of torsional vibrations varies in an indirect proportion with the length of the ship. For a better understanding of these points, we must refer our readers to the original paper and the diagrams by which it is illustrated. That engines of special construction will cause no vibration if placed just above the nodular point, is also true for torsional vibrations.

Mr. Mallock, who, it may be stated, has done much excellent work for the Admiralty in connection with this subject, dealt in his paper with "the determination of the direction and magnitude of the forces and couples which arise from the unbalanced moving parts of marine engines." Something may be done, the author said, towards balancing an engine by the proper disposition of the pistons, connecting-rods, and cranks; but it does not seem practicable to produce a complete balance in any ordinary engine without having recourse to counterbalance weights. In order to determine the weights required, the author has produced a geometrical construction showing, by the aid of arithmetic only, the resultant force and couple due to the unbalanced moving parts of any engine. Without the aid of the diagrams shown at the meeting, it would be impossible to make the explanation clear, even if space permitted us to give the details in full. It will be sufficient to say that the engine is divided up into its component parts, to each of which a value is given, and in this way the resultant force is found and the resultant couple determined. Having got all the information necessary to assign the magnitude and direction of the force and couple which will completely balance the engine, if the force could be applied at the centre of gravity of the moving parts, it would merely remain to decide what weights should be used to produce the required effect. In general the construction of the engine makes this inconvenient, if not impossible, and other positions for the counterbalance weights must be found. This aspect of the problem is then considered in detail by aid of the figures.

The second part of the paper was devoted to showing how the frequency of vibration of any ship, loaded in any manner, can be found by models, and that all the data for shaping these models can be readily obtained from curves which would be in the hands of the ship designer. An example of the apparatus used was shown, the author giving a practical illustration of its working. The course pursued is to make an exact copy of the ship on a very small scale, exactly proportional in all dimensions and identical in material. It is known by theory that the frequency of vibration of the model and ship will be inversely proportional to their lengths. The model is replaced by an exact copy on the same scale, made of some other material—wood—the frequency of the new model differing from that of the former in the ratio

$$\sqrt{\frac{q_s \rho_m}{q_m \rho_s}},$$

where q_m, q_s, and ρ_s are the respective elasticities (Young's Modulus) and densities of the wood and the material of the ship. Next the wooden model is replaced by a plank of the same wood of uniform thickness but variable breadth, the breadth being such that the stiffness of the plank against bending at every cross section is proportional to the stiffness of the model at the corresponding position. Weights are fixed to the plank in such a manner that the weight at any cross section is proportional to the weight at the corresponding section of the model. Then the frequency of the plank, compared with that of the model, can be ascertained by a formula.

In the apparatus shown the plank was supported by two rollers slung from two similar rollers, the latter resting on an overhead railway. The plank was kept vibrating by a magnetic apparatus, and a recording device was added. The rollers supporting the plank gave the position of nodes. It is only when the rollers are at the positions where the nodes would be, if the plank was free from all constraint, that the frequency of the plank will be related to that of the ship as given by the author's formula. The natural nodes are found by varying the position of the rollers until the frequency is a maximum for the type of vibrations under consideration.

The method here introduced by Mr. Mallock is interesting and ingenious, but how far it is applicable to the needs of the naval architect, or whether the average ship builder, if he wish to reduce vibration, will prefer the former method of adjusting the engine to the known conditions of the ship after she is built, are questions which experience alone can decide.

The paper of Mr. Robinson and Captain Sankey dealt largely with the question of vibration in connection with electric light engines, the problem of vibration in the hull of a vessel being thus eliminated. Here again a number of diagrams were used which we cannot now reproduce, and our abstract of this paper must be therefore brief. Investigation showed that in the case of an electric light station the high speed vertical engines, each 200 indicated horse-power, with two cranks set opposite each other, and run at 350 revolutions per minute, were mounted on a large slab of concrete. The engines being vertical, the moving parts had to travel through a greater distance during the upper half of the revolution of the crank pin, than during the lower half. Calculation showed that each line of parts singly tended to lift the engine at up-stroke by about 3·5 tons, and it tended to depress it 2·3 tons. Therefore twice in a revolution a net lifting power of one ton acted upon the engine, and changed an equal number of times into a depressing power of about 1·2 tons. The result was a "pumping action" on the water-soaked soil beneath the concrete slab, and in this way vibration was conveyed to surrounding buildings. The action, it will be seen, was due to the angular movement of the connecting rods, a feature which Herr Schlick said might be neglected; a point in which the authors, naturally, and also Mr. Mallock, by no means agreed with him.

An arrangement of two engines with their framings rigidly connected, and having three cylinders each, was proposed, the object being to neutralise the endways rocking or tilting tendency, and also to give freedom from tendency to vary the downward pressure.

A discussion followed the reading of these papers.

Mr. Hök's paper described a new way of carrying out a known investigation. Whether the new way is better than the old way, is a point which may be decided by experience. The last paper of the meeting, that by Mr. Martin, was of a disappointing nature. Marine engineers have long been asking for an explanation of the hitherto unexplained fact—if fact it be—that "induced draught" is so much better for boilers than "forced draught." Mr. Martin's experiments were quite beside the mark.

The summer meeting of the Institution will be held in Paris, commencing on June 11.

QUESTIONS BEARING ON SPECIFIC STABILITY.[1]

AT the suggestion of your President, I beg to submit three questions to the notice of this Society. They bear on a theoretical problem of much importance, namely, the part played in evolution by "organic stability."

The questions are especially addressed to those who have had experience in breeding, but by no means to breeders only; nor are they addressed only to entomologists, being equally appropriate to the followers of every other branch of natural history. I should be grateful for replies relating to any species of animal or plant, whether based on personal observation or referring to such observations of others as are still scattered through the wide range of periodical literature, not having yet found a place in standard works. The questions are for information on:—

(1) Instances of such strongly marked peculiarities, whether in form, in colour, or in habit, as have occasionally appeared in a single or in a few individuals among a brood; but no record is wanted of monstrosities, or of such other characteristics as are clearly inconsistent with health and vigour.

[1] A paper read at the Entomological Society, April 3, 1895, by Francis Galton, F.R.S.

(2) Instances in which any one of the above peculiarities has appeared in the broods of different parents. In replying to this question, it will be hardly worth while to record the sudden appearance of either albinism or melanism, as both are well known to be of frequent occurrence.

Note.—The question is *not* asked now, whether such peculiarities, or "sports," may be accounted for by atavism or other hypothetical cause.

(3) Instances in which any of these peculiarly characterised individuals have transmitted their peculiarities, hereditarily, to one or more generations. Especial mention should be made, whether the peculiarity was in any case transmitted in all its original intensity, and numerical data would be particularly acceptable, that showed the frequency of its transmission (*a*) in an undiluted form, (*b*) in one that was more or less diluted, and (*c*) of its non-transmission in any perceptible degree.[1]

It is impossible to explain to a general meeting the precise way in which the desired facts would be utilised. An explanation that would be sufficiently brief for the purpose could not be rendered intelligible except to those few who are already familiar with the evidence, and the technical treatment of it by which the law of Regression is established, and with the consequences and requirements of that law. Regressiveness and stability are contrasted conditions, and neither of them can be fully understood apart from the other.

I may as well take this opportunity of appending a list of my various memoirs on these subjects. They appeared from time to time in various forms as the inquiry progressed and as suitable openings occurred for writing or speaking. The more important of these are Nos. 1, 3, part of 6, 7, and 8 in the following list. Nos. 1 to 5 refer to regression only.

LIST OF MEMOIRS, BY MR. F. GALTON, ON REGRESSION AND ORGANIC STABILITY.

(1) Typical Laws of Heredity. *Journal* of the Royal Institution, 1877. (This was the first statement of the law of Regression, as founded on a series of experiments with sweet peas.)

(2) Presidential Address, Anthropological Section of the British Association, 1885. (Here the law of Regression was confirmed by anthropological observations.)

(3) Regression towards Mediocrity in Family Stature. *Journal* of the Anthropological Institute, 1885. (A revised and illustrated reprint of No. 2.)

(4) Family Likeness in Stature. *Proc. Roy. Soc.*, 1886.

(5) Family Likeness in Eye Colour. *Proc. Roy. Soc.*, 1886.

(6) Natural Inheritance. (Macmillan and Co., 1889.) (This volume summarises the results of previous work.)

(7) Patterns in Thumb and Finger Marks . . . and the Resemblance of their Classes to Ordinary Genera. *Phil. Trans. Roy. Soc.*, 1891.

(8) Discontinuity in Evolution. *Mind*, 1894. (An article on Mr. Bateson's work.)

A NEW DETERMINATION OF THE OHM.

A FRESH determination of the value of the ohm in absolute measure has been made by F. Himstedt (*Wiedemann's Annalen*, liv. p. 305). The method employed is that which the author had used in a previous determination, and consists of passing through a galvanometer all the make or break currents induced in a secondary coil when the current in a long primary helix is interrupted a known number of times per second. A known fraction of the primary current is then passed through the same galvanometer. The primary helix in these experiments consists of a single layer of uncovered copper wire, wound, by means of a screw-cutting lathe, in a regular spiral on a glass cylinder. The turns of wire are held in their place, and the insulation improved, by being coated with shellac. As the mean of a number of determinations, the author obtains the value 106·28 cm. as the length of the column of mercury at 0° C., having a cross section of one square millimetre, which has the resistance of 10^9 C.G.S. units. In connection with the above-described experiments, the author has been led to measure some coefficients of self-induction, using for this purpose a modification of the Rayleigh-Maxwell method. The great difficulty in measuring a coefficient of self-induction by this method is that, in order to get a throw of sufficient magnitude to be accurately measured, it is necessary to employ a somewhat strong current. The result is that the temperature of the coil, the self-induction of which is being measured, rises rapidly, and thus the balance of the Wheatstone's bridge for steady currents is upset. Herr Himstedt gets over this difficulty by using the commutator, which he employs in his determination of the ohm, to break the battery circuit a known number of times per second, and to cut the galvanometer out of circuit while either the make or break is taking place. In this way a steady deflection is obtained of sufficient magnitude to be readily measured, even when the current employed is between 0·001 and 0·002 amperes. The above method only differs from that employed by Profs. Ayrton and Perry in their secohm-meter, in that the author takes two separate readings, one with the bridge balanced for steady currents, the other when the commutator is working, instead of bringing the galvanometer deflector to zero by upsetting the steady current balance.

[1] Written communications should be addressed to F. Galton, 42, Rutland Gate, London, S.W.

THE SMITHSONIAN INSTITUTION REPORT FOR 1894.

MR. S. P. LANGLEY'S report of the operations of the Smithsonian Institution for the year ending June 30, 1894, has just reached this country, and it furnishes interesting reading on a number of points relating to the U.S. National Museum, the Bureau of Ethnology, the Bureau of International Exchanges, the National Zoological Park, and the Astrophysical Observatory.

The total permanent funds of the Institution are now 911,000 dollars, and interest at the rate of 6 per cent. per annum is allowed upon this by the Treasury, the interest alone being used in carrying out the aims of the Institution. The total receipts during the fiscal year covered by the Report amounted to 69,967 dollars, and the entire expenditure, including a sum of eight thousand dollars added to the permanent fund, was 67,461 dollars. The Institution also disbursed the Treasury grants of 14,500 dollars for International Exchanges; 40,000 dollars for North American Ethnology; 154,000 dollars for the U.S. National Museum; 50,000 dollars for the National Zoological Park; and 9000 dollars for the Astro-Physical Observatory.

It appears to be an essential portion of the original scheme of the government of the Institution that its secretary should be expected to advance knowledge, whether in letters or in science, by personal research; but the increasing demands of time for labours of administration has greatly limited the possibility of doing this. Mr. Langley has, however, found time to continue his researches upon the solar spectrum (see NATURE, November 1, 1894). This work, carried on in the Astro-Physical Observatory, is certainly of more than common importance. His investigations upon aerodynamics have also been continued intermittently. They are not complete, but they appear to point to conclusions of general and unusual interest.

A widespread interest seems to have been awakened in the Hodgkins competition, with reference to investigations appertaining to the nature and properties of atmospheric air. A letter printed in NATURE of June 21, 1894, announced that the time within which papers might be submitted was extended to the end of last year. The Report informs us that, up to June 30, 1894, 250 memoirs, printed and manuscript, had been received in connection with the competition, representing correspondents in the United States, Mexico, England, Scotland, Norway, Denmark, Russia (including Finland), France, Belgium, Germany, Austria-Hungary, Servia, Italy, and British India.

A few grants have been made from the Hodgkins Fund, in aid of certain important researches. In this connection we notice that Prof. E. W. Morley's work on the determinations of the density of oxygen and hydrogen, aided by special apparatus provided by the Institution, is approaching completion.

The investigations undertaken by Dr. J. S. Billings and Dr. S. Weir Mitchell into the nature of the peculiar substances of organic origin contained in the air expired by human beings, has been continued under a grant from the Hodgkins Fund, and also the researches by Dr. O. Lummer and Dr. E. Pringsheim, of Berlin University, on the determination of an exact measure of the cooling of gases while expanding, with a view to revising the value of that most important constant which is technically termed the "gamma" function.

Mr. Langley refers again to the unsatisfactory condition of the National Museum. The collections have increased so greatly that unless additional space is provided for their proper administration and exhibition, the efficiency of the Museum will be greatly impaired; but though the collections are growing rapidly in certain directions, they are not increasing as symmetrically and consistently as is manifestly desirable—a very common cause of complaint. A defect which calls for instant attention, however, relates to the most undesirable and dangerous storage of collections in wooden sheds near the Smithsonian building, and in the basement of the building itself, where large alcoholic collections in bottles containing, in the bulk, many thousands of gallons of alcohol, have been put away, as space cannot be found for the specimens in the Museum. It appears that a fire communicated to these rooms would sweep through the entire length of the building, and although the building itself is fireproof as against any ordinary danger, it may well be doubted whether any of the collections therein exhibited can be regarded as safe, if the rooms immediately below should be exposed to so peculiarly severe a conflagration as would be caused by the ignition of these large quantities of inflammable material. Such a calamity would affect the whole scientific world, and we trust that the appeal for a change of the present condition of affairs will not be disregarded.

The investigations relating to the ethnology of the American Indians were carried forward during the year, under the efficient control of Major J. W. Powell, the director, aided by Mr. W. J. McGee, ethnologist in charge, as executive officers. These researches of the Bureau of American Ethnology embrace the subjects of archæology, descriptive ethnology, sociology, pictography and sign language, linguistics, mythology, psychology, and bibliography, and the results obtained during the year have never been exceeded in value.

The Smithsonian Exchange Service was inaugurated nearly half a century ago, with the object of carrying out one of the purposes of the founder of the Institution in the diffusion of that knowledge which the Institution itself helped to create. For this purpose it established correspondence with scientific men all over the world, until there is no civilised country or people, however remote, upon the surface of our planet, so far as is known, where the Institution is not thus represented. These correspondents have grown in numbers until at the present time those external to the United States alone number nearly 17,000. More than one hundred tons of books passed through the exchange office during the fiscal year 1893–94.

It was only five years ago since an appropriation was made for the National Zoological Park at Washington. The park has an area of nearly 167 acres, but there are as yet only four permanent buildings, while the animals number 510, of which 200 are of the larger size. Comparing this with similar establishments at other capitals, it is noted that the Gardens of our Zoological Society cover about 36 acres, are crowded with buildings, and that the magnificent collection of animals, some 2300 in number, is housed in a fairly comfortable manner. In Paris the portion of the Jardin des Plantes assigned to animals is a plat of ground some 17 acres in extent, crowded with 900 animals. In Berlin the portion of the Thiergarten appropriated for animals occupies about 60 acres. Fifteen hundred animals are accommodated and, necessarily, much overcrowded. In the United States the principal collections are in Philadelphia, where the grounds occupy about 40 acres, and the collection comprises 881 animals; in Cincinnati, where 36 acres are occupied with about 800 animals; and in New York, where the city maintains about 700 animals in Central Park, occupying an area of approximately 10 acres. In none of these collections are the grounds of sufficient size to give any extensive range for the animals.

Appended to Mr. Langley's general account of the affairs of the Institution and of its bureaus, are the detailed and statistical reports from the officers in charge of the different branches of work. The whole shows how very great and valuable is the work done in the United States "for the increase and diffusion of knowledge among men."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Prof. C. S. Sherrington, F.R.S., has been appointed to the George Holt Chair of Physiology in University College, Liverpool.

Dr. A. W. Crossley, Berkeley Fellow, and Demonstrator of Organic Chemistry, in the Owens College, Manchester, has been elected Demonstrator of Chemistry in the Medical School of St. Thomas's Hospital, in succession to Dr. W. H. Ince, who has been appointed Government Chemist at Trinidad.

Sir Dinshaw Manockjee Petit, Bart., has, through the Principal, Mr. S. Cooke, offered to the Indian Government the sum of 5000 rupees towards the cost of providing residential quarters for Parsee students attending the College of Science at Poona.

The Governors of Colfe's Foundation have selected Mr. F. W. Lucas to be Head Master of Colfe's Grammar School, Lewisham, from September next. Mr. Lucas is at present Head Master of Hipperholme Grammar School, Yorks, and was formerly Senior Assistant and Science Master at Roan School, Greenwich.

We learn from the *Lancet*, that in accordance with the will of the late Dr. G. Y. Heath, Professor of Surgery in the University of Durham, and President of the University of Durham College of Medicine, the trustees of the Heath Scholarship, Prof. W. C. Arnison and Mr. Frederick Page, will award and pay to the writer of the best essay on Surgical Diseases of the Jaws the sum of £200. All graduates in medicine or in surgery of the University of Durham are eligible to compete for this prize. The essay must be typewritten or printed, and delivered to the trustees not later than March 31, 1896. The essay, together with any specimens, drawings, casts, microscopical preparations, or other means of illustration accompanying it, will become the property of the College of Medicine, Newcastle-upon-Tyne, but by permission the essay may be printed for general circulation by the Heath Scholar. Mr. Stephen Scott, of Harrogate, has generously presented to the College of Medicine the sum of £1000, which has been devoted, in accordance with Mr. Scott's wish, to founding a scholarship to promote the study of hernia and allied subjects. Any graduate in medicine or surgery of the University of Durham, or any student of the University of Durham College of Medicine is eligible to compete for the scholarship, provided that such student shall have had at least one academical year in attendance at the College, and that in any case his age does not exceed thirty years at the time when the essay is sent in. The competition takes place every year. Essays for this year's competition must be sent not later than July 31, 1895, to Prof. Arnison, University of Durham College of Medicine, Newcastle-upon-Tyne.

On Friday last, Mr. Acland received a deputation at the Education Office, from the representatives of the Association of Head Masters, respecting the recent regulations which have been issued by the Science and Art Department with reference to organised science schools. After hearing the views of the deputation, Mr. Acland, in reply, said it was not desired to make an upheaval of the arrangements for these schools, but to join together in improving the method and the system on which the teaching was carried on. They were all agreed that to lessen too frequent examination, and to introduce the element of inspection, if reasonably carried on in a friendly spirit, would be of great value to these schools. One of the objects of the Department had been to make it clear that, besides the teaching of science, which was the primary object of these schools, they also desired fully to recognise the element of literature and the teaching of special subjects. In order to meet a point which had been raised, as to the change from the old system of organised science schools to the new, the closing words of the syllabus would be:—"Reasonable latitude will be allowed for two years in any departures which may be made from the prescribed course while the changes from the present to the new system are being brought about." Taking these words, together with the words in the earlier part of the syllabus, as to reasonable latitude being allowed to teachers as to the nature of the course which they might pursue, provided that the instruction was sound, satisfactory in amount, and combined with proper practical work, it would be seen that the Department had no intention of being too despotic, and that if really good and reasonable work was done under some more elastic system, these organised science schools would be found of even more benefit in the future than they had been in the past.

SCIENTIFIC SERIALS.

The Mathematical Gazette, No. 4 (Macmillan).—This is the first number of the enlarged series. We are glad to find that the support accorded to the first year's issue has been sufficient to warrant this enlargement; but to make the *Gazette* a success, and not a drag upon the funds of the Association, it is imperatively necessary that a much larger measure of support should be rendered by the general body of mathematical teachers. The opening paper is one on algebra in schools, which was read before the Association at its annual meeting in January of this year. In this article the author, Mr. Heppel, drawing upon his wide experience as a "coach," states that when pupils have come to him he has found that the work in algebra has usually to be done all over again. The reason of this appears to him to be "the ever-growing divergence there is between the conception of the nature and objects of algebra that dominates school teaching and the conception that regulates the application of algebra to more advanced mathematics." Many of the suggestions are likely to be useful, and we commend them to the notice of our brethren in the craft of teaching.—Mr. T. Wilson contributes a note on mathematics for astronomy and navigation, in which he suggests that the elements of spherical trigonometry might occupy a more prominent place in school teaching than they do, and to cover all ages he winds up with, "let no one despair that he is too old for mathematics."—Mr. Rouse adds a second chapter to his previous interesting article on conics.—"Some old text-books" is a review of John Ward's "The Young Mathematician's Guide" (1747), by Mr. J. H. Hooker, which brings before us matter that was served up for the food of students in the time of "good Queen Anne." The rest of the number is taken up with more extended articles (than before) entitled notes, solutions, new questions, and titles of new books. These latter pages should be of general interest, as they are likely to be useful both to students and teachers.

Bulletin of the American Mathematical Society, series 20, vol. i. No, 6, March 1895.—The notice of "Arthur Cayley," pp. 133–141, which opens this number, is a warm appreciation of the character and writings of our great mathematician, by Dr. Charlotte Scott, and is due to her "intense admiration for his work and personality, and to the fact that for the last fourteen years" she has "been privileged to know him and experience his kindness." It is the fullest account we have yet read, and has many more points of interest for an Englishman than Signor Brioschi's *éloge*, which is naturally confined more closely to an appreciation of his mathematical work. One extract we must make:—"Any sketch of Prof. Cayley is self-condemned if it leaves out of account the child like purity and simplicity of his nature, the entire freedom from the professional touchiness on the score of priority to which mathematicians are as liable as other men. He was ever ready to say what he was working at, to indicate the lines of thought, to state what difficulties he was encountering . . . but his greatness and his simplicity cannot be enshrined in anecdotes.—Prof. Osgood (pp. 142–154) in "The Theory of Functions," analyses, chapter by chapter, Dr. (now Prof.) Forsyth's brilliant work on "The Theory of Functions of a Complex Variable," and winds up thus:—"The book is not one that can safely be put into the hands of the immature student for a first introduction to the study of the theory of functions. But the student who is already familiar with the elements, and who has acquired some degree of critical power, will find its pages incentive to valuable work in this wide field."—A short note follows on the introduction of the notion of hyperbolic functions, by Prof. Haskell, which was read before the Society at its December (1894) meeting.—The second summer meeting of the Society is to be held at Springfield, Mass., on August 27.

Internationales Archiv für Ethnographie, Band vii. Heft iv. 1894. This part commences with a long and thorough study (in German) on the hair-cutting customs of the Southern Slavs, by Friedrich S. Krauss. Several songs are reproduced in the original, which are also translated into German. In this study two elementary ideas of mankind are met with, but imbued with the local colour of the Southern Slavs, and varied in tint according to the stage of culture. Hair-cutting is a means of adoption into kinship, and also as a redemption from the sacrifice of the body or life to the spirit of disease. It is a rite performed for social obligations and for good luck.—Prof. P. J. Veth concludes his exhaustive account (in Dutch) of the Mandrake, which is a valuable contribution to signature-lore or sympathetic magic. The most interesting of the "Notes" is an illustrated communication by A. Herrmann, on the cupping and blood-letting appliances of the wandering gypsies.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 21.—"On the Diselectrification of Air." By Lord Kelvin, P.R.S., Magnus Maclean, and Alexander Galt.

§ 1. The experiment described in § 14 of our paper on the "Electrification of Air and other Gases by bubbling through Water and other Liquids" (*Roy. Soc. Proc.*, February 21, 1895), proves that air, electrified negatively by bubbling through water and caused to pass through a metallic wire gauze strainer, gives up some, but not a large proportion, of its electricity to the metal. We have now made a fresh experimental arrangement for the purpose of investigating diselectrification of air which has been electrified, whether positively or negatively, by other means than bubbling through water: with apparatus represented in Figs. 1 and 2, which is simplified from that of our former paper by the omission of the apparatus for electrification by bubbling, and for collecting large quantities of electrified air.

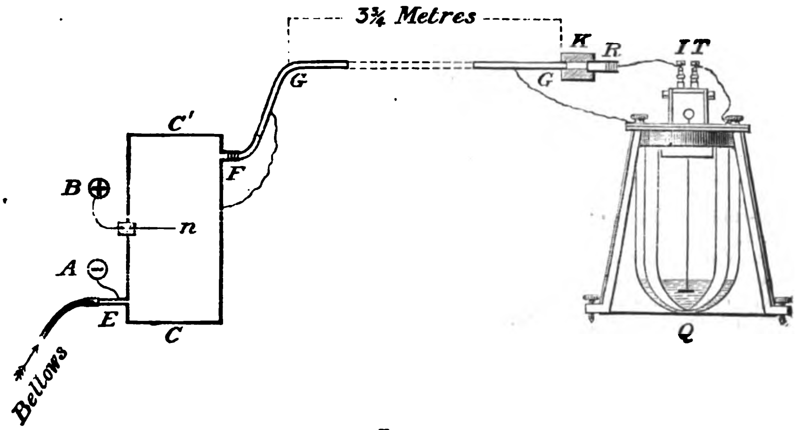

FIG. 1.

§ 2. In Fig. 1, A B represent the two terminals of a Voss electric machine connected, one of them to a metal can, C C′ (a small biscuit canister of tinned iron), and the other to a fine needle, of which the point *n* is in the centre of the can. The wire making the connection to the needle passes through the centre of a hole in the side of the can, stopped by a paraffin plug. Air is blown from bellows through a pipe, E, near the bottom of the can, and allowed to escape from near the top through an electric filter, F, called the tested filter, from which it passes through a long block-tin pipe, G G, about 3¾ metres long and 1 cm. internal diameter, and thence through a short tunnel in a block of paraffin, K. From this, lastly, it passes through a second electric filter, R, into the open air. This second filter, which we sometimes call the *testing filter*, sometimes the *electric receiver*, is kept in metallic connection with the insulated terminal, I, of a quadrant electrometer, Q. The metal can and the block-tin pipe are metallically connected to the outer case and uninsulated terminal, T, of the quadrant electrometer.

§ 3. The testing filter or electric receiver consists of twelve discs of brass-wire cloth fixed across the mouth of a short metal pipe supported on the end of the paraffin tunnel in the manner represented in Fig. 2, on a scale of twice the size of the filter which we have actually used, or of true size for a filter on a tube of 2 cm. diameter, which for some purposes may be better. One of eleven similar discs, of size adapted to a tube of 2 cm. diameter, and an outermost disc with projecting lugs, are shown, true size, and with the gauge of the wire-cloth which we have actually used, shown true size, in Fig. 3. The eleven little circular discs of wire cloth are held in position by bending over them the four lugs belonging to the outermost disc, and all are kept compactly together by a short piece of

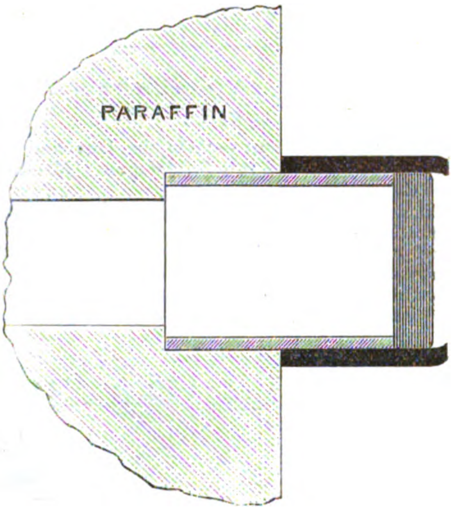

FIG. 2.

india-rubber tube stretched over them outside, as shown in Fig. 2.

§ 4. We commenced with a few experiments to test the efficiency of the testing filter, R, with no tested filter at F, and merely continuous block-tin pipe, F G G, from the can to the paraffin tunnel. First, working the bellows with no electrification of the needle point, we found no sensible electric effect on the electrometer, which proved that, whether from natural electrification of the air of the laboratory, or by the action of the bellows, or by the passage of the air through the long metal pipe, no electrification sensible to our test was produced. After

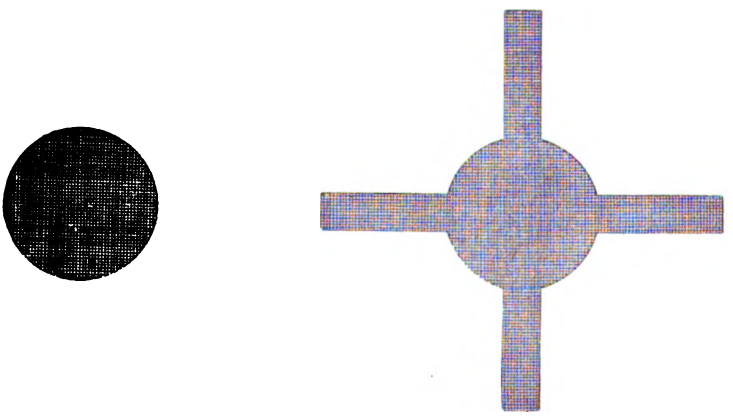

FIG. 3.—Twenty-five wires to the centimetre. Diameter of each wire is 0·16 mm. Hence each aperture is 0·24 mm. square.

that we kept the needle point, *n*, electrified, either positively or negatively, for five or six minutes at a time by turning the little Voss machine, and we found large effects rising to about $3\frac{1}{2}$ volts in five minutes, positive or negative, according as *n* was positive or negative.

§ 5. The apparatus is now ready to test the efficacy of filters or other appliances of different kinds placed at F for the purpose of diselectrifying air which has been electrified, whether positively or negatively, by the electrified needle point *n*. We began with a filter of 12 wire-gauze discs, placed at F and kept in metallic connection with the tin pipe outside. This nearly halved the electricity shown by the electrometer. We then tried 24, 48, 72, 96, 120 wire-gauze discs, successively, placed in groups of 24, and separated from one another by short lengths of 2 cm. of lead tube, in the line of the flow of the air between F and G (Fig. 1), all kept in metallic connection with the block-tin pipe and the outer case of the electrometer. We were surprised with the smallness of the additions to the diselectrifying efficiency of the 12 strainers first tried: for example, the filter of 120 wire gauzes only reduced the electrical indication to a little less than one-half of what it was with the 12 which we first tried.

We found that cotton-wool between the spaces in the groups of 24 wire gauzes largely increased the diselectrifying effect. Thus, with 72 wire gauzes and cotton-wool we succeeded in reducing the electrical effect to about one-twelfth of what it was with only a filter of 12 wire gauzes; but hitherto we have not succeeded in rendering imperceptibly small the electricity yielded by the outflowing air to the testing filter R in our method of observation.

§ 6. We intend trying various methods of obtaining more and more nearly complete diselectrification of the electrified air flowing out of the can at F; and this for air electrified otherwise than by the needle point, as shown in the diagram: for instance, by an electrified flame in place of the needle point; or again by bubbling through water or other liquids. Meantime, the mere fact that the electricity, whether positive or negative, given to air by an electrified needle point, can be conveyed through 3 or 4 metres of small metal tube (1 cm. diameter), and shown on a quadrant electrometer by a receiving filter, is not without interest. We may add now that, with the receiving filter removed and merely a fine platinum wire put in the mouth of the paraffin tunnel, we have found that enough of electricity is taken from the outflowing air to be amply shown by the quadrant electrometer; which renders even more surprising the fact that the diselectrifying power of 120 strainers of fine wire-gauze should be so small as we have found it.

"On the Question of Dielectric Hysteresis." By Alfred W. Porter and David K. Morris.

The experiment described was intended to test whether the dissipation of energy that occurs in the dielectric of a condenser is due to true hysteresis (as claimed by Riccardo Arnò), or simply to viscosity. To discriminate between them it is essential that the condenser be put through a cyclic series of states at such a slow rate that all viscous effects shall have had time to subside before a measurement of the charge corresponding to a certain potential difference is made. It is essential also to arrange

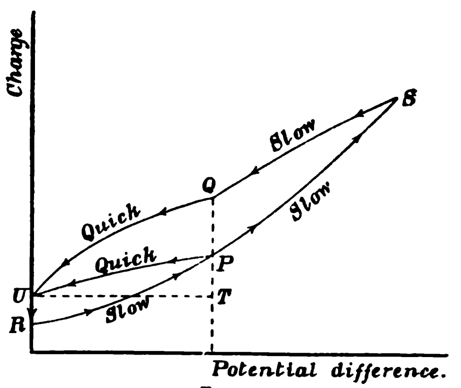

FIG. 1.

that any test of the charge which involves a change of state should itself form part of the cycle. This was accomplished by making the cycles as shown in the figure, the cyclic order being R P U R P S Q U R; the portions P U and Q U representing discharges through a galvanometer. If hysteresis exist, the change of charge Q T will be greater than the change P T. As the result of twelve cycles the ratio QT/PT comes out $1 \div \frac{1}{8760}$; a second series of twelve gives $1 - \frac{1}{10350}$.

Hence the charge is sensibly the same for a given value of the potential difference, whether that value has been arrived at from lower or from higher values than itself.

Fresh evidence is also given of the presence of viscosity.

Thus while the condenser here experimented upon exhibits marked viscous effects, yet the authors could detect no hysteresis.

Entomological Society, April 3.—Prof. R. Meldola, F.R.S., President, in the chair.—Mr. C. J. Gahan exhibited two examples, male and female, of a rare Prioned beetle, *Chariea cyanea*, Serville, which had been kindly sent to him for examination by M. René Oberthür; and stated that Lacordaire was mistaken with regard to the sex of the specimen which he described in the "Genera des Coléoptères." He pointed out that the elytra of the male were relatively much shorter than those of the female; and that the joints of the antennæ from the third to the tenth were biramose. Mr. Gahan also exhibited two species of the genus *Decarthria*, Hope, and said he believed these were the two smallest species of Longicorns known.—Dr. Sharp, F.R.S., exhibited the soldiers and workers of a species of Termites found by Dr. Haviland in South Africa. He stated that these insects possessed eyes and worked in daylight like Hymenopterous ants, and that in habits they resembled harvesting ants by cutting grass and carrying it into holes in the ground. Dr. Sharp said that although these holes were probably the entrance to the nests, Dr. Haviland was unable to find the actual nest, even by prolonged digging, so that the winged forms were still unknown. He thought this species was probably allied to *Termes viarum* of Smeathman, in which the soldiers and workers possessed eyes, and had been observed by Smeathman to issue from holes in the ground, but whose nests could not be discovered. Mr. McLachlan observed that it was possible there might be species of Termites without any winged form whatever.—Mr. Rye called attention to the action of one of the Conservators of Wimbledon Common, who, he stated, had been destroying all the aspens on the Common. He inquired whether it was possible for the Entomological Society to protest against the destruction of the trees. Mr. Goss said he would mention the matter to the Commons' Preservation Society.—Mr. Francis Galton, F.R.S., read a paper entitled "Entomological Queries bearing on the Question of Specific Stability." (See p. 570.)—Mr. Merrifield stated that he received some years ago, from Sheffield, ova of *Selenia illustraria*, the brood from which produced, in addition to typical specimens, four of a dark bronze colour, and from these he bred a number of specimens of a similar colour.—Dr. F. A. Dixey referred to a variety of the larva of *Saturnia carpini* with pink tubercles. He said the imago bred from this larva produced larvæ of which 10 per cent. had pink tubercles. Prof. Poulton, F.R.S., said he had found larvæ of *Smerinthus ocellatus* with red spots, and that this peculiarity had been perpetuated in their descendants. Mr. McLachlan, Canon Fowler, and Prof. Meldola made some further remarks on the subject.—Mr. G. F. Hampson read a paper by Mr. C. W. Barker, entitled "Notes on Seasonal Dimorphism in certain species of Rhopalocera in Natal." Mr. Merrifield said he was of opinion that a record of the temperature at different seasons would be a very desirable addition to observations of seasonal dimorphism. Mr. Hampson said he believed that temperature had very little to do with the alteration of forms. At any rate, according to his experience, in India the wet season form succeeded the dry season form without any apparent difference in the temperature. Prof. Poulton remarked that the apparent temperature as felt must not be relied upon without observations taken by the thermometer. Dr. Dixey, Mr. Barrett, Dr. Sharp, and Prof. Meldola continued the discussion.

Zoological Society, April 2.—W. T. Blanford, F.R.S., Vice-President, in the Chair.—Mr. Boulenger exhibited the type specimens of two new chameleons from Usambara, German East Africa. Special interest attached to them from the fact that they appeared to be more nearly related to the Madagascar species than to any of the numerous forms now known from Continental Africa.—Mr. Walter E. Collinge read a paper on the sensory canal system of fishes, treating of the morphology and innervation of the system in the Physostomous Teleostei.—Dr. Mivart, F.R.S., read a paper descriptive of the skeleton in *Lorius flavopalliatus*, comparing it with that of *Psittacus erithacus*, and pointed out a number of differences in detail.—Mr. G. A. Boulenger, F.R.S., made remarks on some cranial characters of the salmonoid fishes, and expressed the opinion that there was no justification for separating *Coregonus* and *Thymallus* from the Salmonidæ, as had been proposed by Cope and Gill.—Prof. T. W. Bridge read a paper in which he pointed out certain features in the skull of *Osteoglossum*. The author directed attention to the existence of a peculiar oral masticatory mechanism in *Osteoglossum formosum*, distinct from that furnished by the upper and lower jaws and their teeth. The existence of an essentially similar mechanism in the Ganoid *Lepidosteus osseus* was also described, and the conclusion suggested that the two genera offer in this respect an interesting example of parallelism in evolution.

Linnean Society, March 21.—Mr. C. B. Clarke, President, in the chair.—Prof. Stewart exhibited and made remarks upon a series of corals, dwelling upon certain characteristic features which illustrated their structure.—Mr. S. Pace brought forward a collection of shells belonging to the genus *Columbella*, and made some observations concerning the peculiarities and the geographical distribution of some of the species exhibited. A paper was then read by the President, "On the terminal flower in the *Cyperaceæ*." After remarking that the order *Cyperaceæ* had been newly arranged by Dr. Pax in Engler's "Jahrbücher" (1886), and in Engler and Prantl's "Pflanzenfamilien," the character taken for primary division of the order being the inflorescence, he pointed out that in the first sub-order Scirpoideæ with an axillary flower were placed *Cyperus*, *Scirpus*, *Psilocarya*, *Dichromena*, and *Hypolytrum*; in the second sub-order Caricoideæ with a terminal flower were placed *Schoenus Rynchospora*, *Mapania* and also *Carex*, *Scleria*, and their allies. The disruption of *Hypolytrum* from *Mapania*, of *Dichromena* and *Psilocarya* from *Rynchospora*, he thought, proved either that the modern method pursued by Dr. Pax was of limited systematic value, or that he had grievously erred in his ascertainment of the fact whether in such genus the flower is terminal or not. Mr. Clarke exhibited his own analyses of the spikelet in the larger genera in dispute. He held that in *Carex*, *Scleria*, and their allies, the flower, male and female, was strictly axillary; that in *Rynchospora* it was axillary—exactly as in *Dichromena* and *Psilocarya*—while in *Hypolytrum* the flower is terminal exactly as in *Mapania*. He further maintained that these facts could be sufficiently shown by the aid of a penknife and pocket-lens, and that no results which might be hereafter obtained by studies in development could affect either the weight to be attributed to the character of "terminal flower," or to the real affinities of the genera. The paper was illustrated by lantern slides illustrating dissections, and, in the discussion which followed, criticism was offered by Sir D. Brandis, Mr. A. B. Rendle, Dr. Prain, and Dr. D. H. Scott.—On the conclusion of this paper, Dr. H. Field, of Brooklyn, New York, made some remarks on the proposed establishment of a central international bureau for zoological bibliography, and the annual publication of an international Zoological Record.

Mathematical Society, April 4.—Major MacMahon, R.A., F.R.S., President, in the chair.—The Rev. T. C. Simmons read a paper on a new theorem in Probability. The author replied to numerous questions put to him by Messrs. G. H. Bryan, Burton, Cunningham, and the President.—The President (Mr. Kempe, F.R.S., in the chair) communicated a note on the linear equations that present themselves in the method of least squares.—The following paper was taken as read: On the Abelian system of differential equations and their rational and integral algebraic integrals, with a discussion of the periodicity of Abelian functions, by the Rev. W. R. W. Roberts.

Geological Society, March 20.—Dr. Henry Woodward, F.R.S., President, in the chair.—On fluvio-glacial and interglacial deposits in Switzerland, by Dr. C. S. Du Riche Preller. This paper is the outcome of one published in the *Geological Magazine* of January 1894, on the "Three Glaciations in Switzerland," in which the author described various glacial deposits near the lake of Zürich. He now describes a series of fluvio-glacial conglomerates and interglacial lignite-deposits near the lakes of Zürich, Constance, Zug, and Thun, which, together with analogous deposits at the base of the Eastern, Western, and Southern Alps, constitute further evidence of two interglacial periods, and therefore of three general glaciations, the oldest of these being of Upper Pliocene, and the others of Middle and Upper Pleistocene age respectively. As regards the origin, age, and the time required for the formation of several of the Swiss deposits referred to in the paper, the author arrives in several respects at conclusions differing from those recently enunciated by others. The author also argues that the first interglacial period was probably of shorter duration than the second; and in confirming his former conclusion that every general glaciation marks a period of filling-up, and every interglacial period marks a period of erosion of valleys, he avers that, if this conclusion be correct, it must needs be destructive of the theory of glacial erosion.—The Bajocian of the Mid-Cotteswolds, by S. S. Buckman. The Mid-Cotteswolds is defined as the district between the valleys of the Frome and the Chelt. A description of twenty-five sections is given, dealing principally with the strata found between the Upper *Trigonia*-grit and the Upper Freestone.

PARIS.

Academy of Sciences, April 1.—M. Cornu in the chair.—On the composition of drainage waters, by M. P. P. Dehérain. An account is given of experiments made on a large scale with fallow-land and with crops of barley, wheat, beet-root, and the vine. The observations began regularly in March 1892; the results are given for three seasons. Comparing the crops of 1893 and 1894 as regards nitrogen, it is seen that the abundant crop of the latter year leaves the soil no more exhausted than the medium crop of 1893. The nitrates produced in the soil, or added as manure, were better utilised in 1894; with the poorer crop a proportion was lost. The author differs from M. Schlœsing, insomuch as the latter believes the loss of nitrogen in drainage water to be so insignificant as to be able to be neglected in practical farming, whereas his own results confirm the Rothamsted experiments, and show that the loss from fallow-lands is much greater than from lands covered with vegetation. The deduction is drawn that it is good practice to follow up crops such as wheat by some form of autumn growth.—Ultra-violet radiation of the solar corona during the total eclipse of April 16, 1893, by M. H. Deslandres. A description of a photograph of the spectrum of the corona obtained in the Senegal expedition of 1893. The photo-spectrometer used had lenses and prisms of quartz and calcite, and thus enabled a great prolongation of the ultra-violet region to be photographed. In accordance with previous observations, it was found that the ultra-violet spectrum was very feeble in intensity as compared with the red; this may be due in part to the great absorbing power of the atmosphere for light in this region of the spectrum.—Solar observations of the second, third, and fourth quarters of 1894, by M. Tacchini.—On the theory of equations to the derived partials of the second order, by M. E. Goursat.—On the sequences of circular permutations, by M. Désiré André. An analogy is pointed out between circular and rectilinear permutations, and it is shown that the former are, in general, more simple. They are not subject to the irregularity introduced into rectilinear permutations by the terminal terms.—On the application of the theory of probability of errors to levelling operations of precision, by M. M. d'Ocagne.—On gratings used in "photogravure," by M. Ch. Féry. A grating of 40 to 60 lines to the centimetre is used to enable the production of a photograph which can be directly reproduced by mechanical processes. Such a photograph must necessarily be devoid of half-tints; the device of placing a grating at a short distance before the sensitive surface replaces these half-tints by alternate black and white squares of the same size. An explanation of this effect is given by the author on the basis of the elementary theory of shadows. On the "molecular deviation" or the "molecular rotatory power" of active substances, by M. A. Aignan. The author asserts that M. Guye's formula for molecular rotatory power is inexact, and cannot be used instead of Biot's formula for the specific rotatory power in the case of solutions.—On a radiometer of symmetrical construction, turning under the action of unsymmetrical illumination, by M. G. Seguy.—An absolute electrometer for high potentials, standard and simplified types, by MM. H. Abraham and J. Lemoine.—An extremely sensitive galvanometer, by M. Pierre Weiss.—On the oldest French series of meteorological and thermometric observations, by M. l'abbé Maze. An account of the contents of a newly-discovered register, entitled "Ad thermometrum observationes anno 1658 Parisiis: Thermometrum Florentiæ fabricatum."—On the first mercury thermometer, by M. l'abbé Maze. Ismael Boulliau used a mercury thermometer together with his Florence thermometer in March 1659, or sixty-two years before Fahrenheit's invention.—Thermal study of the anhydrous barium and strontium iodides, by M. Tassilly.—On the properties of salts of nickel and cobalt, by M. de Koninck. A priority claim.—On the alcoholates of lime and baryta, by M. de Forcrand. A thermal study of the compounds—$(C_2H_6O)_4(CaO)_3$, $(CH_4O)_4(BaO)_3$, and $(C_2H_6O)_4(BaO)_3$. The action of alcohols on the alkaline-earthy oxides does not give true metallic alcoholates, but addition compounds.—On the ammonium bases derived from hexamethyltriamidotriphenylmethane and their action on the fuchsines, by M. A. Rosenstiehl.—On some new combinations of hexamethylene-amine, by M. Delépine.—On the gases of the swimming bladder of fishes, by M. Jules Richard. These consist of oxygen, nitrogen, and traces of carbon dioxide. The oxygen varies in three cases given from 78·6 to 87·7 per cent.—Action of the nervous system on the principal lymphatic canals, by MM. L. Camus and E. Gley.—On the genus *Eurya*, of the family Ternstræmiaceæ, by M. J. Vesque.—On the basic rocks occurring as narrow veins in the lherzolite of the Pyrenees, by M. A. Lacroix. There are two families of granular basic rocks, without peridote and felspar, which are allied to the peridotites.

BOOKS and SERIALS RECEIVED.

BOOKS.—Rainfall in the East Indian Archipelago, 1893 (Batavia).—Short Studies in Nature Knowledge: W. Gee (Macmillan).—Stéréochemie: E. G. Monod (Paris, Gauthier-Villars).—Practical Microscopy: G. E. Davis, 3rd edition (Allen).—Cambridge Natural History—Molluscs and Brachiopods: Rev. A. H. Cooke, A. E. Shipley, and F. R. C. Reed (Macmillan).—Manual of Geology: Prof. J. D. THE EXPERIMENTAL PHYSIOLOGY OF PLANTS.

Practical Physiology of Plants. By Francis Darwin, M.A., F.R.S., and E. Hamilton Acton, M.A. Cambridge Natural Science Manuals, Biological Series. (Cambridge: University Press, 1894.)

THE physiological course which Mr. Francis Darwin gave at Cambridge in 1883, was the first systematic effort, in this country, to teach the phenomena of plant-life to students by means of actual experiments. As we are told in the preface to this book, the experiments were at first demonstrated in the lecture-room; some years later, the students were required to do the practical work for themselves in the laboratory. The example set at Cambridge has been followed in other universities and colleges, to the great benefit of botanical teaching. We all recognise now that practical laboratory work is no less necessary in physiological than in morphological botany, though in the former it is certainly more difficult to organise. The present book, which embodies the results of the experience gained in practical teaching, is in two parts. Part i., on General Physiology, is the more elementary, and therefore the more widely useful; Part ii., on the Chemistry of Metabolism, is of a more advanced character, and is adapted to those students who desire to make a special study of the chemical physiology of plants. The former, we believe, is mainly the work of Mr. Darwin; the latter, of Mr. Acton.

A volume of this kind was very much needed, and it is a matter for congratulation that the work has fallen into the most competent hands. There was nothing of the kind in English before, and the book will be of the greatest service to both teachers and students. It must be clearly understood that it is a strictly practical laboratory guide, which can only be used by those who are willing to experiment for themselves. The volume is in no sense a treatise on physiology, and thus differs from its German predecessor, Detmer's "Pflanzen-physiologisches Practicum," which is to some extent a compromise between a practical guide and a theoretical text-book. The thoroughly practical character of Messrs. Darwin and Acton's book seems to us a great merit; every word in it is of direct use to the experimental worker, and to him alone.

We cannot attempt to give anything like a summary of the contents of the work, which, in spite of its moderate bulk, covers a great deal of ground. Thus in part i. alone, no less than 265 distinct experiments are described. Of course they vary very much in character, some being quite simple and elementary, while others are more of the nature of original research. It goes without saying that a large proportion of the experiments are of Mr. Darwin's own devising, and that nearly all have been practically tested by the authors. Wherever this is not the case, the reader is told so; and if the experiment is, from any cause, at all likely to fail, he is warned of the possible disappointment. The candour with which the student is treated all through, is a very pleasant feature of the book.

The first chapter is on some of the conditions affecting the life of plants, and as the presence of oxygen is among the most important of these conditions, respiration is taken first. Besides the more usual experiments, ingenious demonstrations of intramolecular respiration, and of the excessive consumption of oxygen by germinating oily seeds, are given.

In the second chapter assimilation takes the first place, and many beautiful experiments are described, including Gardiner's ingenious modification of Sachs's iodine method, in which the sun is made to print off, in starch, a copy of a photograph, from a negative placed on the leaf. An experiment proving that excess of carbon dioxide stops assimilation, is especially interesting. When a second edition is called for, Mr. Blackman's new and important experiments on the function of stomata will no doubt find a place.

In the next chapter, which is also concerned with nutrition, particularly good and complete directions are given for the management of water-cultures; these are quite the best we have met with, and will save the experimenter from many failures. The use of Duckweed (*Lemna*) for demonstrating the effect of various food-solutions on growth, is, we believe, new, and is a very neat method. The same chapter includes experiments on the nutrition of the carnivorous plant, Sundew, a subject on which Mr. Darwin's investigations have become classical.

The question of the movement of water in plants is still unsolved. The data of this problem, however, are very thoroughly taught, by means of the experiments described in the sections on the functions of roots, and on transpiration. The latter process is investigated, in the first instance, by means of the potometer, an instrument devised by Mr. Darwin and his pupil Mr. Phillips, in which the speed of the transpiration-current is measured by the rate of ascent of an air-bubble, which is drawn up a capillary glass-tube by a transpiring shoot connected with it.

A particularly ingenious experiment is one in which the hygroscopic twisting and untwisting of an awn of the grass *Stipa*, is made use of as an index of transpiration.

A chapter on physical and mechanical properties treats of such phemonena as imbibition, turgor, osmosis, and the tensions of tissues. It may be pointed out that in the description of Traube's artificial cells, copper *sulphide* is evidently a misprint, either for copper *chloride*, or *sulphate* (p. 111).

The next chapter is on *growth*, and contains, among many other things, full directions for the use of the various kinds of auxanometer.

The remaining chapters are concerned with curvatures (geotropism, heliotropism, traumatic curvature, &c.), and with other movements. Some of the most fascinating experiments come in this part; we will only mention those on the decapitation of roots, an operation which, as Charles Darwin discovered, prevents the root from perceiving the geotropic stimulus, though it does not hinder the curvature of the growing region which may have been induced by a previous stimulation. Attention is here called to the brilliant experiments of Prof. Pfeffer, which have demonstrated conclusively that the tip of the root is alone sensitive to gravitation, thus finally confirming the conclusion drawn by Darwin from less decisive experiments. The announcement of this discovery by Prof. Pfeffer was one of the most interesting incidents in the Biological Section at the Oxford meeting of the British Association.

A self-recording method for studying the sleep-movements of leaves, strikes us as especially valuable.

The second part of the book, on the chemistry of metabolism, is of quite a different character from part i., and is evidently intended for students with an advanced chemical knowledge, who alone can make intelligent use of it. The object aimed at is sufficiently explained in the opening paragraph:

"The practical study of the transformations which plastic substances undergo in metabolism, is an application of organic chemistry: the immediate problem is generally to determine whether certain substances are present or absent, and, if present, in what amounts in particular tissues."

The mode of determination of all the important organic bodies occurring in plants, such as protein, amides, oils, carbohydrates, tannins, acids, and enzymes, is concisely explained.

There are two appendices, the first of which gives examples of quantitative results obtained in actual experiments, in order to show the degree of accuracy which may fairly be expected; the second is a list of reagents.

Within the short space of ninety small pages, which is all that the second part occupies, it is obviously impossible to give full instruction in such a difficult and complicated subject as the practical physiological chemistry of plants. Those, however, who are already good chemists, will no doubt derive great help from the terse directions given here, especially as these are supplemented by abundant references to the more special literature.

The authors are much to be congratulated on their work, which fills a serious gap in the botanical literature of this country. We think it very desirable that a smaller edition of the book should be published for use in schools, bearing somewhat the same relation to the present handbook as Prof. Bower's "Practical Botany for Beginners" bears to his larger manual on the same subject. It is most important, now that physiological botany is supposed to be taught in so many schools throughout the country, that it should really be taught in the only efficient way, namely by experiment, and that it should no longer be made a mere matter of "cramming," as is now too often the case. A selection from the present book of the simplest and most fundamental experiments, such as could be performed with tolerable certainty of result in ordinary science-schools, would, we are sure, be of the greatest service to conscientious teachers, who desire to make their scientific instruction a reality.

D. H. S.

MUSSEL CULTURE.

Mussel Culture and the Bait Supply, with reference more especially to Scotland. By W. L. Calderwood. (London: Macmillan and Co., 1895.)

THIS little book has been written for the useful purpose of calling public attention to the urgent need of an increased supply of mussel bait in the interests of the line fishermen, and in order that the food supply of the country may be increased. It does not contain new facts, but it summarises many old ones, and puts the results of some biological inquiries in a form in which they will be readily available for consultation by members of County Councils and others who ought to be interested in fish-culture. The general conclusion arrived at is one which has been recently pointed out in the pages of NATURE, viz. that a systematic cultivation of our foreshores, such as is now carried on in several European countries—notably France and Holland—must soon be resorted to if we wish to stop the rapid depletion of our shellfish beds.

Sixty years ago the supply of mussels for bait must have seemed almost inexhaustible, but now that larger boats with more men and much longer lines are employed, the supply of bait is rapidly failing at many places round the coast, with the result that we have to import at considerable expense large quantities of mussels annually from Holland. The fact that it is necessary thus to import a mollusc which grows naturally in great abundance on our own shores, is in itself significant of the mismanagement—or total absence of management—of our bait beds in the past. Mr. Calderwood gives an account of the various mussel scalps or beds round the Scottish coast, describes their former extent and their present condition—in most cases a sad story of wicked waste resulting in woful want—and says: "We have seen our public oyster fisheries slowly decline, and all but expire; we now are watching our mussel beds as they diminish in the same way."

It is a pleasant relief to notice that some few beds really *are* regulated and well managed, with the result that they are in a flourishing condition. For example, those at Montrose, where "the grounds now under cultivation were at one time all but destitute of mussels, but by the exertions of the Ferryden and Usan Society of Fishermen, led by Mr. James Johnston, 'seed' was collected and bedded, and the system of cultivation adopted which has since yielded such excellent results" (p. 24). The interesting account of the enterprise of the fishermen at Nairn, in experimenting with mussel culture on their own account, shows how readily new beds may be formed and important results obtained. If such work is to be done, however, to any great extent, we must adopt the French system of renting, on easy terms, the sea-bottom and foreshore to such individuals as will cultivate the beds, and so render them of increased value to the country.

We are reminded by Mr. Calderwood, as a proof of the enhanced value of bait, that the sands of Dun, in Scotland, which were not considered by the fishermen to be worth £5 a year at the beginning of the century, are now let for £500 per annum. Of the various baits for the long lines—mussel, scallop, squid, lugworm, whelk, cockle, &c.—mussel is the most generally distributed, the most easily grown, and altogether the most serviceable and important. The Mussel Commission stated in 1889 that "nearly all the 50,000 fishermen of Scotland use mussels as their bait during some part of the year." It has been calculated that the fishing lines used in Scotland in 1893 would, if tied together, nearly encircle the world twice, and probably about 47,000,000 hooks have to be baited (each with two mussels) every time all the lines are set. These statements give some rough idea of the magnitude of the demand for this bait. If squid could be obtained in sufficient quantity, it would probably be even more valuable than mussels, but its price is usually prohibitive to most fishermen. A fishing firm in Aberdeen paid during this last winter over £200 for squid bait for a single boat's lines for the three months October to December, and there are fifty to sixty of such boats north of the Tyne.

One section of this book gives a short account of the anatomy, and the reproduction, and an outline of the development of the mussel. Most of this is very simple; but it is not easy to understand the following statement (p. 44), where, speaking of the kidneys, Mr. Calderwood says: "Two internal openings also communicate with the cavity in which the heart is situated, and in this way the organ has a more powerful action in aërating the blood"! Whether "the organ" in question is the heart or the kidney is not very clear, and in either case the statement is equally mysterious.

As a single female mussel produces two or three million young, and as innumerable young mussels all round our coast perish miserably every year for want of suitable objects to attach to, there can be no reasonable doubt that the judicious erection of simple stakes, or "bouchots," would serve a useful purpose, at any rate in the collection of seed, even if the further rearing be carried on by means of the bed system. The importance of transplanting, of cropping the beds by rotation, of exterminating enemies such as starfish and whelks, and of avoiding overcrowding, is pointed out; and we are reminded of the opinion of Prof. M'Intosh, endorsed by the Scottish Fishery Board, that "if properly and wisely managed, a mussel fishery will rapidly repay the small initial expense, and might, indeed, be made largely profitable."

The book concludes with a chapter on the legal aspects of the matter, extracts from the Acts in regard to mussel fisheries, and information on the methods of obtaining fishery "orders" in England, Scotland, and Ireland. Some of these legal processes seem unnecessarily complicated and expensive, and it is certainly unfortunate that our local fishery committees can make regulations in regard to their mussel beds, but cannot improve them by cultivation; and yet in parts of England the mussel is even more important than in Scotland, as it is used not merely as bait, but very largely as food in some districts. The book seems singularly free from typographical errors—a curious slip on p. 11 suggests that the author's mind was so full of his subject that he has mis-spelled Mr. Bateson's name. W. A. H.

HISTORICAL EPIDEMIOLOGY.

A History of Epidemics in Britain. By Charles Creighton, M.A., M.D. Vol. ii. From the Extinction of the Plague to the Present Time. (Cambridge: University Press, 1894.)

THE first volume of this work was reviewed in these columns about three years ago, and Dr. Creighton has now brought his difficult task to completion. The labour of disinterring the facts of epidemiological history from the scattered chronicles in which they lie hidden is very considerable, and, when this is accomplished, the historian is further confronted with the difficulty of identifying, under the confused nomenclature of by-gone days, the various pestilences described, and of assigning to them their proper place in modern nosology.

Dr. Creighton has undoubtedly earned the thanks of all students of epidemiology for the painstaking and laborious compilation of facts and references which he has brought together in the present volume. The magnitude of the labour has been immense—the more so since, as the author remarks in the preface, he has had little help from predecessors in the same field. He has at times incorporated with the strictly historical portions of the work ætiological considerations which, we fear, will hardly commend themselves as of equal merit with the rest; these, however, form but a small part of the whole, and though they call for comment, should not be allowed to interfere with our appreciation of the value of the book.

The opening chapter deals with typhus and other continued fevers, and its historical interest is very great. It well illustrates the close connection which exists between the epidemic prevalence of this group of diseases, and the physical environment and social conditions of the population, nor could an instructive lesson in hygiene have been better presented. It is interesting, too, to trace the gradual rise of more exact pathological notions, whereby the old medley of spotted, putrid, miliary, and comatose fevers has been resolved into our modern typhus, enteric, and relapsing fevers. The grouping together of influenzas and "epidemic agues" in another chapter seems warranted by the etymology of the term ague (Latin: *acutus*), the expression being used in early times for any sharp fever: the term "influenza" did not reach England till 1743.

Small-pox naturally receives a full measure of attention. The statements put forward to show that during the seventeenth century the mortality from this disease had not that excessive incidence on infants which afterwards became the rule, are not, in the necessary absence of any statistical evidence, sufficiently convincing. The history and practice of inoculation are treated of at great length, and the account is full of interest. Dr. Creighton's opinions on the subject of vaccination are well known, and it is a pity that in a purely historical work, any bias should have been allowed to appear. He has perhaps done his best to avoid it by treating vaccination, after the year 1825, as "*ex hypothesi* irrelevant," though this proceeding may raise a smile on the faces of many of his readers. Even in the preface the assumption that variola and vaccinia are two perfectly distinct diseases, calls for some comment in the light of recent investigations, and the omission of any reference to the statistics of the Sheffield epidemic of 1887–8 is a serious blot on any work dealing with the history of small-pox. The immunity from small-pox which infants and children enjoy at the present day, receives the not very satisfying explanation that they now have measles, whooping-cough, scarlatina, and diphtheria instead!

In the later chapters the author deals with the last-mentioned diseases and with infantile diarrhœa, dysentery and cholera, the history of which is traced with great care and accuracy. It would indeed be difficult to praise too highly the pains which the author has taken in the collection and arrangement of his historical facts. But he has chosen to add, in many places, considerations as to the nature and causes of the diseases he chronicles, which frequently do not cover all that is known about the subject, and would have been better omitted or treated separately from the historical portions of the book. It is true that, in some cases, there are strong reasons for believing that the virus of a disease may reside in the soil, but it is by no means true for others. It is true that we are ignorant of the precise nature of the virus of many of the diseases discussed in the book; but it is not the case with all. Yet in no single passage dealing with ætiology do we find any reference to even well-established bacteriological facts. It may be that much studying of the records of the past begets a tendency to a mediæval frame of mind. Certainly Dr. Creighton's views on telluric influences will not commend themselves to the modern pathologist, though, like the subjects he treats of, they may possess a historical interest.

But it is a great merit of the book that it can be read with pleasure and instruction by all, however the reader may differ from the author in pathological creed; and Dr. Creighton may be congratulated upon the completion of so excellent and thorough a history of epidemic diseases in this country.

OUR BOOK SHELF.

Grundzüge der mathematischen Chemie. Von Dr. G. Helm. (Leipzig: Wilhelm Engelmann, 1894).

The treatment of the subject-matter of this book is based on the view that in its present state of development, that branch of physical chemistry which relates to chemical change can be discussed from a general standpoint, inasmuch as it affords the clearest and most complete confirmation of the principle of the conservation of energy.

The applications of this principle to chemical interactions are first illustrated by means of the different kinds of thermal measurements, numerical examples being given, the solutions of which, here as elsewhere in the book, are particularly neat. Mechanical forms of energy attending chemical change, in particular the volume energy of gases, are also discussed. The author next points out that the measures of the different forms of energy are composed of two factors, one of which is all-important in determining the direction of the energy change. Temperature and entropy are shown to be the factors of heat energy, and a clear and concise account of the thermodynamics of perfect gases is given, in order to arrive at the shape of the entropy function, which is of course known in this particular case. The relations between heat energy and volume energy, and between heat energy and electrical energy, are then set out at length.

The author here indicates how terms involving what he calls the "chemical intensity" of the reacting substances enter into the energy equations. Chemical intensity is what Gibbs originally termed the "potential" of the substances, and this function, it is hoped, will eventually be shown to be the mathematical expression of chemical affinity.

The third section of the book is devoted to the properties of chemical intensity. The general method of deriving the law of mass action is given, and chemical equilibrium, the properties of dilute solutions, and the velocity of chemical reactions are brought under the sway of the energy equations. The last section contains the treatment of the phenomena which may be grouped around Gibbs's phase rule, and of reactions depending on several parameters.

The book is the only one which is exclusively devoted to chemical energetics, and to the student possessed of sufficient mathematical knowledge it offers an admirable account of the present state of the subject. J. W. R.

Die Bearbeitung des Glases auf dem Blasetische. Von D. Djakonow und W. Lermantoff. Pp. 154. (Berlin: R. Friedländer and Sohn, 1895.)

The original edition of this book was in Russian, and the authors, one of whom, D. Djakonow, is now dead, were demonstrators in chemistry at St. Petersburg University. The instruments and methods employed by glass-blowers are set forth in detail, together with descriptions of the kinds of glass best suited for different work. A very full and practical account is given of the construction, graduation, and calibration of thermometers; but to carry out these operations thoroughly, some experience is required. Work more suitable for the 'prentice hand fills the greater part of the book. Every operation in glass-blowing and manipulation likely to be needed in physical and chemical laboratories, appears to be described; while the diagrams illustrating the stages in the construction of the different pieces of apparatus, will greatly assist in training students to become skilled workers.

Problems and Solutions in Elementary Electricity and Magnetism. By W. Slingo and A. Brooker. Pp. 108. (London: Longmans, Green, and Co.)

Model answers to examination questions may prove a blessing or a curse, according to the way in which teachers use them. Herein are answers to questions in electricity and magnetism (elementary stage), set at the Science and Art Department's examination from 1885 to 1894, together with a series of original questions. The teacher who wishes to train his class to answer questions clearly and concisely, will find suitable exercises in composition in this book, and he will also find the volume an inducement to cram his students with undigested information.

Qualitative Chemical Analysis of Inorganic Substances. (New York: American Book Company, 1895.)

This work consists of a series of analytical tables, supplemented by explanatory and descriptive notes, and working directions. It makes no pretence to originality, and is hardly a book we should like to see widely adopted by students of elementary practical chemistry. The tables, which were prepared for use in Georgetown College, Washington, D.C., present few points of interest or value to teachers of chemistry in our schools.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Professor Boltzmann's Letter on the Kinetic Theory of Gases.

IN common, I am sure, with all the physical readers of NATURE, I have read Herr Boltzmann's letter with great interest. And I am glad to observe that, though he appears to think I differ from him, that part of his letter which chiefly deals with my criticism on Dr. Watson's idea of what "Boltzmann's Minimum Theorem" is, is simply putting forward, with all his great authority, the view for which I contended. But it is a little hard that Dr. Boltzmann should represent me as endeavouring to *disprove* his theorem when I expressly stated that while I did not know *his* proof, *I supposed that it was all right*. True, I said that I found it hard to conceive how any proof on the lines of Dr. Watson's could be valid *because that proof appeared to me to be a purely dynamical proof*, and I applied the reversibility argument *to show that a purely dynamical proof was impossible*, so that the H-theorem could not be a purely dynamical theorem; and after indicating the lines on which it appeared that there might be an *average dynamical* theorem, I asked if some one would say what the H-theorem really was.

Thereupon Mr. Burbury wrote a helpful letter, which he followed up by a still more helpful correspondence, in which verbal misunderstandings were gradually cleared away, which showed that the proof of the H-theorem considered as a dynamical theorem, not as a theorem in probabilities, assumed that in one respect the configuration was, before each set of collisions, already perfectly average, and that this condition is violated in the reversed motion; so that the theorem, regarded as a dynamical theorem, is not proved for configurations in general, but for those possessing a certain amount of "average" already—a restriction which comes to the same thing as the limitation imposed by Prof. Boltzmann when he says *the theorem is not a dynamical theorem, but one in probabilities*.

Shortly after Mr. Burbury's letter appeared, Dr. Watson wrote denying that the criticism from reversibility applied, and claiming that the theorem was a general dynamical theorem, in the sense that it applied to *all* configurations. Enlightened by Mr. Burbury, I now see that Dr. Watson's reasoning is not open to the objection that it proves a general dynamical theorem; but I cannot blame myself for thinking that it did, for that was what Dr. Watson himself believed it to do, and what his language naturally implies. Moreover, after perceiving the oversight which vitiates the proof in its present form, I did not examine it further.

Prof. Boltzmann has misunderstood Mr. Burbury and me in one or two particulars. He denies that there are as many configurations for which dH/dt is positive as there are for which it is negative. He evidently thinks that we mean something different from the bare meaning of the words, which are certainly true. It is easy to explain what we do not mean (I say *we*, for I am sure Mr. Burbury will agree with me). Suppose $H = 10$ to be the minimum value of H for a given system of molecules, we do not mean that among all the configurations for which $H = 50$, there are as many which will, if left to themselves, turn into configurations for which $H = 60$, as will turn into configurations for which $H = 40$. The illustration, which to my mind has most clearly removed the apparent contradiction in the statement that there are as many configurations for which H will increase as decrease, while yet the probability is that H will on the whole decrease, is that of a *y* turned upside down, thus ʎ. For every downward path there is an upward path, *i.e.* the reversed direction; yet starting from the angle there are two ways down for one way up, so that there is a greater probability of going down than up. If in the reversibility argument one could assert, not merely that there are *as many* configurations for which H tends to increase as to decrease, but that *for any given value of* H there were as many configurations which tend to increase as to decrease, then the conclusion that H was as likely to increase as to decrease could be deduced. But the argument is quite invalid when we set off a configuration for which H increases against one for which it decreases, *although the values of H for each are different*. As an illustration more closely allied to the case of a gas, we might take a tree turned upside down, with an infinite number of branches passing through each point of its substance in all directions, there being at every point more branches tending downward than upward (because those whose tangents are horizontal may be said to tend downward on each side), and every upward branch finally turns downward and tends to become nearly horizontal at last, when H is near its minimum value.

To my mind this appears a far better way of meeting the difficulty than Prof. Boltzmann's illustration of the dice, for so far as I can see, all that he has shown is that if you start from an exceptionally high ordinate, *i.e.* one over the average, you are likely, after a considerable time, to get to lower ordinates in whichever direction you go, and an opponent might answer that if you start from an exceptionally low ordinate you are likely to get higher ones in whichever direction you go, and that there must of course be as many deviations below the average as above it, so that if you start from an arbitrary point in an arbitrary direction, you are just as likely to get to higher as to lower ordinates. In point of fact this appears to be the case for his curve, while it is not true for the tree or for a gas.

Prof. Boltzmann must have put an entirely wrong construction on something or other, which I suppose I have written, when he says I object to the Maxwell Law of distribution because it would ultimately lead to the total kinetic energy of the universe being equally distributed among every degree of freedom of every particle in the universe. Instead of considering that to be *à priori* improbable, I hold exactly the view put forward by Prof. Boltzmann.

With regard to the first portion of Prof. Boltzmann's letter, there is so much that is speculative in it that any discussion would occupy more space than I feel entitled to claim. I will only say that the idea that a gas takes years to come to thermal equilibrium seems hardly consistent with vibrational portion of the kinetic theory being of practical value, when applied to gas which has only had a few hours to settle down.

EDWARD P. CULVERWELL.

Trinity College, Dublin, March 6.

IT seems to me that my meaning has not been expressed quite clearly; therefore, it may be worth while to add one remark. Not for every curve, but only for the particular form of the H-curve, disymmetrical in the upward and downward direction, can it be proved that H has a tendency to decrease. This particular form is very well illustrated by Mr. Culverwell's suggestion of an inverted tree. The H-curve is composed of a succession of such trees. Almost all these trees are extremely low, and have branches very nearly horizontal. Here H has nearly the minimum value. Only very few trees are higher, and have branches inclined to the axis of abscissæ, and the improbability of such a tree increases enormously with its height. The difficulty consists only in imagining all these branches infinitely short.

Finally there is the difference between the ordinary cases, where H decreases or is near to its minimum value, and the very rare cases, where H is far from the minimum value and still increasing. In the last cases, H will reach, probably in a very short time, a maximum value. Then it will decrease from that value to the well-known minimum value.

Paris, April 6. LUDWIG BOLTZMANN.

The Recent Auroral Phenomenon.

ON the evening of March 13, from 7.35 to 8.5, Greenwich mean time, I was a spectator of the abnormal display of Aurora Borealis which attracted so much attention at various places throughout the country. It appeared here as a belt of light spanning nearly the whole sky in a great circle from east to west. When first noticed by me at 7.35, the streak extended from near the hind quarters of Leo to the head of Aries, or from R.A. 169°, Decl. + 16° to R.A. 24°, Decl. + 22°.

At the time the streak was altogether cometary in appearance, beginning in a fine point, but it gradually changed in form, moving at the same time towards the south. Eventually it also shortened so considerably that just before my last view of it, it only extended from γ Geminorum to γ Ceti. Its greatest breadth was about 12°.

The following figures represent the most striking phases, as nearly as may be at intervals of five minutes.

Fig. 1 shows how the streak extended from the cometary head so as to form a long wavy tail, and represents also the streak at its greatest length. As indicated in the sketch, there was a central portion much more brilliant than the rest, running from the head into the body of the streak.

In Fig. 2 the streak is seen when it had more the appearance of a rainbow than of a comet; and it was very noticeable that one side—that towards the north—was much brighter than the other.

Fig. 3 shows how the "head" began to shrivel up—shortening the streak. The glimmering appearance of the "shrivelling" put me very much in mind of the motion of the air over a "hot heap" (of slag); the tail end began to broaden out somewhat.

In Fig. 4 the streak has taken a very pronounced arrow-headed shape, and, as if to complete the resemblance, the

North.

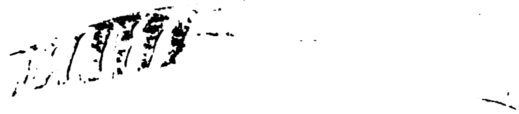

Fig. 3.

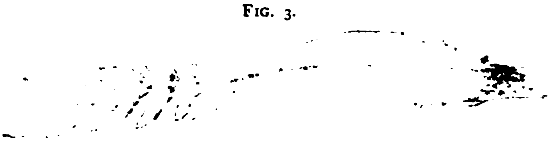

Fig. 4.

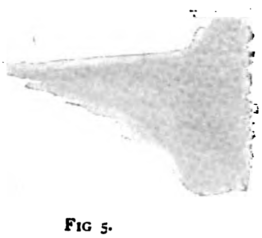

Fig 5.

South.

shimmering part took the form of the feathering; whereas in the preceding figure it had more the appearance of comb-teeth. The more brilliant parts are indicated by darker shading.

In Fig. 5 the streak has considerably shortened and broadened out in the west, where it soon afterwards mingled with faint auroral rays which had come round from the northern horizon.

I may say, in general, that the appearances were singularly noticeable and brilliant. The sky was very clear at the time, and every star was visible through the most brilliant parts of the streak. During the time the streak was visible there was a faint display of aurora on the northern horizon, which, as I have already said, worked round to the west and caught the last of the streak.

Jas. G. Richmond.

Muirkirk, N.B.

THE AGE OF THE EARTH.[1]

ILL-HEALTH has hitherto prevented my making the comments which seemed called for by Lord Kelvin's friendly article of March 7, in reply to my communication of January 3. Perhaps I may be allowed not merely to restrict my remarks to this article, but to deal more generally with the subject, in the hope of clearing away the misapprehensions which exist between modern geologists and palæontologists, who are no longer uniformitarians, and physicists who are represented by Lord Kelvin.

The arguments as to the age of life on the earth are based on considerations of (1) geology and palæontology; (2) tidal retardation and shape of the earth; (3) the cooling of the earth from an initially hot condition; (4) the age of the sun.

(1) From geology. The leading geologists declare that the great thickness of sedimentary rocks created since the Lower Cambrian, which are almost the oldest fossiliferous rocks, can only have been produced during many millions of years.

It is difficult to get geologists to give even wide limits for the age of the Lower Cambrian.[2] Their calculations are based not upon the rate of accumulation of sediment in one of our quiet oceans, but upon the rate of degradation in valleys where the rate is greatest at the present time. They make this declaration, thinking that for the last thirty-three years it has been authoritatively declared by physicists that such an estimate is absurdly great. I have no doubt that they have done their best to keep this estimate as low as possible, for they have a great interest in making geological theory agree with physics. Some physicists tell them that the flaw in the geologists' reasoning consists in their not taking into account the much greater tidal actions of the past. When tides rose and fell many hundreds of feet, and swept over tens or hundreds of miles of foreshore, there must undoubtedly have been a more rapid formation of sedimentary rock than anything of which we now have experience. The geologists' answer is:—We acknowledge that all nature's actions were on the whole, possibly, more intense in the past. We know from Prof. Darwin's development of Prof. Purser's theory that the moon was undoubtedly nearer the earth in palæozoic times, and the tide influence was therefore greater. But there seems to be no method of even approximately calculating how much greater the tidal influence was. Whilst one great astronomical authority speaks of tides of 500 feet deep in palæozoic times, Prof. Darwin himself thinks that two or three times as great as at present may be an excessive estimate. There is a good deal of geological evidence for much smaller seas than at present, and even if tidal influence were greater the actual tides may have been much smaller than now. Of positive evidence in our favour, we have the fact that numerous examples exist of palæozoic rocks which are identical in almost every physical way with tertiary rocks, and it is difficult to believe that they can have been deposited under very different conditions. Again, nearly all the old sedimentary rocks were laid down near coasts where tidal action would be most violent. Yet even low down in the Cambrian we find the remains of creatures

[1] In this paper free use has been made of many suggestions from Prof. Fitzgerald,

[2] Their data are of this nature:—Of fossiliferous rocks successively formed the total thickness may be taken as not less than 80,000 feet. Over the areas of the basins drained by many rivers the rate of denudation is known with sufficient accuracy for approximate calculation. Of the basin of the Mississippi a thickness of one foot of rock is removed in 6000 years; the Ganges, 2358; the Hoang Ho, 1464; the Rhone, 1528; the Danube, 6846; the Po, 729; the Nith, 4723 (Sir A. Geikie, Geol. Soc. of Glasgow, 1868). I have heard that Prof. Sollas demands less time than other geologists; but since this paper was written, I have seen (Nature, April 4) that even he does not care to put the age of the Lower Cambrian at much less than 17 million years.

which still have attached to them delicate antennæ. In sandstones we find most delicate ripple marks and the marks of rain-drops. But over and above all this, denudation along coast-lines can hardly be regarded as of much importance compared with subaerial denudation (Sir A. Geikie, *Trans.* Geol. Soc. of Glasgow, 1868). Was there more rain? and did it fall more suddenly? Did the wind blow more strongly? Were atmospheric actions more vigorous in the past? There is no great reason for believing that they were. As Prof. G. Darwin observes, fossil trees do not seem to have been built more strongly than modern trees, and this gives some evidence as to the relative violence of aerial forces.

All the geological evidence points to rates of denudation and deposition in the past which may, on the average, have been greater than the average rate at present, but which were not on the average greater than the greatest rates at present.

The palæontologist now comes in. A study of fossils shows that there has been a gradual development, sometimes more quickly perhaps, and sometimes more slowly, but on the whole a continuous development of animal life in the past. We believe from all our study of nature that the development has been continuous. As more and more strata are studied, many of the apparent discontinuities are being converted into continuities. Now even in the lower parts of the Cambrian, *Brachiopoda* are found. Biologists tell us that in all probability these were gradually developed from creatures like worms; their structures are sufficiently complex for us to know that the time taken to develop the Brachiopod from the worm may have been as great as the age of known fossiliferous rocks. There are many rocks, evidently sedimentary, enormously older than the Cambrian, and when laid down there was certainly water on the earth, and hence it was neither too hot nor too cold for animal life. In these lower formations there are conglomerates containing pieces of still older rocks. Although in pre-Cambrian strata traces of animal remains are said to occur, we may say that the palæontological record is almost lost below the Cambrian, most of the earlier rocks having been subjected to great metamorphic action. If we keep to our principle of continuity in nature's actions, we see that the first beginning of life must have taken place at a date many times earlier than the very earliest geological record.

But the most experienced geologists and palæontologists state that they are satisfied with a few hundred million years as the possible age of life or the existence of water on the earth.

2. The considerations drawn from tidal retardation are as follows:—

(*a*) The shape of the earth now is the same as its shape when it solidified. (*β*) The shape of a liquid earth tells us its rate of revolution on its axis, therefore we know the rate of revolution of the earth on its axis when it solidified. (*γ*) Assuming that we know, with a fair amount of accuracy, the rate at which the length of the day is altering, we know the date of the earth's solidification, and certainly this is later than 1000 million years ago.

When I referred to the fallacy in this argument, I did not know that it had already been pointed out by the Rev. M. H. Close and Mr. Clarence King and Prof. George Darwin. It lies in the fact that (*a*) is certainly wrong. A solid body like the earth will, under the action of great forces, alter its shape in time. Such alteration is continually going on. Again (*γ*) is very doubtful.

(3) I now come to the considerations from the cooling of the earth. Lord Kelvin proved that, if the earth was once at a uniform temperature of 7000° F. or 3870° C., of material the heat properties of which are the same as the average of three rocks experimented upon at Edinburgh —these remaining constant throughout—and if the rate of increase of temperature downwards in the crust is now 1 Centigrade degree for every 90 feet, 100 million years have elapsed since cooling began; but there is a possible maximum of 400 millions.

In the article on this subject, published in NATURE, January 3, 1895, I showed that, if we assume greater conductivity in the interior than at the surface, we increase this limit of age. I took a number of examples, which could be worked mathematically. I did not pretend that any one of these represented the actual state of the earth. They merely proved that there were *possible* internal conditions which might give enormously greater ages than physicists had been inclined to allow. Of my various results, I did not give one as more correct than another, although some may have seemed more probable than others. It was not my object to obtain a correct estimate. Indeed I tried to show that it was impossible for a physicist to obtain such an estimate, as there were all kinds of possible assumptions which led to many different answers.

The validity of my reasoning in no degree rests upon the accuracy of R. Weber's results as quoted by me. Indeed, I only discovered these results when writing to Prof. Tait. In NATURE, February 7, p. 341, I have shown the extent to which the possible limit of the earth's age is increased if k and c increase with temperature and k/c remains constant. But I published this as an interesting mathematical result, and was careful to add—"It must be understood that my conclusions are really independent of whether R. Weber's results are correct or not." It is comparatively unimportant, but R. Weber has published another set of results which confirm those which I quoted. The results, published on March 7 for the first time, differ so utterly from the two previous sets, that I venture to think there may be mistakes in transcribing. However that may be, I am not concerned either to support or refute them.

I mentioned the possible great quasi-conductivity due to the interior of the earth being a honey-combed mass containing liquid, and to the possible greater conduction due to the presence of iron and other metals. Almost anything is possible as to the present internal state of the earth. Dr. Ramsay seems to think that there must be great quantities of sulphides inside, and these would probably be much better conductors than the surface rocks.

Prof. Schuster, in discussing the diurnal variation of terrestrial magnetism (*Phil. Trans.* 1889, p. 467), comes to the conclusion that the *electric* conductivity of the earth must be considerably greater inside than at the surface.

In all probability there are no great masses of liquid inside the earth *at the present time*, but it is quite possible that until recent times convection in such masses may have been conveying heat from the very inner earth towards its surface, and the latent heat given out by such masses of liquid as they solidified would be another potent factor. Some distinguished geologists say that the excessive folding which has occurred on the earth's surface cannot be accounted for by the current assumption of physicists, which involves the result that, practically, no cooling has yet taken place below the depth of 120 miles: my assumption is that cooling has taken place to much greater depths.

All these things, like the numbers published by R. Weber, support the argument if they are correct, but they do not in any way destroy it if they are wrong. I was not looking for a *probable* age of the earth from the point of view of mere physics. I wished to show that the physics' higher limit was greater than a few hundred of millions of years.

Mr. Clarence King's paper appears somewhat inconclusive. He assumes, possibly rightly, that the earth's crust may have the properties of *Diabase*; experiment has shown what is the rate of increase of the melting temperature with increase of pressure of this rock: Laplace's hypothetical law of increase of density downwards in the earth cannot be very wrong, and from this a law of increase of pressure downwards may be formulated. From these data Mr. King finds what are the temperatures at various depths, which if exceeded would mean liquidity. A liquid layer inside the earth's crust being assumed to be impossible, Mr. King, trying all sorts of Kelvin solutions of a solid earth of uniform conductivity and uniform temperature, initially finds a maximum age of 25 million years, the initial temperature being not greater than 2000° C.! Furthermore, higher initial temperatures are not possible!

Now it is evident that if we take any probable law of temperature of convective equilibrium at the beginning and assume that there may be greater conductivity inside than on the surface rocks, Mr. King's ingenious test for liquidity will not bar us from almost any great age.

(4) There remain, lastly, considerations drawn from the age of the sun. On the assumption that all the energy possessed by the sun was that due to the mutual gravitation of its parts, and that the sun is now of uniform density, Helmholtz found that the sun may have in the past radiated as much as 22 million times his present annual loss. Langley found that the sun's present rate of radiation was under-estimated, and the statement of Prof. Newcomb may be taken as that of Helmholtz, corrected. Newcomb says ("Popular Astronomy," p. 523): "If we take the doctrine of the sun's contraction as furnishing the complete explanation of the solar heat during the whole period of the sun's existence, we can readily compute . . . It is thus found that if the sun had, in the beginning, filled all space, the amount of heat generated by his contraction to his present volume would have been sufficient to last 18 million years at his present rate of radiation."

Lord Kelvin pointed out (pp. 364–65, vol. i. "Pop. Lectures") that Helmholtz had assumed a sun of uniform density, whereas the sun's density must increase very much towards his centre, and as a result of calculation on the assumption that only half of the original energy was available (p. 374), that the radiation was greater in the past, and that the original collisions occurred practically simultaneously, he says: "We may therefore accept as the lowest estimate for the sun's initial heat 10,000,000 times a year's supply at present rate, but 50,000,000 or 100,000,000 as possible, in consequence of the sun's greater density in his central parts." And again (p. 375): "It seems therefore, on the whole, most probable that the sun has not illuminated the earth for 100,000,000 years, and almost certain that he has not done so for 500,000,000 years. This last number, then, is Lord Kelvin's higher limit. After six years, in 1868, Lord Kelvin returned to the question, and he says (p. 53, vol. ii. "Pop. Lect. and Addresses"): "The estimates here are necessarily very vague, but yet vague as they are, I do not know that it is possible, upon any reasonable estimate, founded on known properties of matter, to say that we can believe the sun has really illuminated the earth for five hundred million years."

In his R.I. address of 1887 Lord Kelvin gave no higher limit. I think that, on his specified assumptions in giving these large numbers, he has been very generous; for, taking Mr. Homer Lane's determination of the internal density of the sun, I find that the Helmholtz total energy need only be multiplied by about 2½. If, however, instead of taking, as Mr. H. Lane did, 1·4 as the ratio of specific heat, we take a less number, and there is no reason why we should not, we find much greater densities towards the centre, and a much greater total energy and age. Still, I think that it is only when we escape from the above assumptions that we can see our way to increase the higher limits which have been quoted.

To justify the Helmholtz hypothesis of mere mutual attraction, initially, between the portions of matter which form the sun, Lord Kelvin ("Pop. Lect.," vol. i., pp. 411–3) dwells upon the great improbability that any parts of the sun possessed much initial velocity. He shows that if two bodies, A and B, came together to form the sun, when the bodies were still far apart before collision, the motion of the centre of B relatively to A, must have been directed with great exactness to pass nearly through the centre of A (as the sun has a comparatively small moment of momentum), and this was very improbable if the bodies had initial velocities. But this argument is only satisfactory when the bodies coming together are two in number. For example, let us imagine in early times a sun of half the mass of the present one, but of many times its diameter. It is possible that its radiant energy was supplied by meteors. If the meteor feeding was in excess, the sun became larger in volume. If there was too little meteor feeding, the sun became smaller. Even if there was a very excessive supply for a short time, say by the incoming of a huge meteor, we need not assume excessive radiation in consequence. Such meteors may have come from stellar space with great initial velocities, and may have possessed before collision many times the kinetic energy which a mere solar system meteor of the same mass would possess.[1] If there were many such meteors, their paths might be enormously out of line with one another and with the centre of the sun, and yet we need not imagine them to alter much the moment of momentum of the sun about its axis. If we look for the *probable* age of the sun as deduced from mere physics, we ought to take Helmholtz' condition of mere mutual attraction, the Helmholtz calculation being corrected of course for greater internal density; but if we look for a higher limit to the age of the sun, it is difficult to see why we may not multiply Lord Kelvin's total energy and age of 500 million years.

Again, the ages determined by Von Helmholtz, Prof. Newcomb, and Lord Kelvin, are given on the uniformitarian assumption that the sun has been radiating energy always at his present rate. If we may imagine that for long periods the sun radiated at a smaller rate, whether because his mass was smaller, or because of his atmosphere, we again have an increase to the calculated age. Prof. Newcomb seems to have noticed this, and to meet the objection (p. 525, "Popular Astronomy") he says, "that a diminution of the solar heat by less than one-fourth of its amount would probably make our earth so cold, that all the water on its surface would freeze, while an increase by much more than one-half would probably boil the water all away." On account of this exigency, indeed, he reduces his previous estimate in the ratio of nine to five. This statement ought to have the careful consideration of men who know more about astronomical physics than I do. It means that if the earth were now 15½ per cent. further away from the sun, there would be no water and no life, only ice; and if we were 18·4 per cent. nearer the sun, there would be again no water and no life, only steam. It becomes an important question, is there no life, is there no water on the planet Venus which has twice our solar radiation? Is all its water in its atmosphere as steam? Again, Mars has only 40 per cent. of our solar radiation; is there no life, no water, only ice upon Mars? I have no right to speak on such a subject, but I understood that the atmosphere of Venus was much like that of our own planet, and that the water of Mars is not all ice, for his polar

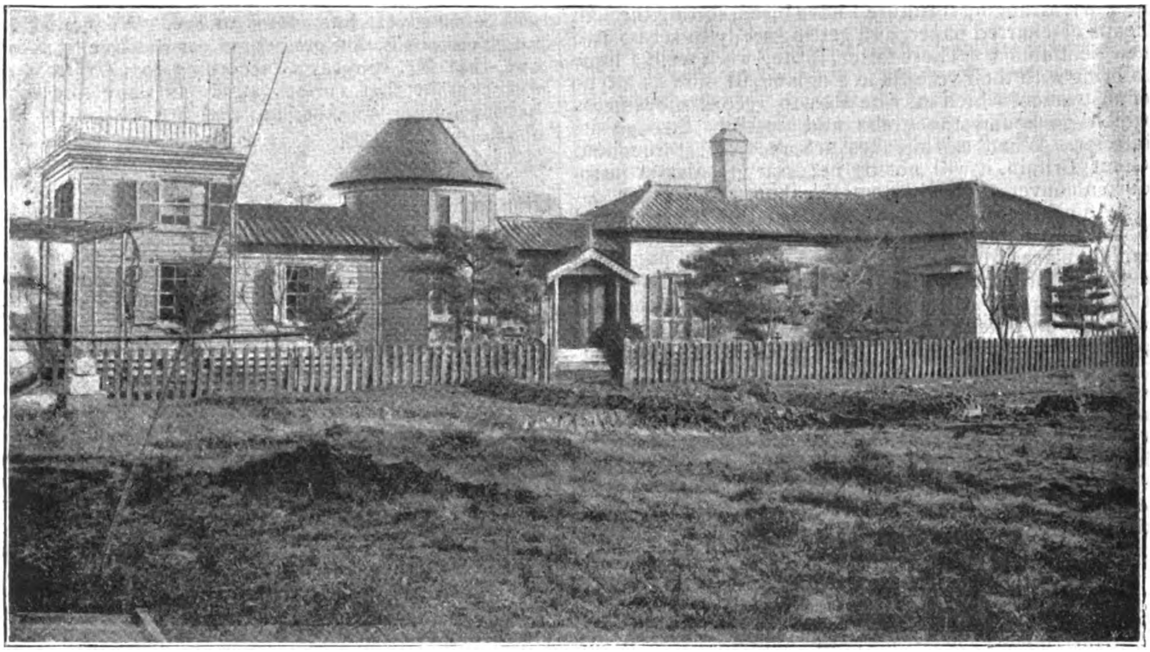
[1] The velocities of stars are probably much less than the possible velocities of smaller bodies.

snow-caps are seen to melt in summer. True, they may be solid carbonic acid, but I have recently read that the green colour of vegetation had been observed to appear and disappear regularly on the planet. If there is little water on the surface of Mars, I should imagine that this is rather due to its having soaked into the crust, which is probably colder underground than ours. Prof. Newcomb has evidently not thought of Mars in this connection, for elsewhere he says: "If there are any astronomers on Mars . . ." On this question I venture to quote Lord Kelvin, who said, in 1887 ("Pop. Lect.," vol. i. p. 376), that "the intensity of the solar radiation to the earth is 6½ per cent. greater in January than in July; and neither at the equator nor in the northern or southern hemispheres has this difference been discovered by experience or general observation of any kind." It is difficult to imagine that if the effect of 6½ per cent. cannot be detected, 25 per cent. should convert all the water to ice and destroy all life.

Even if a small diminution of the solar radiation produced a very cold climate on our present earth, we must remember that the earth's atmosphere may have been very different in the past; the earth may have been very greatly blanketed, and the surface may have been actually warmer, although there was much less solar radiation. That the atmosphere is far more important in this connection than the amount of solar radiation, is evident if we consider Langley's determination that in the tropics, if there were no atmosphere, the temperature of the surface of the earth would be −200° C. Any addition to the quantity of air in our present atmosphere means an increase of the temperature of the rocky surface. But in the past, not only may there have been more atmosphere, but there may have been a very different kind of atmosphere. Again, we must consider a possible great amelioration of climate due to the earth's internal heat. It could not occur by mere conduction, but it is quite possible that for many millions of years there was great blanketing by clouds of watery vapour, and that underneath these blankets half the surface of the globe may have been a lake, or a number of lakes, of melted lava, which may have carried large amounts of heat convectively from considerable depths, this heat again being carried about convectively by the earth's atmosphere, keeping the solid parts of the earth's surface in a fit state for the existence of low forms of animal life. It is possible that at the present time the surface of Jupiter, which receives a very small intensity of solar radiation, may have solid parts surrounding watery lakes and oceans capable of supporting life because of the existence of many lakes of melted lava.

To sum up, we can find no published record of any lower maximum age of life on the earth as calculated by physicists (I leave out the estimates based upon the assumption of uniform density in the sun, and also that of Mr. Clarence King) than 400 million years. From the three physical arguments, Lord Kelvin's higher limits are 1000, 400, and 500 million years. I have shown that we have reasons for believing that the age, from all three, may be very considerably under-estimated. It is to be observed that if we exclude everything but the arguments from mere physics, the *probable* age of life on the earth is much less than any of the above estimates; but if the palæontologists have good reasons for demanding much greater times, I see nothing from the physicist's point of view which denies them four times the greatest of these estimates.

JOHN PERRY.



The Tokio Seismological Observatory.

THE SEISMOLOGICAL OBSERVATORY DESTROYED AT TOKIO.

THE destruction by fire of the Seismological Observatory and Library, at Tokio, Japan, has already been referred to in these columns (p. 533). The valuable work which Prof. Milne has accomplished during his long stay in Japan is well known to our readers; and it is to be hoped that means for its continuance will be fully provided. By the kindness of Japanese friends, Prof. Milne has been able to make observations in a temporary home since the fire, and it will not be for lack of enthusiasm and activity if a new observatory is not soon in working order. We print below extracts from Prof. Milne's optimistic account of the fire, and accompany it with a view of the Observatory buildings and house.

"It came at last. On Sunday morning, the 17th February, at 7.30 a.m., I was alarmed by the cry of fire, and at 8 o'clock I was looking at smoking ruins in the midst of my two armsful of salvage (which I took good care should include my last year's photographic records), receiving cards of condolence from high personages and presents from the neighbouring shop-keepers—like bottles of beer, boxes of eggs, and oranges—and all this while the fire engines were vigorously pumping. I saw that nothing more was to be saved, but before the flames were out, my colleague, Mr. C. D. West, set to work to take a series of snap-shots with his hand-camera. The results look like fogged plates, but they show amongst other things the effects of heat upon my big stone column. On Tuesday, I used some of the pieces as illustrations to a geological class as illustrative of the action of lava streams upon rocks they occasionally flow over. The President of the University, who very kindly had hurried from his house to see me and my ruins, had a new house ready for me before my own had done smoking, and I am now in it arranging furniture I have hired, sorting through heaps of charred paper, and getting ready to set up two new pendulums. These latter, if they work well, I hope to bring with their records to England, to show as a type of instrument which may be able to record movements which go round the globe and possibly through its interior. When earthquakes are recorded throughout Great Britain, it will not be necessary to always introduce a conversation with remarks about the weather.

"As nearly all the *Transactions* of the Seismological Society were packed up to go to Europe, a few that had middle places in the boxes may be saved, but I doubt if even out of 2500 copies I shall get more than two or three hundred. All my old earthquake books, some of which even dated from 1500 and 1600, but which were perhaps more curious than useful, seem to have gone.

"Instruments were fused or vapourised. Sixteen specially constructed clocks, which would turn drums once a day, once a week, or drive a band of paper for two years, together with seismographs and horizontal pendulums, self-recording thermometers and barometers, microscopes, and a museum of old and new contrivances, are now on the scrap heap. Until to-day, I felt that I had the observatory I intended to put up in England completely furnished, and I was proud of the furniture.

"The fire broke out in the midst of a pile of wood in an out-house, and this with a nice wind blowing on a Sunday morning when there was no one near to help.

"And now I have next to nothing—decorations, medals, diplomas, clothes, manuscripts, extending over twenty-five years, and everything else has gone to smoke; still it is not altogether a misfortune.

"Looked at in the right way, like an earthquake, a fire may after all be a blessing in disguise; but, of course, it is sometimes pretty well wrapped up.

"Dies iræ, dies illa,
Solvet saeclum in favilla."

TERRESTRIAL HELIUM?

I HAVE received the following letter and enclosure from Prof. Thorpe:—

"University of Glasgow, April 16.

"MY DEAR LOCKYER,—The enclosed extract from a letter just received from Cleve of Upsala may be of interest to you.

"Ever yours,
"T. E. THORPE."

"I have got from Mr. Crookes a letter in which he informs me that the gas in Cleveite contains the long-searched for helium.

"This letter arrived exactly the very day one of my pupils, Mr. Langlett, tried to get the gas of Cleveite in my laboratory. The gas given off from my mineral did not contain a trace of argon. The spectrum has been examined by Thalén, who found an exact coincidence of the line of the gas with the helium line and besides some others:—

Wave-length.	Intensity.
6677	half-strong
5875·9	strong: helium
5048	half-strong
5016	strong
4922	half-strong
4713·5	weaker

"I have sent a letter about it to Berthelot. If you like, you may communicate the result to the Chemical Society, Mr. Ramsay, Crookes, and other friends. . . . An experiment to determine the specific gravity did not give trustworthy results, but seems to indicate that it is a very light gas, still more heavy than hydrogen. Will this gas fill the gap between hydrogen and lithium? It will become very interesting to see. What makes me much curious is that our helium gas was free from argon, and that Mr. Ramsay's (according to *Comptes rendus*) did contain that curious stuff. Is there any relation between argon and helium, and are we facing a new epoch in chemistry?"

Although my results are not yet complete for publication, the foregoing communication makes it desirable that I should state at once that immediately on the publication of Prof. Ramsay's statement, by the kindness of Mr. L. Fletcher I was enabled to study the gases given off by Cleveite by heating in vacuo, a method I have used for metals and meteorites.

A very small quantity of Cleveite is all that is necessary to obtain a considerable volume of the new gas, which comes off associated with hydrogen.

I have now examined several tubes. I have found no argon lines; I have not found the lines, other than the yellow one, given by Crookes; but lines have been recorded near some of the wave-lengths given by Thalén, especially the one at 6677, near a line I discovered in the chromosphere in 1868. So far the sky has not been clear enough to enable me to determine by direct comparison with the chromosphere the position of the line in the yellow with great dispersion.

J. NORMAN LOCKYER.

NOTES.

IN honour of M. Berthelot, and as a demonstration of the power and progress of science in France, a banquet was held at Paris a few days ago. Nearly eight hundred guests were present, among them being M. Brisson, President of the Chamber of Deputies, and M. Poincaré, Minister of Public Instruction. Upon the invitation cards were printed the words: "Hommage à la science, source de l'affranchissement de la pensée." M. Poincaré made an eloquent speech in praise of the work done by the eminent Secretary of the Paris Academy of Sciences, and M. Berthelot, in his reply, dwelt, at some length, upon the beneficial influence of science on social and moral, as well as material, progress. Science, he said, had for its only guide the love of truth, and confidence in its final triumph. Proved under all circumstances, and strengthened every day by success, the scientific method had become the principal source of the moral and material progress of society. In fact, science was the source of all progress accomplished by the human race. Every one knew that, during this century science had conferred great benefits upon civilised peoples by the application of its results and laws to mechanical, chemical, and electrical industries. But M. Berthelot held that material progress was the least of the fruits of scientific work; he claimed for science the more extensive domains of the moral and social world, and vindicated the position taken up by him in his article on "Science et la Morale," which appeared in the *Revue de Paris*. The speech and the banquet may be taken as an effectual reply to those who question the benefits of scientific investigation in France.

ONLY last week, in announcing the publication of the fourth edition of Prof. James D. Dana's "Manual of Geology," we referred to the extraordinary activity of the author. We regret this week to have to record his death, at eighty-three years of age. Another eminent man of science who has just passed away is Prof. Lothar von Meyer, at the age of sixty-five.

REUTER'S correspondent at Toronto reports that the Provincial Legislative Assembly of Ontario has authorised a grant of 7500 dollars towards defraying the expenses of a meeting of the British Association for the Advancement of Science to be held in Toronto in 1897, should the Association accept the invitation to hold a meeting there.

MR. R. FITCH, whose name is especially well known among archæologists and geologists of Norfolk and Norwich, and who, three years ago, presented his collections to the Norwich Museum, and provided cases for them, has just died, at the advanced age of ninety-three.

JOHN ADAMS RYDER, Professor of Embryology at the University of Pennsylvania, died on March 26.

PROF. JAMES E. OLIVER, the mathematician, who was connected with the Cornell University faculty for twenty-five years, died at Ithaca, on March 27. He was born in Portland, Me., July 27, 1829. He graduated at Harvard in 1849, and received in the same year the appointment of assistant editor in the office of the American Nautical Almanac. He became in 1871 assistant professor of mathematics at Cornell University, and in 1873 was appointed to the chair as Professor. He was a member of the American Academy of Arts and Sciences, the American Philosophical Society, and the National Academy of Sciences.

A MONUMENT to the late Prof. Villemin, who added so much to the knowledge of the nature of tuberculosis, has just been unveiled at Val-de-Grâce. A monumental souvenir of the late Prof. G. Pouchet was also unveiled a few days ago, at Père-Lachaise.

THE Home Secretary, on the application of the East Riding County Council, has made an order prohibiting the taking or destroying of wild birds' eggs on the promontory of Spurn for a period of five years. Spurn Point is one of the chief places of deposit by sea birds of their eggs on the Yorkshire coast, and of late years there has been wanton destruction of both sea-gulls and their eggs.

A CORRESPONDENT informs us that a very bright meteor was seen at Tayport, N.B., at 10h. 4m. p.m., on Saturday, April 13. It started at a point a little to the east of Vega, and was moving almost directly towards Saturn. It was visible for about six seconds, and seemed to have a jerky motion. It was more brilliant than Venus, and was elongated in shape. The weather was very clear and quiet at the time of observation. The meteor's direction of flight was, approximately, from $270° + 40°$ to $221° - 7°$.

SIR JOSEPH FAYRER, Sir Guyer Hunter, and Mr. Jonathan Hutchinson, the adjudicators, have (says the *British Medical Journal*) awarded a prize of fifty guineas to each of the following essays, sent in in response to the invitation of the Leprosy Fund: "On the history of the decline and final extinction of leprosy as an endemic disease in the British Islands," by Dr. George Newman; "On the conditions under which leprosy has declined in Iceland and on the extent of its former and present prevalence," Dr. Edward Ehlers (Copenhagen); "On the facts as to the recent increase of leprosy at the Cape and its present prevalence in South Africa," Dr. S. P. Impey (Medical Superintendent, Robbin Island); "On the reputed recent increase of leprosy on the Australian Continent; its extent and possible causes," Dr. Ashburton Thompson; "On the conditions under which leprosy prevails in China, Cochin China, Batavia, and the Malay Peninsula," Dr. James Cantlie (Hong Kong). On some of the subjects for which prizes were offered no essays were sent in, and some of the essays sent in were held not to meet the terms of the competition. The successful essays will be printed and published at the expense of the Fund.

ABOUT 11.15 on Sunday night, shocks of earthquake of varying intensity were felt over a considerable portion of Austria-Hungary, extending from Vienna to the Adriatic coast and the adjoining islands in one direction, and from Salzburg to Agram in another. In Vienna, according to the *Times* correspondent, the shocks were slight. Clocks were stopped, however, in parts of the town, and windows were heard to rattle. The vibrations are reported to have proceeded from south to north. The earthquake would seem to have reached its greatest intensity within a triangle formed by Laibach, Trieste, and Fiume. At Laibach no fewer than twenty-five shocks were noticed, and they continued until seven o'clock on Monday morning. The collections in the Laibach Museum are said to have been almost entirely destroyed. At Trieste several vibrations were felt, one of which was of ten seconds duration. Many buildings have been more or less damaged. Tremors of still longer duration are reported from Krainburg. Shocks of less violence occurred at Klagenfurt, Leibnitz, Luttenberg, Agram, and elsewhere. Four distinct vibrations were felt at Venice: the first, which took place at 11.17 p.m., was very severe, and lasted twelve seconds. Severe shocks of earthquake were also felt in Italy, at Ferrara, Udine, Treviso, and Padua.

WE have on various occasions given short descriptions in these pages of experiments carried on by different investigators with a view to discovering a practicable method of telegraphing over a considerable distance without metallic wires connecting the two stations. Among the observers who have devoted a considerable time to this problem may be mentioned Mr. Preece, the chief engineer of the Telegraph Department of the Post Office; and it is to this gentleman we owe the first practical application of the method of telegraphing by induction. During last week the submarine cable connecting Oban with Auchnacraig broke down, and the telegraphic messages have since been passed between these two places (distant about six miles) by means of Mr. Preece's inductive method. A gutta-percha insulated wire, one and a half miles long, was laid along the ground from Morven, whilst on the Island of Mull use was made of the ordinary overhead line connecting Craignure with Aros. The distance between the two parallel wires was about 3½ miles, the Sound of Mull being here at its narrowest. Using a vibrator as transmitter, and a telephone as receiver, the usual messages were successfully dealt with until the cable was repaired, the whole experiment forming a very interesting event in the annals of telegraphy.

A paper which will have considerable interest for those who have to design and use electrical apparatus, where wood or slate is often used as the insulator, appears in the *Proceedings* of the American Academy. The subject of the paper is the electrical resistance of certain poor conductors, such as wood and stone, and is by Mr. B. O. Peirce. The author has examined a great number of samples of different kinds of woods and stones under different conditions as to dryness, a most important point, and although, as might be expected, the individual results differ somewhat widely, he considers the mean results give a very fair idea of what may be expected in practice. The author has also tried the effect of soaking the different materials in hot melted paraffin, and finds in every case, especially if the specimen has been previously well dried, that such treatment not only increases the specific resistance, but by preventing the absorption of moisture prevents the falling off in the resistance otherwise observed when such bodies as stone or wood are exposed in a damp place. The following are some of the results for the specific resistance obtained in megohms; the first number denotes in each case the lowest value observed, and the second number the mean value:—Mahogany 310, 610; hard pine 17, 1050; white pine 360, 1470; vulcanised fibre 3, 60; slate 184, 280; white marble 2000, 8800. The samples of wood were all well seasoned, and the resistance was measured in the direction of the grain, the resistance across the grain being generally from 20 to 50 per cent. higher. The samples of stone were dried in the sun for about three weeks before being tested.

A simplified phonograph is described by A. Költzow in the *Centralzeitung für Optik und Mechanik*. A conical tracing point is used for recording the sound waves. This has the advantage of durability, and if it should wear out on one side, it need only be turned round its axis. The tracing-point is attached to one arm of a lever, the second and longer arm being provided with a membrane. For some purposes the membrane is replaced by a stretched string. The cylinders consist of a very hard soap. They will stand several hundred renderings. After use they can be turned down by 0·02 mm., so that one cylinder will suffice for 200,000 words.

In the *Comptes rendus* of the Paris Academy of Sciences of the 1st inst., as briefly stated in our abstract last week (p. 576), Prof. Mascart presented a note by the Abbé Maze, stating that in a collection of astronomical documents at the National Observatory, a register had been found containing thermometrical and other observations made by the astronomer I. Boulliau, between 25 May, 1658, and 19 September, 1660. Up to the present time, it was not known that observations had been made at Paris prior to those of Lahire. These observations are of some interest, being among the earliest thermometrical readings on the continent, and they fill up a gap in the climatological history of Paris. It is also noteworthy that the thermometer used was one of the Academy del Cimento.

A recent number of *Modern Medicine and Bacteriological Review* contains a notice of Dr. Pictet's interesting experiments on the application of intense cold as a therapeutic measure. According to this investigator's observations, calorific radiations of a lower temperature than $-65°$ pass through all the ordinary conductors of heat; a fur overcoat or a wooden board offering no more resistance than a pane of glass or other transparent medium to the passage of a sunbeam. Dr. Pictet experimented upon himself in a frigorific well, in which a temperature of $-100°$ C. to $110°$ C. was maintained. He was wrapped in warm clothes and thick furs, and at the end of four minutes he stated that he experienced intense hunger, which increased; after eight applications of eight or ten minutes duration his appetite became normal, and his digestion greatly improved.

The last number of the *Bolletino* of the Italian Geographical Society criticises the proposed nomenclature of some of the rivers of East Africa, as given in a sketch map in the *Geographical Journal* illustrating the explorations of the American traveller, Dr. Donaldson Smith. The names to which the Italian Society objects are those of Dr. Smith himself and of his English companion, Mr. Gillett, which have been applied to the upper and middle course of the Webi Shebeli and the Web respectively. We are bound to admit that the criticism is well-founded, as it is contrary to authorised usage to apply European names when the native names can be ascertained. We have little doubt that Dr. Smith will, before the end of his explorations, discover some features still unknown which may fitly be called after him and perpetuate the memory of his excellent geographical work.

Mr. H. Rutgers Marshall, whose work on "Pain, Pleasure, and Æsthetics" was reviewed in Nature (vol. l. p. 3), contributes to the April number of *Mind* an article, "Emotions *versus* Pleasure-Pain," in further elucidation of his views. Mr. Marshall is fully alive to the importance of evolutionary development, and his treatment of the emotions is therefore of interest to students of comparative psychology. It is unfortunate, however, that the term "instinct" is used in an extended sense which will scarcely be acceptable to those who approach the subject from the biological side. The phrases, "imitation impulse," "art impulse," "benevolent impulse," would appeal to them as more satisfactory than "imitation instinct," "art nstinct," &c., since they have grown accustomed to the application of the term instinct to the manifestation of particular activities. But a consensus of opinion on psychological nomenclature seems at present impossible. And in any case, Mr. Marshall's views are well worthy of careful consideration.

An experiment of considerable interest in connection with the transmission of optical signals has been performed by M. Charles Henry at the Depôt des Phares. The question was whether rhythm in a succession of signals increases or diminishes their visibility? This was solved by means of a revolving drum, the surface of which contained sixty holes illuminated by a source of light placed at the axle. The drum was 3 feet across, and was driven by clockwork. By varying the speed of the drum and the brightness of the light, and by closing some of the holes at regular or irregular intervals, all the conditions of the experiment could be varied at pleasure. The chief difficulty in this, as in most physiological experiments, lay in bringing the eye back to its original state after each experiment. It was sometimes found impossible, even after keeping in the dark for close upon half an hour, to restore the observer's eye to its original state of sensibility. But it was conclusively shown that it is possible to increase the range through which an optical signal will carry by arranging the succession of flashes according to a sufficiently complex non-rhythmical law.

Probably no better example of an invention borrowed or adapted from nature could be found than is afforded by the sand-blast. As is well known, the invention, now a quarter of a century old, consists of a stream of sand or other abrasive powder, usually dry, but sometimes mixed with water, projected with more or less force and velocity to strike and pulverise the surfaces of glass, stone, metal, and other materials upon which it is directed. The many applications of this method of abrasion were recently described by Mr. J. J. Holtzapffel, at the Society of Arts. It appears that glass is almost immediately depolished by the blasts now in use, and but a comparatively short time is required to pierce and cut apertures through sheet and plate glass. Stone, marble, slate, and granite are just as amenable to the action of the sand-blast. Iron, steel, and other metals have their surfaces easily reduced, and smoothly or coarsely granulated, according to the force and abrasive powder used. It is remarkable that it is by no means necessary that the abrasive be harder than the material to which it is applied; thus, hardened steel and corundum are readily pierced with sand. The blast is not only in use for producing a uniform granulation on sheet glass; it is also employed for frosting the bubbles of incandescent lamps and the like; for the decoration of glass ware, and the labelling of graduated measures. In metal, the hard scale, so destructive to cutting tools, is removed from castings and forgings by the blast. On stone, slate, and granite the sand-blast is used for incised carving and inscriptions in intaglio or relief, and for delicate drawing for lithography. A print of a child's head, exhibited by Mr. Holtzapffel, was an astonishing example of the delicacy of treatment obtainable by the process. Among other purposes, the blast is employed for removing fur and deposits in tubes and tanks; for cleaning off accumulations of paint and dirt within iron ships; for decorating coat and other buttons; for piercing the apertures in glass ventilators; for marking pottery, and in the manufacture of ornamental tiles; for refacing grindstones, emery, and corundum wheels; for granulating celluloid films for photography; and on wood, to bring out the grain in relief, and, latterly, for blocks for printing. These many and various applications of sand-blast processes show that the art has developed in an extraordinary manner since it was introduced by Mr. Tilghmann in 1870.

DR. H. WILD has published, in the *Zapiski* of the St. Petersburg Academy of Sciences, a very important investigation, entitled "New Normal Air-Temperatures for the Russian Empire." In a former paper upon this subject, the data for the monthly, yearly, and five-yearly means were brought down to the year 1875, while in the present work observations have been included to the year 1890, and comprise materials from no less than 575 stations, of which 244 are new.

THE additions to the Zoological Society's Gardens during the past week include an Irish Stoat (*Putorius hibernicus*) from Ireland, presented by Viscount Powerscourt; a Grey Parrot (*Psittacus erithacus*) from West Africa, presented by Mr. A. A. Dowty; a Cape Viper (*Causus rhombeatus*) from South Africa, presented by Mr. J. E. Matcham; two Elephantine Tortoises (*Testudo elephantina*) from the Aldabra Islands, Seychelles; four Indian Pythons (*Python molurus*) from India, deposited; a Barbary Wild Sheep (*Ovis tragelaphus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

LUNAR RIVER BEDS AND VARIABLE SPOTS.—The highly favourable atmospheric conditions at Arequipa have enabled Prof. W. H. Pickering to make numerous observations which have a special bearing on the question of the existence of water on the moon (*Annals Harvard College Observatory*, vol. xxxii. part 1). In addition to the ordinary rills, Prof. Pickering has catalogued thirty-five narrower ones, which, from their resemblance to terrestrial watercourses, he does not hesitate to regard as "river beds." These are wider at one end than at the other, and the wide end always terminates in a pear-shaped craterlet. Most of them are only a few miles in length, and a few hundred feet in width at the widest part, and, except when very deep, they are very difficult objects. The largest and most readily observed has its origin in the Mount Hadley range n the Apennines; its course lies a little north of west, and its otal length is about sixty-five miles. There does not appear to be any reason to suppose that these formations actually contain water at the present time, but Prof. Pickering brings forward other evidence in favour of the presence of a small amount of moisture on the lunar surface.

Certain variable dark spots have been detected in different regions, many of them lying inside craters, others symmetrically surrounding craterlets, and others in the dark *maria*, or "seas." In the central craters, such as Alphonsus, the spots are darkest just after full moon, when shadows are geometrically impossible, and they are invisible when the shadows are strongest. "If called upon to offer an explanation of the phenomenon, we seem forced to call in the aid of water as an active agent." Still, the dark spots cannot be simply ponds, as one of the spots in Alphonsus for a portion of the time covers and darkens the slopes of a small hill near the crater-wall. "This seems to effectually overthrow the hypothesis of a free liquid surface, as well as the suggestion that the dark colouration may be due to frozen ground that has partially thawed. . . . Vegetation would undoubtedly explain away all our difficulties; but before we resort to such an extremity, it is evident that we need more facts upon which to base our theories."

The Mare Tranquilitatis is said to be almost covered by these variable spots, and Prof. Pickering states that the changes may be seen with the smallest telescope, or even with the naked eye; until past first quarter this area is lighter than the Mare Crisium; it then rapidly becomes the darker of the two until after full moon, when it again becomes lighter.

The changes in some of the spots are readily seen in the beautiful photographs which illustrate the memoir.

THE ULTRA-VIOLET SPECTRUM OF THE CORONA.—With spectroscopes in which the optical parts are made of glass, it is only possible to photograph the spectrum in the ultra-violet as far as wave-length 360; but when the spectroscopic train consists of quartz and Iceland spar, a more refrangible region is open to investigation. One of the spectroscopes employed in Africa by M. Deslandres during the total eclipse of the sun on April 16, 1893, was of the latter form, and a plate exposed for four minutes gives for the first time some information as to the coronal spectrum in the extreme ultra-violet (*Comptes rendus*, April 1). The slit of the spectroscope cut the image of the corona along the equatorial diameter, and to facilitate the reduction of wave-lengths, the spark-spectrum of iron was photographed on the same plate. The photograph shows the spectrum of the corona to consist of bright lines superposed on a continuous spectrum. In the blue, the continuous spectrum reaches a height equal to two-thirds the sun's diameter, but it diminishes both in height and intensity until about λ 300 it is almost reduced to zero. Forty lines are tabulated from λ 308 to λ 362; one at λ 3170·9 appears to reach a great height in the solar atmosphere, and others at λ 3164·5, 3189·5, and 3237·1, are comparable with the hydrogen lines H_δ, H_ϵ, and H_ζ. The remaining lines may belong either to the chromosphere or corona; but M. Deslandres considers the fact that they are shown with a small image on the slit, to be in favour of the view that they are coronal. Most of the lines cannot be identified with known substances, and they probably represent gases of low atomic weight.

STELLAR PARALLAXES.—A very suggestive investigation of stellar parallaxes in relation to magnitudes and proper motions, has been carried out by Mr. T. Lewis (*Observatory*, April). The parallaxes adopted are the means of the values obtained by various observers, and from these the velocities across the line of sight have been derived by dividing the proper motions by the parallaxes and reducing to miles per second. The conclusions suggested by the tables given are: "(1) Leaving out a few of the brightest stars, the parallaxes are constant down to 2·7 magnitude. (2) After 2·7 mag. is reached, the parallaxes are doubled and remain practically constant to 8·4 mag. (3) Up to the 3rd mag. the velocities are very small, averaging about 9 miles per second, while after the 3rd mag. the velocity is 38 miles per second." It seems probable that in our immediate neighbourhood there are a few stars of exceptional brilliancy (about 8) and a few smaller stars, of which nearly 40 are at present known; while stars of mag. 1 to 3 are as a class far outside this inner space, and have very small velocities. The investigation confirms the accepted idea that a measurable parallax accompanies a large proper motion, and shows, further, that this holds good whatever the magnitude of the star may be.

THE SUN'S PLACE IN NATURE.[1]

IV.

THE difference in the appearance of spectral lines and flutings having been explained, I now go on to state that the luminosity referred to, as seen in the meteorite experiment was not one of the lines in the spectrum of magnesium, but one of the flutings. I will next throw this on the screen (Fig. 17), and you will at once see the point. Here is the spectrum of magnesium obtained at the lowest temperature at which we can get any light from it at all. We have a fluting, which resembles closely the carbon fluting, but in a different part of the spectrum. We see that its brightest part is coincident with a certain part of the solar spectrum; and it so happens that the position of the line which Dr. Huggins had observed in the nebulæ lies very near the same position of the solar spectrum.

That, then, was one argument out of a great number in favour of the view that the luminosity to which the bright line of the nebula was due, might really be produced in the nebulæ by collisions of meteorites among themselves, rendering luminous the vapours of magnesium which we knew to be wherever there are meteorites.

Now, an additional argument for that view was found in the fact that almost every observer, including Dr. Huggins himself, had stated that as seen in the spectrum of a nebula the line did look somewhat different on one side to what it did on the other, and references were made to its being more degraded on the left-hand side than it was on the right. I had frequently

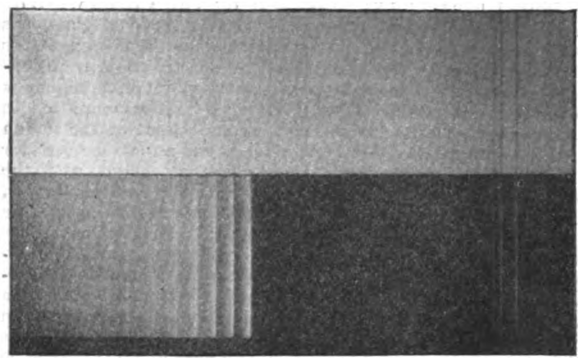


FIG. 17.—Spectra of burning magnesium compared with solar spectrum. (1) Sun. (2) Magnesium.

observed myself that the line representing the chief line of the nebulæ was degraded to the left, never to the right, over parts of the nebula of Orion which were more brilliant than the others; and at the same time that another line—about which more presently—instead of being degraded to the left, like this one, was equally eased off on both sides (Fig. 18), so that the argument was complete that the appearances presented by this line were not due to any instrumental defect, because, in that case, all the lines would have behaved in the same abnormal manner. Hence then I found myself justified in concluding and subsequently stating (1) that the position of the meteoritic dust-line was coincident with the line of the nebulæ in the apparatus which I used, and (2) that it resembled it in appearance.

What I had next to do in the matter was, of course, to carry the thing as far towards the truth as I could. We can never find out the whole truth, but it is better to have a part of the truth than none at all. Hence I started a new method of attack, which, you will note, differs very considerably from anything you have seen before. I have here a beautiful instrument invented by that eminent Frenchman Foucault, called a "siderostat." The essential part is a plane mirror (Fig. 19) which, when it is properly adjusted to the sun or moon or any star in any part of the sky, lays hold of a beam of light from it about twelve inches in diameter, and sends that beam in a horizontal direction due south, and keeps it there; so that the light falls fairly on the optical apparatus, and we can go on observing it for a long time. Next the instrument was adjusted to throw the light from the nebula of Orion on a powerful horizontal telescope placed in front of a large spectroscope, both rigidly fixed. In order to check the observations as far as possible, I placed in front of the object-glass of the telescope an arrangement by which the light from a magnesium wire might enter the slit of the spectroscope at the same time as the light of the nebula, so that if the light from the nebula and the light from the magnesium wire perfectly agreed in wave-length, we should get one line; if it differed, we should get two.

The slit of this spectroscope was exactly in the focus of the ten-inch object-glass, and then the light was passed through four dense prisms, so that we got a considerable amount of dispersion, and the exact position of the line, whether single or double, was observed. That of course was a very much more powerful dispersion than had been employed by Dr. Huggins in his first observations, and much more powerful than had been employed by myself in my first investigation. But what I wished to do in those first investigations was to understand and to clearly follow the observations which had been made previously by others; if therefore I had attempted to go over the ground with instruments ten times better, giving me ten times finer results than my predecessors had obtained, it would have been the worst possible way to go to work, because it was essential for me to make the necessary comparisons with the old observations while not exceeding the instrumental means which had been employed to obtain them.

The long and short of my various methods of observation was that they seemed entirely to confirm the idea which I got in the first instance from using telescopes and spectroscopes of very much smaller power. That, however, fortunately for

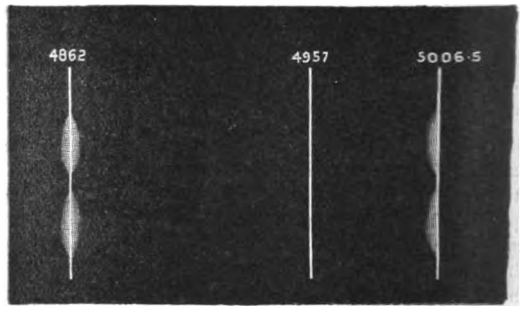

FIG. 18.—Appearance of principal lines in spectrum of Orion nebula, as observed at Westgate-on-Sea.

science, did not satisfy Dr. Huggins; he very wisely appealed to the American astronomers, and I am glad to say that the skilful astronomers of the Lick Observatory took up this work with interest, and employed instruments in the investigation more powerful than any I possessed, thus carrying matters a stage further. There were really two distinct bits of work to be done: first of all, one wanted the exact position of the line in the nebulæ, and after having got its right position, its origin could be thought out. We wanted also to see what the real physical appearance of the line was, *i.e.* whether it was most likely a line or a fluting. It is not a little curious to note that all the statements which had been made suggesting a fluted character of the line were at once withdrawn when I referred its origin to the magnesium fluting.

The Lick telescope is one of very considerable power indeed, and it is so solidly built that a very powerful spectroscope can be put on one end of it and used under almost the best possible conditions for determining the position of lines. Still the Lick telescope is not the best possible telescope to employ for any branch of work connected with nebulæ, if the work requires a great amount of light, because the longer the telescope, the larger the image which the object-glass gives; for instance, if you are dealing with a nebula one degree in diameter, if your one degree is written on a circle with a radius of sixty feet, it will be a very much bigger thing than if on a radius of ten feet, so you get a large image without increasing the light, and therefore are spreading your light over a very large area. As the slit of the spectroscope is a very small thing, all the light which is thrown outside the slit is of no use for your spectroscopic observation, so, whatever the size of the spectroscope may be, you want to deal with the smallest and

[1] Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December, 1894. (Continued from page 567.)

brightest possible image in order to get the best use out of your spectroscope, and that cannot be done with a long focus telescope. However, the important question for the American observers was to determine the exact position of the line; and we have lately been given some very interesting results.

Fig. 20 represents the way in which Dr. Keeler puts his last result. The upper part is a representation of the solar spectrum; the numbers represent wave-lengths on Rowland's scale. According to his latest value the wave-length of the nebular line is 5007·05. He also shows in relation to it the lines of nitrogen as well as the fluting of magnesium, and you see at once that, although according to this drawing the magnesium does not quite correspond with the line of the nebulæ, it is very much nearer to it than is either the line of lead or the lines of nitrogen. The publication of this result necessitated a fresh investigation, to see what the exact facts were when we no longer compared the nebula with magnesium, but compared the magnesium with the solar spectrum, and therefore sought the true position in which to place the magnesium line in relation to the solar spectrum.

Here is the result. You will see that there is a very small difference between the position of the magnesium fluting and the nebular line. In short, the more the work done on this question the more and more coincident have these lines become, and there are some considerations which have not yet been taken into account.

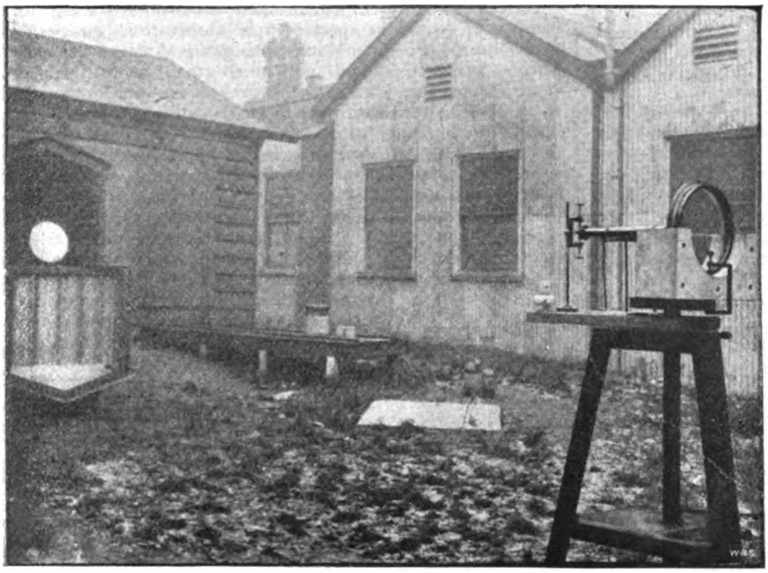

FIG. 19.—Showing object-glass of horizontal telescope used with siderostat.

I have referred to this point somewhat at length, although the coincidence with the fluting of magnesium is not fundamental for the establishment of the view which even Dr. Huggins has now accepted, in the way I have already stated.

Now, what was the chemical constitution of the nebulæ stated to be as a result of the first spectroscopic observations? Dr. Huggins, in his paper of 1865, to which I have already referred, was of opinion that the chief line was due to nitrogen.

Here are two tubes, one containing hydrogen, the other nitrogen. You will see at once that these two gases, when I set them glowing by the passage of an electric current, are very different in colour; we get in one an excess of red light, in the other we have a purple tinge. When nitrogen is observed by means of a spectroscope, a double line is seen very nearly coincident with the line of the nebulæ. Dr. Huggins thought that one of the constituent lines was exactly coincident with it, and because there was apparently no line whatever corresponding with the other, he thought also that the nitrogen might not be nitrogen like that with which we are familiar, but an unknown form of it. There was no doubt from the beginning that another line was a line of hydrogen, although there was some slight doubt as to whether the hydrogen in the nebulæ behaved exactly like hydrogen on the earth.

Nobody believes in the nitrogen constituent of the nebulæ now; and I presume Dr. Huggins has withdrawn in fact, if not in words, his statement concerning the coincidence, for in his address as President of the British Association, in which, as I have already stated, he withdrew his published statement as to the position of the nebulæ among the various bodies that people space, he remarks, "the progress of science has been greatly retarded by resting important conclusions upon the apparent coincidence of single lines in spectroscopes of very small resolving power," an *apologia* of which every one will see the propriety, for you will gather from Dr. Keeler's diagram that the nearest nitrogen line is three times further removed from his position of the nebula line than is the magnesium fluting. I trust I shall not be thought to be exceeding the bounds of decorous criticism when I remark that while Dr. Huggins has referred to the inaccuracy of my work in relation to this line, which is apparently indicated by Dr. Keeler's results, he has never pointed out the three times greater inaccuracy of his own.

In order to give you an idea of the relative accuracy which all these references to wave-length indicate, let us suppose that we are trying to define the position of a place in London on an E. and W. line running through Charing Cross, and then you will see exactly how matters stand. Assuming Dr. Keeler's value to be absolutely true—and I expect it is as near the truth as we are likely to get for some time—we will suppose that it represents the nebular line situated on the statue of King Charles at Charing Cross. When Mr. Huggins first measured it, he brought it to the East India Docks; his next attempt brought it to Hammersmith. Dr. Keeler's first observation brought it to Albert Gate; his next, in 1891, brought it to St. James's Palace. Subsequent work at Kensington, not yet completed, has brought it nearer still.

There is another argument in favour of the now accepted view which may be gathered from a careful examination of the forms of these different nebulæ, and by endeavouring to reason out from the form what the actual conditions at work may be. One of the most wonderful spiral nebulæ in the heavens is that in the constellation of Canes Vanatici, which has been photographed by Dr. Roberts (Fig. 7, p. 397). This is a nebula which we look down upon; we see it in plan; we are, so to speak, at the pole of the system, so that it is not foreshortened.

There is no question about the wonderful spirals being connected with the central condensation and stretching away from it, and the point which I made with regard to the one in Ursa Major is even more decided here, when I call your attention to these points of condensation right along one of the spiral branches, and when you get the possible intrusion of two spirals one on the other you see a confused mass of light. Now, if we imagine ourselves dealing there with a mass of pure gas, whether it is hydrogen or nitrogen or ammonia—that is, a combination of both—or any other, it would be extremely difficult to see why there should be any change in temperature in different parts of that mass; but the moment you assume that you are dealing with cool materials—meteoritic dust—you will see that such a picture as this is important to us, for the reason not that it shows us what is there, but because it shows us what is going on there. These bright spots do not represent the presence of matter, and the dark ones the absence of matter; but these brighter portions represent the stream lines where collision is possible—the intervals those regions where collisions are less likely, and you will see from the very configuration of this system, that if all the dust, or meteorites, or conglomerations of particles, whatever they may be, are going the same way, there will be a condition in which we shall get a minimum of collisions, and therefore a minimum of temperature.

The probability, therefore, is that we are not dealing with gas, but with masses of matter in certain regions of which, in consequence of general action, there is greater luminosity given off by the particles of which the nebulæ are composed; in

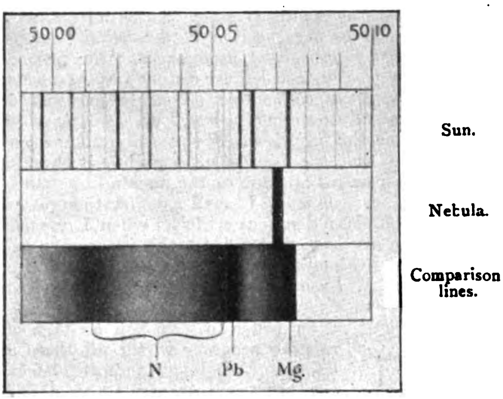

FIG. 20.—Normal position of the chief nebular line, according to Keeler.

other regions where there is less action, we have lower temperature and less light.

If, as was at first imagined, these nebulæ are gases at enormous temperatures, it would be a question of seeing them or not seeing them; there would be no special parts to be picked out at all. But, in the case of those nebulæ to which modern photographic methods have been applied, we find that

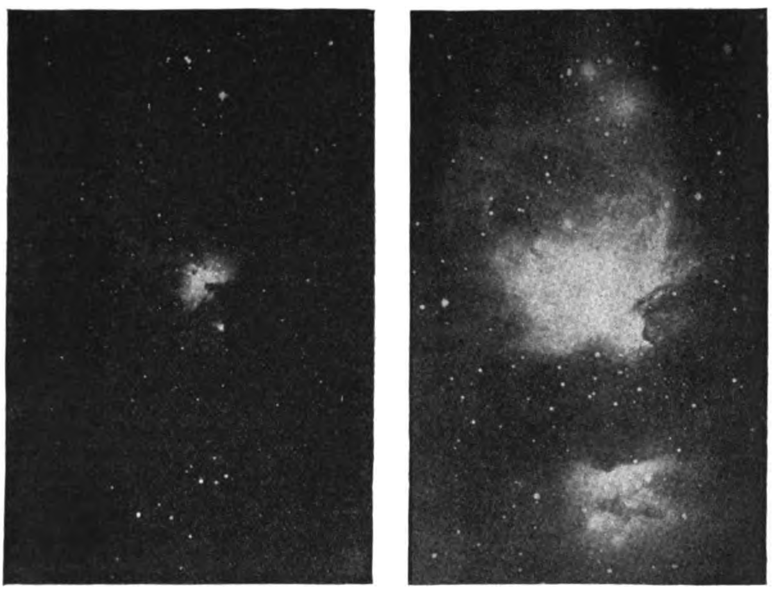

FIG. 21.—Orion nebula photographed with short and long exposures.

the nebula which we see ordinarily in our telescopes is only a very, very small fraction of the real nebula as it really exists, when we can get at it under the best possible observing conditions. Many of you, I hope, have seen the nebula of Orion in an ordinary telescope. Here it is as it has been photographed by means of a telescope powerful enough to give us the brighter portions. Here is another photograph of the nebula exactly on the same scale, in which the nebula that we usually see occupies only a very small portion; the only difference between the two photographs is that one has been exposed for a very long time to enable us to fix and to study the very dim reproduction of certain parts of it, whilst the first one was exposed only for a short time, in order that we might dwell effectively on that part only of the nebula which is generally visible to the human eye with an ordinary telescope. (Fig. 2.) If we were dealing with incandescent gas, the incandescent gas ought to leave off suddenly; but all round this nebula, where there appears to be nothing at all, the longer exposure brings before us other portions of the nebula just as rich in details, just as exquisite in their variety and tone as those ordinarily seen with the naked eye. Such a condition as that cannot be brought about by a mere homogeneous mass of gas at high temperature, but we can explain it quite easily by assuming that in such a nebula as that we are dealing with, the luminosity is brought about by disturbances, these disturbances giving rise to collisions among the particles which are apt to collide and give out luminosity. The nearer they are to the centre of gravity of the swarm, the greater will be their chance of collision, and the greater will be the luminosity of their central portion.

Still another consideration. Astronomers, since the time of Rutherfurd, who was the first to begin stellar spectroscopic work in the United States, between 1860 and 1870, have established many different classes of stars as defined by the chemical substances of which their atmospheres seem to be composed, so far as spectroscopic observations enable us to determine their composition. One group of stars is remarkable for the presence of hydrogen in enormous quantities; we assume that because the lines of hydrogen are inordinately thick. In another we get not so much hydrogen, although it is still there, but the predominant substance is iron. In other stars we get little hydrogen, if any, apparently no iron, but carbon in enormous quantities, and again there is another substance, the quantity of which varies enormously, and that is calcium. Now, if stars contain all these different substances, and if they represent epochs of evolution, they must be produced from something which actually or potentially contained these substances, so that there again you get a considerable argument in favour of the chemical complexity of the nebulæ.

Finally, we reach the second point. It is now generally conceded that the first stage in the development of cosmical bodies is not a hot gas, but a swarm of cold meteorites. From the point of view of evolution, keeping well in touch with the laws of thermodynamics, the nebulæ must begin cool if they are to develop into hot stars.

J. NORMAN LOCKYER.

(*To be continued*).

NEW COMPOUNDS OF PHOSPHORUS, NITROGEN, AND CHLORINE.

A SERIES of new compounds of phosphorus, nitrogen, and chlorine, and likewise a series of acids derived from them, have been discovered by Mr. H. N. Stokes, and an account of them is contributed to the *American Chemical Journal*. A familiar compound of the three elements in question, the chlorophosphuret of nitrogen, discovered by Liebig in 1832, has been the subject of frequent study, and its nature has comparatively recently been very fully demonstrated by Dr. Gladstone. It has been shown, from vapour density determinations, that this remarkably stable compound, which may be distilled in steam and boiled with acids and alkalies without appreciable change, possesses the molecular composition $P_3N_3Cl_6$. Mr. Stokes now shows that this substance is only one of a homologous series of compounds having the general formula $(PNCl_2)n$, and that these are the chlorides of a series of acids $(PNO_2H_2)n$, which he terms metaphosphimic acids. The second member of the series, $(PNCl_2)_4$, has been isolated from the product of Dr Gladstone's reaction for the preparation of $(PNCl_2)_3$, that be tween phosphorus pentachloride and ammonium chloride; it is a substance almost as stable as the triple compound, and yields on saponification the acid $(PNO_2H_2)_4$, which is likewise a stable body. Moreover, the acid corresponding to the triple compound has been isolated, and also a higher chloride $(PNCl_2)x$ of an oily character, and whose molecular weight has not yet been ascertained. In describing his repetition of Dr. Gladstone's work, Mr. Stokes incidentally mentions the interesting circumstance that the triple compound readily forms enormous crystals, well-developed prisms several inches long and of considerable thickness being frequently deposited from benzene, and indeed their size appears only to be limited by that of the containing vessel and the bulk of solution. These crystals melt at 114°. The quadruple compound melts at 123°·5, and boils at the normal pressure at 256°·5. It crystallises well in colourless prisms, which are usually much smaller than those of the triple compound, and exhibit great tendency to develop an acicular character. It is less soluble in alcohol and benzene than the latter compound; it may be recrystallised from glacial acetic acid, but it exhibits a great aversion for water, not being wet by it, and consequently the crystals float on water. It dissolves in hot concentrated oil of vitriol, but upon boiling most of it sublimes unchanged, an evidence of its great stability. Its vapour is endowed with a pleasant aromatic odour, but inhalation of more than traces is followed in two or three hours by alarming difficulty in breathing and persistent irritation of the air passages. Its vapour density was determined in an atmosphere of hydrogen, and indicated the quadruple formula. Even boiling water exerts only a very slight action upon it; but a smooth decomposition is effected by dissolving in ether, and repeatedly agitating with water. The acid produced is deposited from the water in crystals having the composition $(PNO_2H_2)4 + 2H_2O$. This interesting acid readily decomposes soluble chlorides, nitrates, and sulphates, forming three series of salts, in which respectively one-fourth, one-half, and all the hydrogen is replaced by the metal. The free acid is so highly stable that it may be boiled for hours with nitric acid or *aqua regia* without decomposition. Further details concerning it, and the other compounds isolated, will shortly be published.

BIOLOGICAL WORK ON THE ILLINOIS RIVER.

ILLINOIS possesses a good Laboratory of Natural History, in which Prof. S. A. Forbes, with a number of assistant entomologists and zoologists, carry on investigations of value to science and the State. A report on the work of the Laboratory during the past two years has recently been issue d. To us the points of special interest with which it deals are (1) the establishment, in 1894, of a biological station for the continuous investigation of the aquatic life of the Illinois River, and its dependent waters, near Havana; and (2) an elaborate experimental research carried on during the past year to determine means for the destruction of the chinch bug, and especially for the dissemination of the contagious diseases of that insect. This investigation was undertaken by the Laboratory staff, with the co-operation of the State Agricultural Experiment Station.

We have already noted the establishment of the biological station (NATURE, vol. l. p. 275, 1894), but as it is the first inland aquatic biological station in America, manned and equipped for continuous investigation, the following further details are interesting. By the kindness of Prof. Forbes, we are able to illustrate the description with two of the fifteen fine process plates contained in his report.

The Station was opened just a year ago. Its general objects are to provide additional facilities and resources for the study of the natural history survey of the State, now being carried on by the State Laboratory of Natural History; to contribute to a thorough scientific knowledge of the whole system of life existing in the waters of this State, with a view to economic as well as educational applications, and especially with reference to the improvement of fish culture and to the prevention of a progressive pollution of Illinois streams and lakes; to occupy a rich and promising field of original biological investigation hitherto largely overlooked or neglected, not only in America but throughout the world; and to increase the resources of the zoological and botanical departments of the University of Illinois, by providing means and facilities for special lines of both graduate and undergraduate work and study, for those taking major courses in these departments.

The Station differs from most of the small number of similar stations thus far established in the United States, in the fact that its main object is investigation instead of instruction, the latter being a secondary, and at present an incidental, object only. It has for its field the entire system of life in the Illinois River and connected lakes and other adjacent waters, and it is Prof. Forbes' intention to extend the work as rapidly as possible to the Mississippi River system, thus making a beginning on a comprehensive work in the general field of the aquatic life of the Mississippi Valley, in all its relations, scientific and economic.

The special subject which Prof. Forbes fixed upon as the point of direction towards which all the studies shall tend, is the effect, on the aquatic plant and animal life of a region, produced by the periodical overflow and gradual recession of the waters of great rivers, phenomena of which the Illinois and Mississippi rivers afford excellent and strongly marked examples. This field of research is entirely fresh, and at the same time is highly interesting and important.

As an incidental, but by no means unimportant, result of the work, material will be accumulated for a comparison of the chemical and biological conditions of the waters of the Illinois River, at the present time, and after the opening of the Chicago drainage canal.

The practical importance of the undertaking, as affording the only sound basis for a scientific fish culture, will be fully recognised by all who are seeking to apply scientific methods of investigation to economic problems.

It is pointed out that the Station will also serve as a centre of interest and activity for University students engaged on zoological and botanical subjects. Not many years ago biological instruction in American colleges was mostly derived from books; of late it has been largely obtained in laboratories instead; but Prof. Forbes believes that the mere book-worm is hardly narrower and more mechanical than the mere laboratory grub. Both have suffered, and almost equally, from a lack of opportunity to study nature alive. One knows about as much as the other of the real aspect of living nature, and of the ways in which living things limit and determine each others' activities and characters, or in which all are determined by the inorganic environment.

Means are provided by which students, and intending teachers of biology, may be given a wider knowledge of their subject, and where they may investigate experimentally the problems of mutual influences and relationship in the living world.

Possibly still more important is the opportunity which the Station will offer, when permanently established and fairly well developed, to the independent student and investigator, zoological or botanical, who may desire to pursue his studies in the field covered by the operations. It is a part of the plan of organisation and equipment to receive and assist in every practicable way advanced students and investigators of this description, from whatever place they may come.

Havana was selected as the site of the Station because of several unique advantages offered by that locality. Streams and lakes illustrating practically all the typical Illinois River situations are to be found there, convenient of access from a central point, and from each other. An extensive sandy bluff, commonly well shaded and oozing spring water at its foot, borders the river bottom on the east, and introduces several unusual features of interest to the œcologist, besides affording a clean and hard shore to work from, dry, shady, and well-drained camping ground, and an abundance of very pure cold water at all times of the year.

A "cabin boat" was used as a field headquarters, and stationed on Quiver Lake, two and a half miles above Havana. It carried the seines, sounding lines, aërial and aquatic thermometers, dredges, surface nets, Birge nets, insect nets, plankton apparatus, and other collecting equipment, together with microscopes, reagents, a small working library, a large number of special breeding cages for rearing aquatic insects, and a few small aquaria. This boat was provided with sleeping accommodation for four men, and with a well-furnished kitchen.

The greater part of the field work was done on seven regular stations, visited periodically throughout the year; two on the

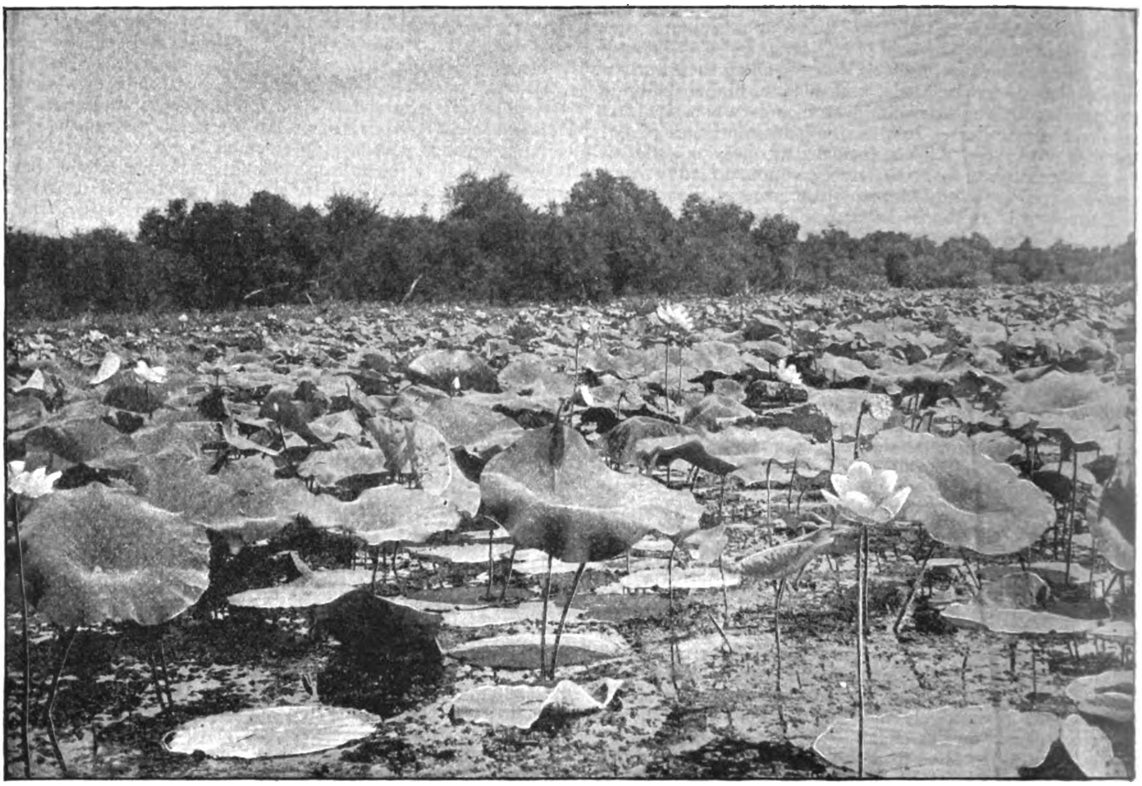

Fig. 1.—Lotus Bed, near Head of Quiver Lake, West Side.

Fig. 2.—Dead Fish and Mussels. Bed of Phelps Lake.

Illinois River, three on Quiver Lake, and one each on Phelps and Thompson's Lakes.

Quiver Lake (Fig. 1), in which the headquarters' boat was placed, is an abandoned portion of the old bed of the river. It varies in length (when the water is low enough to define it clearly) from one and a half to two and a half miles, and has a usual width of about five hundred feet at low-water mark. It lies nearly parallel with the main river, into which it opens, even in the lowest stage of water, at its lower or southern end, by about half its greatest width.

Thomson's Lake lies wholly within the bottom lands of the main river, and its banks are consequently everywhere low and flat. It is five miles in length by about half a mile in width at an average midsummer stage. Neither this nor Quiver Lake ever goes dry, the water in the deepest places being not less than three and a half or four feet during the dryest seasons. Phelps Lake (Fig. 2), on the other hand, is a pond about half a mile long by a fourth as wide, having neither inlet nor outlet after the overflow has receded, rarely drying up entirely, but not infrequently being reduced to a few shallow pools. It is completely surrounded by a bottom-land forest, and its bed is a mere shallow depression in the mud.

The results of the first season's work are, of course, but just beginning to appear. Indeed, the problems to be solved in such situations have scarcely more than dimly shown themselves as yet, but the promise is nevertheless already very interesting. Notable contrasts in kind and number appear between animals of the springy shore of river or lake, and those of the muddy bottom, only a few rods away on the other side; between river and lake; between Quiver and Thompson's Lakes; between each of these and Matanzas Lake; and between all the other lakes and the temporary pond distinguished locally as Phelps Lake—contrasts sometimes easily comprehensible; and sometimes peculiarly puzzling, like that between Quiver Lake on the one hand, the waters of which are choked in midsummer with a dense growth of aquatic vegetation, but contain fewer of the smaller animal forms (Entomostraca, and the like) than the open current of the river itself, and Thompson's Lake, on the other hand, where the water is relatively clear of aquatic plants but abounds in rotifers and Entomostraca. Still more curious is the contrast between the similarly situated and very similar lakes, Quiver and Matanzas, the waters of one loaded and clogged with plants, and swarming with small molluscs and insect larvæ, and those of the other with scarcely a trace of even microscopic vegetation, and with a correspondingly insignificant quantity of animal life.

One surprising result is the abundance of minute life in the main stream, which sometimes contains a greater abundance of animal forms than most of the lakes connected with it; and another is the relatively small difference between the animals frequenting widely unlike situations in the same body of water. A large number of new forms were found, especially among rotifers, worms, and insect larvæ. The collections of the season, preserved for detailed study, are included under nine hundred and fifty-eight collection numbers, representing as many different lots of specimens. In connection with these, Prof. Forbes and his assistants are now engaged upon determination work and other laboratory studies, and the preparation of reports. The papers and reports embodying these studies will be printed in the *Bulletin* of the Illinois State Laboratory of Natural History. So far as possible, each general taxonomic paper will be preceded by a thoroughly practical synopsis of genera and species, illustrated by figures of typical forms, and intended to open up to the student and teacher of natural history in Illinois many interesting and important parts of the local zoology.

THE VARIETIES OF THE HUMAN SPECIES.[1]

IN man, as in other animals, we find physical characteristics of two kinds, external and internal. The first are principally those pertaining to the cutis and certain cutaneous appendages, and include the colouring of the skin and hair, the structure and form of the hair, and also the colouring of the eyes. The chief internal characteristics are the bones from which the form and figure of all the members are taken, as well as those of the separate parts of the body clothed with soft tissues, such as muscles and fat. The cranium is the most important and most characteristic part of the entire human skeleton.

The cranium is a bony case which encloses a viscus of the first order, the brain, which in man is, in relation to the animal series, better developed, both in its forms and functions. It is known that the brain and cranium, from the embryological to the adult state, are in a parallel manner and gradually connected in evolution, and the external form of the one corresponds to that of the other. Most certainly it is not the cranium which gives form to the brain of man; it is more probable that it is the brain which moulds its organ of protection. Given hereditary conditions, we may affirm that the form of the cranium is correlative to that of the brain. If we could discover why the brain takes or has taken different forms, we would possibly understand better its correspondence with the exterior structure of the cranium by which it is surrounded. We might be able to learn also what functional and especially what psychological characteristics are united to the cerebral forms which are revealed by cranial forms. All that is obscure for us, and also unexplored, because unsuspected; for in place of that, and in an inexact manner, the volume has been taken into account, and therefore the weight of the brain, as being the only means of making an anthropological diagnosis of its functional value, the volume and weight corresponding to the capacity of the cranium.

But besides the cranium commonly called cerebral, there is the face, which, from the morphologic point of view, is not less important. The face has generally given more positive means for distinguishing human groups, not only on account of the colouring of the skin, but on account of the form and disposition of its parts, of the nose, of the cheeks, of the molar teeth, and on account of other characteristics which, when considered together, disclose differences not immediately revealed by the cerebral cranium.

The other parts of the skeleton also have differences more or less profound in the different ethnic groups, the stature, the length of the extremities both absolutely and relatively to the stature and to the trunk; the thoracic form, and so on. But such differences are but slightly characteristic in comparison to those presented by the cranium and the face; until now, moreover, they have had but slight value, the reason being that they are derived from characteristics which are merely secondary.

We are ignorant what may have been the primitive type or the primitive human types, considered in all their internal and external characteristics; that is, what skeletal forms certain ethnic groups of differently coloured skin possessed; or, on the other hand, what colour of skin and hair belonged to certain skeletal forms. That difficulty is caused by a fact easy to understand, by the mingling of different types among each other, and by the hybrid forms from which man is derived. It is true, however, that certain hybrid results seem to be limited to certain regions and to a few human groups; and that, on account of this, the elements which have furnished such products may be learned up to a certain point; but in the beginning, at least, it will be necessary to learn the structures of the parts from which hybrids are derived.

It is impossible not to admit human hybridism, since it is demonstrated clearly by all anthropologists; in this direction America alone shows us a perfect example of experimental anthropology. It has been determined from observations that human hybridism is multiform among all peoples; but what we learn from the facts relates to the exchange of external characteristics and their mixture with those internal, that is, the union of the external characteristics of one ethnic type with the internal characteristics of another type. Thus, one may observe the colour of the skin and hair with its special form united to characteristics of skeletons which do not generally belong to types of that colour, and *vice versâ*. That may be observed concerning certain characteristics, and not of all; such as the stature, or the face, with its soft covering, or the form of the cranium only.

If we study our European populations which are called white, but which have many gradations of whiteness, we may note the great mixture of characteristics, a mixture which is changeable, from which results a great variety of forms of individual types, constituted of characteristics differing from each other. An analysis must be very accurate and very minute to discriminate these different elements which exist in the composition of the ethnic characteristics of individuals

[1] Extracted from a translation of Prof. Giuseppe Sergi's "Le Varietà Umane," published by the Smithsonian Institution.

and peoples. These mixtures and these combinations of characteristics differ according to the character and number of elements existing in the various nations of the south, the centre, or the north of Europe. They arise from different relations with mixed peoples.

What is most important in this human hybridism, so various and so complex, is the lack of the blending of the external and internal characteristics from which new human varieties may be had. Among the different ethnic elements there exists only a relation of position, called syncretism, or propinquity of characteristics, and therefore a facility for forming small groups. Such a phenomenon has already been recognised in America, and it is evident in Europe among peoples who appear little homogeneous, if a careful observation separates the characteristics constituting ethnic types and those of individuals in a mixed population.

If there were no other cause for such an absence of blending among the characteristics of human hybridism, this cause would exist, that the relations which produce the mixtures are not equal and constant, but are varied and inconstant. If there should be the union of two pure ethnic types only, for several generations, we should be able to derive a hybrid product constant and fixed, as among animals and plants; but a third element, either pure or mixed, arrives in the second or third generation of man, and so on indefinitely. Thus it is easy to understand how unstable must be the characteristics of the hybrid, for they can scarcely survive in one individual for a generation. The hybrids which follow may have characteristics of different types, with the tendency each time to have these reappear by heredity, although not blended and not fixed in the individual.

To this should be added another fact, that of individual variation, which is present in man, as in other animals, increased by his constant interminglings, which may be considered stimulants of this phenomenon, as has been suggested by Darwin and Wallace.

Hence, I conclude from my observations, that human hybridism is a syncretism of characteristics belonging to many varieties, and that these do not modify the skeletal forms as do individual variations, and that hybridism may affect different parts of the skeleton, constituting characteristics in themselves distinct. The stature, the thoracic form, the proportion of the long bones, may be united with external characteristics differing from each other, as well as from different cranial structures. The cranial form may be associated with different facial forms, and inversely. It happens, however, that the structures taken separately remain in part unvaried in the hybrid constitution. The face preserves its own characteristics in spite of the union of different cranial forms; so also the cranium preserves its structures, associating them with different facial forms. The stature preserves its own proportions in spite of its associations with different cranial and facial types, and in spite of the different colouration of the skin and the form and colour of the hair. All this may be affirmed, particularly of much larger human groups which, according to external characteristics, may be considered much nearer than they really are in geographical position, as the so-called white races in Europe, the negroes in Africa, in Melanesia, and so on.

Now, granting that all peoples exhibit the characteristics of hybridism in the manner just described, it will be necessary to learn how races, groups and human families may be classified. Let us observe for a moment the classification by means of external characteristics, most common among anthropologists from Linnæus to Quatrefages and Flower, and we shall see:

(1) That the colour of the human skin in one great group of a type, such as yellow, black, or white, is of different gradations, and not uniform.

(2) Since, as above stated, all peoples, at least in a great measure, are composed of hybrid elements, it happens that different elements are united under one category, which is, in this instance, the colour of the skin.

(3) We must not forget that the external characteristics are more easily lost, and much easier to acquire, by intermixture and heredity.

A curious example of what I state is found in human classification according to Quatrefages, which perhaps is now the most complete, considered only as a classification by external characteristics. He places the Abyssinians within the white race notwithstanding that they have the negro colouring, and he does so because he believes that the characteristic form of the skeleton or internal characteristics of the Abyssinians are those of the white race. This is without doubt inconsistent when the principle of classification by colour is accepted. This inconsistency itself shows the defect of the method and of the principles mentioned as applied to human characteristics and their combination.

(4) Finally, as we perceive, the theory is not justified that man be classified as a single species with three, five, or more variations.

If the characteristics which present greater stability are internal or skeletal, they should serve for human classification:

(*a*) Because, notwithstanding amalgamation and consequent hybridism, the characteristics originating in the skeleton are persistent.

(*b*) Because they may be taken as fixed points with which other characteristics may be associated, and may be also external, as I shall demonstrate.

(*c*) Because, finally, the internal characteristics can demonstrate the full number of divisions and subdivisions in classifying ethnic groups, and in analysing peoples which are a combination of a great number of hybrids.

It remains to determine which internal characteristics should have the preference in deciding the value of types for classification. If we consider the human skeleton, with that object in view, we find three parts which may serve for that purpose, the cerebral cranium, the face, and the stature, with the long bones.

Stature.—The stature is a good, but an insufficient characteristic, because it gives only linear differences, and in its value resembles greatly other external characteristics, and is associated with all the most dissimilar derived from the skeleton.

Face.—The face offers very important characteristics for classification, because it shows typical differences in the ethnic groups. The face has given more points for the distinction of human types than the other parts of the human body, and would appear better adapted for that purpose than the cerebral cranium. But the face is more disposed to individual variations than any other part, because it is very complex, being composed of numerous small bones, clothed with muscles which have continuous and important functions relating to the physiognomy, to the expression of psychical conditions, and to the nutritive functions. These facts render its typical form less constant, and are, or may be, the cause of a multiplication of types.

Cranium.—The cerebral cranium is itself also liable to variations. More than any other organ, it exhibits a phenomenon often observed and clearly demonstrated by me, that is, the persistence of forms from immemorial epochs, and their reproduction through numerous generations notwithstanding amalgamation with other types. I have demonstrated such a persistence of cranial forms in the varieties of the Mediterranean from the Neolithic and from the most ancient Egyptian epochs; other anthropologists have recognised such persistence in European types of the Quatenary epoch, and in others, very ancient, from America. This cannot be said of the structure of the face.

Therefore if the human cranium is accepted as a basis for the classification of human groups, positive results may be had:

(*a*) In groups which have been subjected to mixture in whatever epoch or however many times, the distinctive ethnic elements may be discerned by examining the cerebral cranium only, which, remaining unaltered in type, may be found united by hybridism with other internal and external characteristics. For the cranium is the point about which revolve all other variations of form, either in hybridism or in the human form itself.

(*b*) Knowing the cranial types of a people who seem more or less homogeneous, we are sure of learning of what and how many ethnic elements it is composed, notwithstanding the hybridism present.

(*c*) Having classified all the cranial types in different regions and among different peoples, we may learn by their geographical distribution the numerical extension of types and also their geographical origin; that is, the place of departure and the course of emigration and dispersion of such forms.

(*d*) Then it will be easy to learn what cranial characteristics are found among populations which already have ethnic names, ancient and modern, and to discover among them points of similarity and difference.

Being, therefore, obliged on account of universal human hybridism to select as a guide to classification the most important and the most useful of the internal characteristics, we find greater advantages in choosing the human cranium, about which all the other characteristics, internal and external, are grouped. If we select one characteristic, or a number of variable characteristics, we shall find ourselves in the same position as other anthropologists who classify by external or accessory traits. It follows that, accepting the cranium as the principal internal characteristic, we impliedly accept the brain in its various forms, and the brain is the most important of human organs.

The classification of man by means of the cranium alone is by no means new. It will be well to consider these schemes, from that of Retzius down to the last, that of Kollmann. Nor, indeed, is the conception of the importance and superiority of the cranium for distinguishing ethnic groups by any means recent. To show that, we have but to refer to the enormous work which has been done, from Morton to Davis and Thurman, from Broca to G. Retzius, to De Quatrefages, to von Holder, to Ecker, to His and Rutimeyer, to Virchow, to Ranke, to others still more numerous, in Italy, from Nicolucci to Mantegazza.

Notwithstanding so much labour expended on the human cranium, satisfactory results were not reached, nor, indeed, I may affirm, have we yet reached them, at least not in the signification which I intend these results to have. The fault lies in the nature of the method of studying the human cranium, and in the value attributed to craniometry.

The classification of Retzius is based upon a single characteristic of the cranium, which, however, is merely the numerical expression of the *norma verticalis* of Blumenbach, that is, the cephalic index.

According to Retzius we have only two forms of crania, the long and short; though, in fact, many forms of short and long crania are found differing very much from each other.

When craniometry was developed in a systematic manner, following principally the work of Broca, it appeared the key of anthropology, and took the first place among means of investigations, as being the most effectual method for distinguishing human races. The French exaggerated its value; the Italians followed with zeal, in spite of the scepticism of Mantegazza, the head of the Florentine school of anthropology; the Germans have been more rational, and with them the Swiss, represented by His and Rutimeyer. At the head of them I would place Blumenbach, who based his small but valuable book upon a rational foundation.[1] The Germans try to establish cranial type almost or entirely independent of the cephalic index; as one may see from the works of von Holder, of Ecker, of His and Rutimeyer, of Virchow, of Kollmann, of Ranke and others. In my opinion the German method is an approximation to the truth, but unfortunately the conception of type is undeveloped and, I should say, has remained rudimental, because craniometry, like a pernicious weed among the grain, injures the harvest. Virchow, the most pronounced scholar in anthropology, and the man who has studied more than all others the crania of all peoples, believes that the germ of a sound anthropology should develop from it, and concedes only a secondary value to craniometry.

According to my observations upon craniometry, which has now become cabalistic, especially in France, on account of the abuse of measures and numerical ciphers, the indices of the cranium and face are taken as a means of distinguishing races, human groups, as we might call them, and other measures are either omitted or applied only to individuals. In order to be convinced we should carefully and conscientiously study the craniometrical works of Dr. Danielli, of Florence, upon the Nias and Bengalese. The author has not been able to find satisfactory results after persevering researches, but whoever would seek evidence of individual variations will find more than enough. It seems to me, therefore, that the method by measurement may serve this purpose, that is, to discover numerically individual differences, but never those typical of a race. But such a discovery is useless, since we are all convinced of the existence of individual differences. I will therefore add that such differences, to be valuable, must be sought, not among forms differing from each other, but among individuals of the same type. That implies, therefore, necessarily and always, the search for types and their distinction, which is not possible by means of the craniometrical method.

If it were true, and there were no doubt respecting the value of the celebrated cephalic index in determining cranial forms, it would follow that all human crania of whatever type and volume should be placed in the three categories of dolicho-, meso-, and brachycephalic, or of hypsi-, ortho-, and chamæcephalic. Thus all the populations of the earth, either of white, yellow, black or red skin, would have crania belonging to the three categories. A classification solely according to the cephalic index is therefore an absurdity. It is incoherent and without meaning, as are those of Retzius and Kollmann.

This conclusion is so true that such anthropologists are obliged to add descriptions to the forms of each part of the cranium, in order to distinguish it, recognising the insufficiency of cranial data. Such descriptions can, to a certain degree only, supply the defect of the method, but they always remain incomplete, and leave the forms or types of the human cranium of various populations and regions indefinite. The French school has gone still farther, and has supplied the deficiency with an infinite number of measurements, which only increase the obscurity, leaving the conception of the form more uncertain, and fatiguing the most patient student, who becomes convinced of never reaching any satisfactory result from such a confused accumulation of numbers.

In order to render classification more definite, or for the sake of finding a second characteristic which might be associated with the cephalic index, Retzius turned his attention to the prognathism and the orthognathism of the molar teeth; Kollmann to the facial index. Use could be made of the nasal index instead of the facial, or the orbital index, or any isolated characteristic, and we should have the same results. The combinations given by Retzius and Kollmann are possible, but cannot indicate races or varieties, from the fact that they are hybrid associations.

I need not make a longer demonstration of what I have affirmed, that classifications of human groups have been attempted by means of the cerebral cranium, but have not been successful on account of deficiency of method; and that the craniometrical method, still so undeveloped, has not yet, nor cannot, give those results while there is an exaggeration of an exact principle, that of expressing numerically facts relating to the cranium. It seems to me, after several years of study, and after having adopted the accepted form of craniometry, for want of a better, that it is time to establish for our use and for the study of the variations of man, a natural method, resembling that which is used in zoology and botany, and of which I laid the foundation about two years ago.

With the observations and the methods which I propose, I believe that many errors will be eliminated from anthropology. Those errors have been accepted because we have never possessed natural scientific methods for the study of human classification, such as we have in zoology. Blumenbach, in a valuable little book, attempts to apply the zoological method to man, not only for classification, but for the explanation of the causes of animal and human varieties. De Quatrefages, in his last work, employs the same method and the same scientific freedom. Unfortunately the followers or successors of both have only followed their masters in form, but not in method. Blumenbach, who, after various researches, reduces the human species to five varieties, finds, however, that human variations are infinite in number. If his method had been followed strictly, the number of human varieties would long ago have been increased, both in respect to the structure and the cranial forms.

The neglect of such methods and the failure to distinguish human varieties by means of the cranium has caused a curious error, that of regarding certain forms which are typically normal, as pathological, as I shall have occasion to demonstrate in the future when I speak of classified forms. This is apt to happen when new and unrecognised forms are placed before the observer.

One of the important characteristics in classifying the cranial varieties of man is the *cranial capacity*, which has a direct relation to the volume and weight of the brain; hence classification by crania means the classification of brains estimated by their form and external configuration. Its importance is for us increased by the fact that that which we find among races of animals occurs also in man; that there are races of small and large animals, races differing in size. This is also repeated in man, and we therefore have large, medium and small varieties, as measured by stature. The origin of such varieties is perfectly analogous to that in other animals. Nor is it an accidental phenomenon, because it is confirmed by heredity, through numerous and indefinite generations.

I have concluded, in studying cranial varieties morphologic-

[1] "De generis humani varietate nativa." IIIa edit. (Göttingen, 1795.)

ally as human varieties, that is, by their characteristic structures, that the volume has a direct relation to the form, in other words, many forms have limited and definite capacities, while other forms have sub-varieties differing in capacity. Such varieties are analogous to the stature of the large and small varieties of animals. The cranial capacity, therefore, while it is one of the integral characteristics of the cranium in regard to its classification, is also the indication of different varieties according to size. I discovered this fact when I classified for the first time the crania of Melanesia, and subsequently I defined it more accurately when I examined and classified thousands of other human crania.

This fact points to a correction of the value of cranial capacity and, therefore, of the weight of the brain, until now calculated by the average without distinction among different varieties. The cranial capacity of man varies from 1000 cc. to about 2000 cc. in the masculine sex; this enormous difference is admitted as individual variation, and it is thus conceded that there may be a least limit of normality possible which can be ascribed to the function of the brain, crania which descend to 1150 cc. being considered as pathological microcephali, according to Broca, and more or less according to other anthropologists; giving, on the other hand, a great value to a large capacity. Both conclusions are contrary to the real significance of the facts. I have found normal masculine capacities of 1000 cc. and a little greater, representing small human varieties, not being sporadic and individual phenomena; and, on the other hand, anthropologists have registered for eminent men, like Dante, Gauss, and others, very mediocre capacities, even very low, while for ordinary men they have recorded a much higher capacity. I have found in Melanesia normally constituted heads absolutely microcephalic, together with megalocephalic heads, belonging to varieties which have the same social value; they are both inferior, some anthropophagous, and live mixed together as one people. That which I have asserted concerning Melanesia may be said of the ancient and modern populations of the Mediterranean, among which are the Sicilians, the Sardinians, and the inhabitants of Central and Southern Italy; and I do not believe it can be said that there are no signs of human superiority in those regions. There are not, therefore, individual differences so great as from 1000 to 1500 cc., and from 1500 to 2000 cc., but characteristic differences of variety in human forms. The general average I therefore maintain is inexact and also arbitrary, because it is the average of incommensurate quantities. The exact average is that between individuals of the same variety, and the difference is the true individual variation.

But there is another error to correct, due to the signification which I am able to give to varieties distinguished by means of my method. It is considered by some a demonstrated fact that the cranial capacity has been increased in the course of social evolution from prehistoric epochs to historic times. Eminent men have affirmed it, but I have already placed their conclusions in doubt, because the facts do not appear to me evident and affirmative. I wrote some years ago:[1] "The most important physical evolution of man would be that which related to the organ of the mental functions, the brain. But the facts are still very doubtful and very obscure which relate to the weight and volume of the brain, and consequently to the cranial capacity. In a recent work of Prof. Schmidt, I find that the cranial capacity of the ancient pure Egyptians is 1394 cc. in the masculine, and 1257 in the feminine sex; in the pure modern Egyptians it is 1421 in the males, 1206 in the females. According to these figures there would be an increase of the cranial capacity of the modern over the ancient males, but a decrease in the females. The reverse would be true of the Egypto-Nubian cranium, which is 1335 in the modern males, and 1205·8 in the females. Broca found that the Egyptians of the IV. Dynasty had, males 1534, females 1397 cc.; those of the XI., males 1443, females 1328; and, finally, those of the XXIII., the most recent, males 1464, females 1322. There would be in such a case no increase, but decrease, but that is not possible; the cause of these facts lies in the mixtures of races at different times and in different proportions."

Now I conclude from my recent studies upon the Egyptians of different dynasties, from the most ancient to the present, that according to my method of classification there are capacities of 1260 cc., of 1390, of 1480, of 1550, of 1710, and still other capacities differing according to the varieties determined.[2] As is easily understood, a general average necessarily alters the facts, according to the number of varieties which enter as components of the average in the different series in anthropological museums; hence the curious results above indicated.

Another important point is as follows:

"But the fact which surprises us is the high figure of the capacity given by prehistoric crania. The masculine crania of Lozère have given 1606 cc., the feminine 1507; also of Lozère, masculine 1578, feminine 1473; crania from the *pietra levigata*, masculine 1531, feminine 1320; the contemporaneous Parisians, masculine 1559, feminine 1337. The approximate average of crania from the *pietra levigata* is 1560, equal to that of modern Europeans, as is related by Topinard."[1]

In another of my recent works, I have demonstrated that of the crania of the neolithic age[2] the *Isobathyplatycephalus* has a capacity from 1230 to 1405 in the feminine, and the *Eucampy*… varies from 1470 to 1564 in the masculine. The two varieties, still persistent in Sicily, do not vary in capacity in the modern series, and at the same time show that in the neolithic epochs, as among modern populations, large and small varieties are found just as the same types are now found through persistence of forms.

From this it is evident how much there is to reform in anthropology when we study by natural methods facts until the present misinterpreted, respecting the classification as well as the physical and psychological characteristics of man in time and space. Perhaps in the future, when we know all cranial forms by natural classification, it will be possible to find a correspondence of psychological characteristics in populations according to the predominance or superiority of types, a fact which has until now escaped research, because the capacity of the cranium in its absolute sense is not in correlation to the development of the mental functions, notwithstanding what is commonly affirmed.

The following are the varieties into which Dr. Sergi classifies the forms of skulls in the *norma verticalis* of Blumenbach:—(1) Ellipsoid (*ellipsoides*); (2) Pentagonoid (*pentagonoides*); (3) Rhomboid (*rhomboides*); (4) Ovoid (*ovoides*); (5) Sphenoid (*sphenoides*); (6) Spheroid (*sphæroides*); (7) Byrsoid (*byrsoides*); (8) Parallelepipedoid (*parallelepipedoides*); (9) Cylindroid (*cylindroides*); (10) Cuboid (*cuboides*); (11) Trapezoid (*trapezoides*); (12) Acmonoid (*acmonoides*); (13) Lophocephalic (*lophocephalus*); (14) Chomatocephalus (*chomatocephalus*); (15) Platycephalic (*platycephalus*); (16) Skopeloid (*skopeloides*).

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

WE have received a verbatim report of the interview which a deputation from the Association of Technical Institutions recently had with Mr. Acland. Several suggestions were made, some of which have already received the attention of the Science and Art Department. Prof. Wertheimer pleaded for an advisory voice in the construction of the Department's schemes before they were finally adopted, in a manner similar to that by which the Education Department allowed the managers of public elementary schools to express their views on the Code under which they had to work before it was finally adopted. Mr. Acland, in the course of his reply, said it was the intention of the Department not to publish near the summer months anything which will be in the nature of an important change. The recent form dealing with organised science schools had been issued early, with a view to embodying it in the Directory next autumn, the Department in the meantime being open to suggestions. During the course of the Vice-President's remarks, the question of the publication of the dates of the May examinations was raised, and, in reply to an inquiry, Sir John Donnelly said he saw no difficulty, if the schools wanted it, in publishing in May the dates of the subsequent May examinations. As to the question of the proper basis for the calculation of the Government grant, Mr. Acland expressed the hope that some day a part of the principle, which is shortly to be applied to organised science schools, will also be applied to evening classes; that is to say, there is every prospect that the grants will in a year or two be awarded more on the Inspector's reports as to the soundness of the teaching than on the results of examination.

THERE are 119 Universities in the world, says the *Oxford University Extension Gazette*. Dr. Kukula in his list names

1 "Human Evolution." (Review of Scientific Philosophy, 1888, Milan.)
2 "Concerning the Primitive Inhabitants of the Mediterranean." (Archives of Anthropology, Florence, 1892, vol. xxii.)

1 See "Human Evolution."
2 "Crania of the Neolithic Age." (Boll. Paletnol. Italiana, Parma, 1892.)

114, but he omits the Universities of London, of Paris, of the State of New York and of Wales, and the New University of Brussels. Excluding the first three, which, being of the Napoleonic type, have no resident students, the undergraduate population of the Universities of the world is estimated by this academic statistician as amounting to 157,513 persons. Berlin is the most populous University, Urbino the smallest. The first has 7771 students, the latter only 74. In point of numbers Oxford comes tenth on the list; Cambridge, twelfth; Victoria, sixty-fourth, and Durham ninety-eighth.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 21.—"On the Development of the Branches of the Fifth Cranial Nerve in Man." By A. Francis Dixon.

In this paper "detailed descriptions of the fifth nerve branches are given for five different stages of the human embryo, beginning with an embryo of four weeks, at which time merely the three main divisions of the nerve are represented, and ending with one of the eighth week. The observations on the human embryo have been checked by further observations on rat embryos, and an almost complete correspondence between the two has been made out." In mammals, the three divisions of the fifth nerve are found to rise independently from the Gasserian ganglion, and the nasal nerve is found to be the first representative of the ophthalmic division, the frontal being formed later. In like manner, the inferior dental nerve represents the first formed inferior maxillary nerve, the lingual branch appearing later. No special ganglion is present either for the nasal or for the ophthalmic nerve in mammals in the sense of a ganglion of a posterior nerve root. The ciliary ganglion does not represent such a ganglion, and when first found is more closely connected with the fourth and frontal than with the third and nasal nerves. The fourth and frontal nerves from an early period are closely connected. At the beginning of the sixth week nearly all the named branches of the fifth nerve of the adult are represented in the embryo; also at this time the accessory ganglia of the fifth nerve are recognisable. No evidence was found to show that the cells of these smaller ganglia are derived directly from those of the Gasserian. None of the different nerves which in the adult connect the fifth with the other cranial nerves are to be considered branches of the fifth nerve; thus the chorda tympani and the Vidian are found to be derived from the facial, and the nerve of Jacobson from the Glossopharyngeal.

"On the Conditions affecting Bacterial Life in Thames Water." By Dr. E. Frankland, F.R.S.

Since May, 1892, the author has been making monthly determinations of the number of bacteria capable of development on a peptone-gelatine plate in a given volume of Thames water collected at the intakes of the metropolitan water companies at Hampton. The number of microbes per cubic centimetre of water varied during this time between 631 and 56,630, the highest numbers having, as a rule, been found in winter or when the temperature of the water was low, and the lowest in summer or when the temperature was high.

The complete observations demonstrate that the number of microbes in Thames water depends upon the rate of flow of the river or, in other words, upon the rainfall, and but slightly, if at all, upon either the presence or absence of sunshine or a high or low temperature.

With regard to the effect of sunshine upon bacterial life, the author remarks that the interesting researches of Dr. Marshall Ward leave no doubt that sunlight is a powerful germicide; but it is probable that its potency, in this respect, is greatly diminished, if not entirely annulled, when the solar rays have to pass through a stratum of water even of comparatively small thickness before they reach the living organisms. If this be the case, it is held to be no matter for surprise that the effect of sunshine upon bacterial life in the great mass of Thames water should be nearly, if not quite, imperceptible.

Geological Society, April 3.—Dr. Henry Woodward, F.R.S., President, in the chair.—Dr. K. de Kroustchoff, St. Petersburg, was elected a Foreign Correspondent of the Society.—Physical features and geology of Mauritius, by Major H. de Haga Haig, R.E. The author gave full details of the physical geography of the island, including the nature and composition of the mountain ranges, the depth of the ravines, the occurrence of caverns in the lavas, and the character of the coral reef surrounding the island. Information was furnished concerning the neighbouring islands, and reference made to the possible former existence of an extensive tract of land at no great distance from Mauritius.—On a comparison of the Permian freshwater Lamellibranchiata from Russia with those from the Karoo formation of Africa, by Dr. Wladimir Amalitsky, Professor of Geology in Warsaw University. The freshwater shells from the Russian Permian deposits belonging to the genus *Palæomutela* are also known from the Karoo beds of South and Central Africa, as pointed out by the author in 1892. He had recently had the opportunity of studying the actual specimens from the Karoo beds, and found in them species of the groups *Palæomutela Inostranzewi*, *P. Keyserlingi*, *P. Verneuilii*, and *P. Murchisoni*; also of a new genus, the forms of which he had previously referred to *Naiadites*, Dawson. All these groups are found also in Russia, and a list was given of species found in the upper horizons (A, B, and C) of the Permian beds of Russia and in the Karoo beds. These upper beds of Russia have been determined by the author as the freshwater equivalents of the Zechstein; consequently the Beaufort beds of the Karoo series, if considered as the homotaxial equivalent of the European strata referred to above, should be regarded as Upper Permian. The Upper Permian group of freshwater lamellibranchiata of Russia, which bears traces of genetic relationship with the Carboniferous Anthracosidæ, and which was already well represented in Permo-Carboniferous and Lower Permian times, is, according to the author, much older than the African fauna of the Beaufort beds. These may be concluded to have migrated from Russia, the Gondwana beds of India having probably been the connecting-link between all these deposits. The author gave a description of the fossils of the Karoo series which he had examined, including a diagnosis of the new genus in which he placed the fossils already alluded to as having been previously referred to the genus *Naiadites*.

PARIS.

Academy of Sciences, April 8.—M. Marey in the chair.—On the fluted spectrum, by M. H. Poincaré. A mathematical paper in which it is shown that a complete analysis of the phenomena of Fizeau and Foucault's experiment confirms Fizeau's deduction concerning the permanence of luminous movement during a large number of oscillations.—Official plans and reports relating to the removal of the capital of Brazil to a new site, by M. H. Faye. A series of reports printed in Portuguese and French. The district in which the proposed new site for a Brazilian capital is situated lies between the parallels 15° 40′ and 16° 8′ and the meridians 3° 18′ and 3° 24′ at an altitude of above 1000 metres.—Structure of the hymen in a species of *Marasmius*. An abstract of a memoir by M. J. de Seynes.—On substitutions, by M. Zochios. An algebraical paper.—Removal of the Brazilian capital. A letter to M. Faye, by M. Cruls. A short account of the main features of the survey work undertaken on the new site.—On geodetic work in the basin of the Amour, by M. Venukoff.—On the determination of the mass of the cubic decimetre of distilled water at 4°, by M. J. Macé de Lepinay. This datum is yet imperfectly determined. Shuckburg and Kater give 1000·480 grams, whereas Stampfer finds the value 999·653 grams. The author proposes a new method of determination by which he expects to determine this constant within 6 mgm. The proposed method includes (1) the study of the geometrical form and dimensions of a certain solid as related to the standard metre, (2) the measurement of the loss of weight of this solid immersed in pure air-free water at its temperature of maximum density in terms of the standard kilogram. The solid taken is a parallelopipedon formed of transparent quartz. Its thickness in different directions will be examined optically by means of Talbot's fringes.—New apparatus for the measurement of the specific inductive power of solids and liquids, by M. H. Pellat.—On a new form of spectroscope termed the "héma-spectroscope comparateur," by M. M. de Thierry.—On a simple experiment demonstrating the presence of argon in atmospheric nitrogen, by M. Guntz. The author obtains argon by replacing magnesium by electrolytic lithium. Owing to the lower temperature at which lithium completely absorbs nitrogen, it is possible to pass atmospheric nitrogen over several heated iron boats containing lithium, and collect argon over mercury at the exit end of the apparatus.—On the spectra of selenium and some natural selenides, by M. A. de Gramont. The minerals examined are: Berzéline Cu_2 Se, Zorgite ($PbCu_2$) Se, Clausthalite PbSe, Eucaïrite $Cu_2 Se.Ag_2Se$, Guanajuatite or Frenzélite Bi_2Se_3.—On the estimation of thiophene in benzene, by M. G. Denigès. Two methods are given, both depending on the use of the mercury reagent previously described. In aqueous solution the reagent precipitates the compound $(SO_4HgOHg)_2.C_4H_4S$ when heated with the impure benzene in a closed flask at 100° for about fifteen minutes with frequent shaking. In methyl alcohol solution the precipitate $SO_4(HgO)_2Hg.C_4H_4S$ is produced; in this case the benzene is miscible with the reagent, and hence the reaction is much facilitated.—On the action of potassium permanganate on various organic substances, by M. E. Maumené.—On the calcium phosphate of milk, by M. L. Vaudin. The conclusions are drawn that: (1) Milk contains citric acid as alkaline citrate, which aids in keeping its calcium phosphate in solution. (2) This solution occurs owing to the effect of lactose in preventing the precipitation of calcium citrate from solution. (3) Every influence modifying or destroying the molecular equilibrium of the salts dissolved in milk, tends to precipitate tricalcic phosphate together with calcium citrate.—The sandstone of Taveyannaz and its relationships with the "flysch," by MM. L. Duparc and E. Ritter.—On the calcium carbonate of lake-waters, by M. André Delebecque.—On the connection of latitudinal displacements of lines of barometric maxima with the movements in declination of the moon, by M. A. Poincaré. The mean atmospheric conditions are powerfully and regularly influenced by the moon at each tropical revolution, and at each revolution of the node.

THURSDAY, APRIL 25, 1895.

CONTROVERSIAL GEOLOGY.

Collected Papers on some Controverted Questions of Geology. By Joseph Prestwich, D.C.L. (Oxon), F.R.S., F.G.S., Corr. Inst. France (Acad. Sci.); Acad. R. Lyncei, Rome; Imp. Geol. Inst., Vienna; Acad. Roy., Brussels; Amer. Phil. Soc., Philad.; &c. (London: Macmillan and Co., 1895.)

"WITH respect to the main facts of Geology, we geologists are in general of one opinion, but with respect to the explanation of many of those facts, we hold very divergent opinions." In these opening words of his preface, the author explains and justifies the publication of this collection of essays. Prof. Prestwich's position, as the acknowledged *doyen* among British geologists, demands that these articles—the latest fruits of his ripe experience—should receive the most thoughtful consideration from his fellow geologists; but, quite apart from the position and authority of their author, all of the memoirs included in this volume are of the greatest value as contributions to science; and in reading them it is difficult to say whether we are more impressed by the wealth of knowledge or the literary grace which they display.

The key-note of the volume is struck in the first article, "The Position of Geology—a Chapter on Uniformitarianism," published in the *Nineteenth Century* of October 1893. In this short and admirably written essay, the author clearly defines his own attitude with respect to the doctrine of uniformity. He credits most English geologists with a belief in an absolute uniformity *both in kind and degree*, while he and many continental geologists, who fully accept uniformity *in kind*, altogether reject the notion that the actions going on at the present day can be accepted as *measures* of the rate of similar changes in the past. We cannot help thinking, however, in reading this essay, that the issue is not quite so simple as the author implies. The strictest uniformitarian would never maintain that no action that has taken place in past geological times could possibly have exceeded in violence, or in the effects produced by it, the phenomena which we may have happened to have witnessed during that century or two, in which systematic studies of terrestrial changes have been carried on. In 1783 a volcano in Iceland threw out lava having a volume equal to that of Mont Blanc; and in 1883, another volcano in the Sunda Straits projected materials to the height of sixteen miles into the atmosphere. Now no geologist would maintain that there could not possibly have occurred, in the long periods of the past, more violent eruptions than these. The uniformitarian only asks that in the explanation of the past we confine ourselves to operations *of the same order of magnitude*, as those now occurring upon the earth. We should be surely justified, for example, in asking for very definite evidence that in past times a single geological eruption had thrown out materials equal to the volume of the whole Alpine chain, or that another had projected materials to the height of 150 miles. If a gorge can be shown to have been cut by an existing river in 1000 years, it would hardly be legitimate to infer that a similar gorge was cut in ten years by a river of 100 times the volume, unless at the same time it were shown that there were very strong reasons for believing that rivers of the proportions assumed actually existed in the past.

Prof. Prestwich puts what he conceives to be the position of the uniformitarians in the following simile:—"What if it were suggested that the brick-built pyramid of Hawâra had been laid brick by brick by a single workman? Given time, this would not be beyond the bounds of possibility. But nature, like the Pharaohs, had greater forces at her command to do the work better and more expeditiously than is admitted by the uniformitarians." We cannot accept the parallel as a just one. Large brick structures are not at the present day erected by a single bricklayer, and the historian—who is equally uniformitarian in his practice with the geologist—does not feel called upon to suggest any such improbable origin for a pyramid. But if, on the contrary, it were asserted that the pyramids are so vast that they must have been erected by a race of beings of larger stature and greater physical strength than the men of the present day, a position would be taken up similar to that of the opponents of a rational uniformitarianism. The historian justly asks that before such a view be accepted, it shall be shown that the work of pyramid-building could not be performed by ordinary men working in sufficient numbers for a long period of time. Nor would the historian be very greatly concerned if it were argued that by ordinary men such a task of pyramid building might extend over several reigns, or would even require centuries for its accomplishment. Every historian, in fact, takes up the same attitude as the uniformitarian geologist when he refuses to credit the men of bygone ages with gigantic stature, prodigious strength, abnormal wisdom, or extraordinary longevity.

While, however, we demur to the principles and ideas ascribed by the author of this volume to the uniformitarians, we gladly accept his work as an additional proof, if such were required, that old-fashioned "catastrophism" in geology is now quite extinct. More than this, we think that the protests and cautions of so distinguished and able a reasoner as Prof. Prestwich will render a real service to geology in calling attention to somewhat unwarrantable assumptions that have been made by some theorists. With our author's complaint against what he justly compares to *the closure*, as applied by physicists and mathematicians to the legitimate speculations of the geologist, we entirely sympathise. "It would," as he justly says, "be an unfortunate day for any science to have free discussion and inquiry barred by assumed postulates, and not by the ordinary rules of evidence as established by the facts, however divergent the conclusions to which those facts lead may be from the prevailing belief."

The second essay in the volume is a weighty criticism of the astronomical theory of glacial epochs. The only objection which we think can be taken to the essay is that the author identifies the upholders of this theory with the uniformitarians. The late Sir Charles Lyel never accepted the theory of Mr. Croll, and many holding the strongest uniformitarian views have always maintained that geological facts are opposed to any of those explanations of vicissitudes in climate in past geological times, which are based on astronomical considerations.

In the third article, Prof. Prestwich discusses "the primitive characters of the flint implements of the chalk plateau of Kent, with reference to the question of age and make." The author of this essay, thirty-six years ago, took a leading part in making known the evidence in the Somme Valley and elsewhere, which is now universally accepted as establishing the antiquity of man. In the essay before us, he insists that, before the times when men fashioned the beautifully chipped implements of our river valleys and caves, a still more primitive people employed rough flints as scrapers, just as did the recently extinct race of Tasmanians. The beautiful series of plates accompanying this article will, we think, carry conviction to the minds of most archæologists and geologists, that the existence of such primitive races has been established by the author. Prof. Prestwich, however, argues that the antiquity of the men of the river valleys and caves, and of still more primitive people who used the flints of the Plateau period, though very great, was probably less than some theorists have imagined.

The three last articles, "On the Agency of Water in Volcanic Eruptions," "On the Thickness and Mobility of the Earth's Crust," and "On Underground Temperatures," are well known to all geologists; but for the present volume these memoirs have been revised, and some very important and valuable additions have been made to them. They will be much more convenient for purpose of reference than in the journals in which they originally appeared.

There is one aspect of the work before us to which we cannot avoid alluding before concluding this notice. All the articles are controversial, as indicated by the title; but the work might fairly be cited as an example of the spirit in which scientific discussions ought to be carried on. No geologist, who takes up this work, but will find cherished ideas reasoned against, or pet notions boldly assailed. But from beginning to end of the volume, he will find that no word has been written which is calculated to give pain to the most sensitive opponent. This is high praise; but it is not higher than might have been anticipated as the due of one who has in a long career inspired such universal admiration, esteem, and affection as the successor to the chair of Buckland and Phillips in the University of Oxford. JOHN W. JUDD.

POPULAR WEATHER FORECASTS.

My Weather-wise Companion. Presented by B. T. (Edinburgh and London: William Blackwood and Sons, 1895.)

DOES "B. T." stand for Barometer and Thermometer, the instruments which some people are foolish enough to think necessary for forecasting the weather, or in this simple guise does modesty shelter itself from too great publicity and the evils that popularity brings? The connection is curious, but probably accidental, for the book is free from all scientific technicalities, and the author would like us to forget that such things existed, and adopt processes that can be practised by all, without any outlay on costly apparatus, without telegraphic information, and the weariness of preparing synoptic charts. Herein "B. T." is wise, for he is assured of a much larger audience, since the instruments with which he works are in the hands of every one, and no previous knowledge is required for their use. The sky, the clouds, the moon, animals, plants, &c., these are the tools our author uses; but even these may at times be a little inconvenient and difficult in their application. For instance, some of us might very well have wished to know that the winter through which we have just passed was likely to prove more than ordinarily severe, in order to take necessary precautions about water-pipes and such-like necessary evils. Here is the method of test: "If the mole dig his hole two feet and a half deep [this sounds like a sum in simple proportion, but such a conclusion would be premature], expect a very severe winter; if two feet deep, not so severe; if one foot deep, a mild winter." No one would probably care to contradict this: it may be perfectly true, but then as a rule people do not go about the country with pickaxe and shovel, looking for mole-holes, and laboriously and exactly determining their depth. Such severe exercise would be undertaken only by a very ardent meteorologist, and even he might be discouraged, for the author does not say that the winter will be severe or otherwise, but only that it may be expected.

In another respect our author shows much worldly wisdom. It may be assumed that what the public look for from the maintenance of Weather Bureaus and Meteorological Offices, is to know whether it is going to rain. A forecast that says that the wind will be from the south-east, possesses little general interest; what a man wants to know is whether it be possible to dispense with an umbrella, or whether one must submit to the extra care and anxiety the carriage of one entails. It may be to some a matter of the keenest excitement to know whether a depression exists on the coast of Ireland; while some, again, will even speak disrespectfully of an anticyclone in Central Europe; but the "man in the street" will be perfectly satisfied if he can be assured that the next hour or two will remain fine. Hence the author wisely concerns himself principally with the signs that make for rain. This kind of information, as the author is careful to point out, is welcome alike "to the prince and peasant, to the anxious hostess who trembles for the success of her garden-party, to the tinker who seeks the friendly shelter of a wayside hedge, down to the dandy in Pall Mall, who hates to carry an umbrella." And on the subject of this umbrella we think we have some right to complain. He, it would seem, has carried one and the same umbrella through a period of fifteen years, carried it, nay used it, amidst aristocratic surroundings, and occasionally under circumstances likely to test the constitution of the most carefully constructed; and yet we gather that it is still a presentable article, and one that could be unfurled in Piccadilly with confidence by the most fastidious. Why could he not have given us the recipe that preserves to an umbrella such a long life of usefulness? This contribution to economics would have been a valuable testimony to the accuracy of his conclusions and the keenness of his observation, since it might be fairly inferred that this protection was not carried when it was not wanted. But, alas, we have to content ourselves with a collection of rules and portents, the belief in which we fondly thought the Education Act and the School Board had utterly abolished.

And even here our old friends, when brought out for our edification, are not in the form in which they are familiar, and have been long beloved. Look at the baldness of the assertion—"Expect bad weather if cats wash their faces and lick their bodies." Contrast it with the majestic roll of the well known couplet—

> Puss on the hearth, with velvet paws,
> Sits, wiping o'er her whiskered jaws.

We distinctly feel that we are robbed of something; there is such a pleasant jingle in the old rhyme, that it carried conviction with it. How disappointing, too, to be told only to *expect*. We may just mention, in passing, that this is not the conclusion which we should expect the average fourth standard boy to draw from witnessing the operation on the part of "puss." We should expect that young gentleman to remark that "cat's hair appeared to be slightly hygroscopic."

Altogether this little book reminds us of those admirable compilations in which the theory of whist is sometimes exposed: a vast number of rules is given, which if one could remember and select at the right time he would never make a mistake; but, unfortunately, the combinations on which the rules are founded have a knack of eluding the unlucky player, and never seem applicable to the hand in play, with the consequence that in his efforts to remember some rule, he trumps a thirteenth at an inopportune moment, and earns the contempt of a long-suffering partner. In the same manner one can conceive the city man, armed with this collection of precious and invaluable rules for determining the weather of the coming day, debating with himself whether it was last night or this morning that the sky was red; did he, while shaving, see his dog eating grass on the lawn; and what is the exact age of the moon—finally getting confused by the knowledge that the train is nearly due, rashly seizing his mackintosh and umbrella in the middle of a well-determined summer anticyclone, and so forfeiting his hard-earned position of a trustworthy weather prophet and a man of keenness and nicety of observation.

THE MYCETOZOA.

A Monograph of the Mycetozoa; being a Descriptive Catalogue of the Species in the British Museum. Illustrated with seventy-eight plates and fifty-one woodcuts. By Arthur Lister. (Printed by order of the Trustees. London: 1894.)

ALTHOUGH this is an official publication of the Natural History Department of the British Museum, that part of the title referring thereto is somewhat misleading, because the author includes everything published belonging to this curious group of organisms. At the same time it is not a monograph in the strict sense of the word, because the author had no opportunity of examining a large number of the reputed species inhabiting Central Europe, Scandinavia and North America. Thus, out of 15 species of *Badhamia*, only 9 came under his observation; of *Physarum*, 30 out of 45; of *Didymium*, 8 out of 17, and so on all through. It is true that he repeats, in English, the authors' descriptions, and frequently suggests the affinities of the species in question.

Further, apart from the fact that the book was published under the authority of the Trustees of the British Museum, and the fact that "every species of which I have given the characters can be examined either in bulk, or as a mounted object in the British Museum," it might with equal propriety have been entitled a descriptive catalogue of Mr. Lister's own herbarium, or of the Kew herbarium, because, as he acknowledges, he had full use of the Kew set, including all Berkeley's numerous types.

However, this does not affect the character and quality of the work. Mr. Lister's previous contributions to the literature of these curious and debatable organisms were a sufficient guarantee of good and really original work, and he has no doubt met all reasonable expectations on this point. Indeed few works have recently been issued embodying so much original research. The *Mycetozoa*, as limited by De Bary, Rostafinski, Lister, and others, are essentially the same as the *Myxogastres* of Fries and the *Myxomycetes* of Wallroth. The first name was substituted for the older ones because it was discovered that the spores, instead of producing a mycelium as in fungi, gave birth to swarm-cells which coalesce to form a plasmodium; thus indicating a relationship with the lower forms of animal life. Mr. Lister adopts this designation, and defines the group as follows:—

"A spore provided with a firm wall produces on germination an amœboid swarm-cell which soon acquires a flagellum. The swarm-cells multiply by division and subsequently coalesce to form a plasmodium which exhibits a rhythmic streaming. The plasmodium gives rise to fruits which consist of supporting structures and spores; in the *Endosporeæ*, these have the form of sporangia, each having a wall within which the free spores are developed. A capillitium or system of threads forming a scaffolding among the spores is present in most genera. In the *Exosporeæ* the fruits consist of sporophores bearing numerous spores on their surface."

He then proceeds to describe in detail the development and various stages, in fact the life history of these organisms, and this he has done in a simple and lucid style worthy of all admiration. The movements of the swarm-cells—creeping and dancing movements—are most interesting, as well as that of the plasmodium, or aggregation of cells; but the feeding of the swarm-cells is most exciting. Mr. Lister had previously published accounts of his observations of the ingestion of food-material by the *Mycetozoa* in this stage of their development; yet a sh rt extract relating to this process is not out of place:—

"If bacteria are introduced into a cultivation of swarm-cells on the stage of the microscope, they are seen to be laid hold of by the pseudopodia and drawn into the body of the swarm-cells, where they are enclosed in a digestive vacuole. Several bacteria are brought in turn to the same chamber, or fresh captures are conveyed into one or more additional vacuoles. The protrusion of pseudopodia usually ceases after such ingestion, and that part of the swarm-cells takes a rounded form. In the course of an hour or two the bacteria are assimilated and the digestive vacuoles disappear. Unicellular algæ and inorganic matter are sometimes taken in, which after a time are again discharged. Both ingress and egress are observed to take place only at the posterior end."

It should be explained that an ordinary swarm-cell in the feeding stage is an elongated body tapering at one end into a long cilium or lash, and more or less truncated at the end with several short cilia, the so-called pseudopodia. Within the body of the cell is a nucleus and several vacuoles.

With regard to hybrids between the plasmodia of different species, Mr. Lister is in accord with De Bary, and doubts the accuracy of Mr. Massee's observations.

Another point of great interest is the very wide geographical distribution of most of the species; and the main characters, Mr. Lister states, are remarkably constant in specimens gathered in all parts of the world. Mr. Lister gives a number of instances in which specimens obtained from Europe, India, and North and South America are identical in the most minute microscopic detail. But there are exceptions, in which individuals of the same species from tropical and temperate regions exhibit differences in form; the tropical ones being of more elegant growth.

In his description of the sclerotium, or resting stage, of the plasmodia, Mr. Lister states that the sclerotium of *Badhamia utricularis* can be revived, after preservation in a dry state for three years, by being placed in water. He also gives the results of a number of interesting experiments on the vitality of various other *Mycetozoa*. Altogether Mr. Lister's "Introduction" is most instructive, and his descriptions are so clear, that this book should go far to popularise the study of these organisms. The plates, which are collotype reproductions of water-colour drawings, are very good, but much of the beauty of the originals is lost in the process. It is a pity that they were not reproduced in colour. And this leads one to ask why the coloured figures in Massee's "Monograph" are not cited. It is true there are references to the pages of that work, which would lead one to the figures, if one knew of their existence. It is disappointing, too, that the author has attempted no review of the previously existing literature, and has not even thought it necessary to devote two or three pages to bibliography. These omissions are all the more surprising when one considers the facilities the author enjoyed in the prosecution of his studies.

A NEW WORK ON DYEING.

La Pratique du Teinturier. By Jules Garçon. Two vols. Pp. 148 and 391. (Paris: Gauthier-Villars et Fils, 1893 and 1894.)

THE art of dyeing has in recent years developed so rapidly—having been practically revolutionised and to a large extent remodelled during the last thirty years—that text-books and works of reference dealing with the subject rapidly become defective. We are therefore always glad to welcome any new work which, as far as possible, epitomises the information up to date.

The great energy and enterprise exhibited by the large firms of colour manufacturers in such a marked degree, has, moreover, a tendency to develop what may be distinguished as the *art* of dyeing, more rapidly than the *handicraft*. It is, therefore, pleasant to note that, as an engineer, the author of the book under review fully appreciates the importance of the manipulative and mechanical side of the subject, and gives a luci scription of many of the recently introduced appli

The plan of the book differs somewhat from usually found in works on dyeing. There is, for ins no description of the character and properties textile fibres or of the colouring matters; but the va theories which have been put forward to accou dyeing processes, although of necessity based on facts, are discussed at considerable length. A chemistry, as expressed by symbols and equatio conspicuous by its absence; but a lengthy chapt the elements of chromatics is introduced. Howeve the book is as yet incomplete (a third volume in course of preparation), it is too early to defin consider these as omissions.

Volume i. contains a very short and sketchy histo introduction, followed by a few notes regarding relative advantage of the natural and artificial dye-st A classification of the colouring matters—following usual lines—is then given, with some very general r with regard to the application of each class of col to the various fibres. This section of the book m certainly have been considerably extended with ad tage, since undue compression necessitates a too generalisation and an inadequate explanation of the fa For instance, it is not sufficient to state (p. 13) tha acid used in dyeing with sulphonic acid colouring mat (always employed as salts) serves to liberate the colour acid. This is really a very secondary acti requiring only a small fraction of the amount of a used, the principal function of which is to prepare wool for combination with the dye.

The methods of dyeing linen, jute, China grass, feath &c., are also noticed, a useful bibliography on the dyei of feathers being introduced. This commendable feat is also noticed in several other sections of the book.

The second part of the first volume is concerned wi the actual processes of scouring, dyeing, and finishi The space allotted to this is again very small; the d scription of the bleaching of cotton and of wool occup ing less than half a page. Some useful hints are, ho ever, given with respect to the choice of dye-stuffs, t storing, dissolving and examination of colours, the caus of defects, &c.

M. Garçon devotes considerable attention to the que tion of the fastness of colours, and discusses the influenc in respect to this property, of the nature of the fibre an the colouring matter employed, of the method of apply ing the colour, of the character of the light and th atmospheric conditions. With regard to the relationshi between the chemical constitution of the colouring matter and its behaviour on exposure to light, it is noted that although most members of any particular group act in a similar manner, a slight difference in constitution is sometimes sufficient to cause a great difference in permanence; thus, although most of the anthracene colours are "fast," and all the triphenylmethane derivatives "fugitive," gallein is much more resistant than the closely allied eosin dyes, and by simply sulphonating indigotin, one of the most permanent dyes is changed into a very fugitive colour. It may be added that derivatives of methyl anthracene appear to be comparatively fugitive to light.

It is thus not safe to put forward any assumptions, based either upon chemical relationship or similarity of general properties, concerning the behaviour of colouring matters in this respect; and therefore, recognising the value of a systematic examination, the author gives, at considerable length, the results obtained in recent years by Hummel.

When discussing certain experiments in which arc lamps have been employed as the source of illumination, it is stated that the electric light behaves similarly, but less energetically, than sunlight; the average bleaching action of sunlight having been estimated at 30 per cent. of its total luminosity, while that of the electric arc is only about 6 per cent.

The third section of the first volume deals with operations subsequent to dyeing, such as soaping, milling, steaming, &c. It is very short, extending only to four pages. Two appendices, the first dealing with theories of dyeing, and the second with the elements of chromatics, are added, and the volume ends with a very complete bibliography of the works on dyeing published during the last 100 years.

The second volume is devoted to a description of the machinery used in dyeing and allied processes, a very large space, equal in fact to the whole of the first volume, being occupied by the subject of water purification; which, although of great importance to the dyer, certainly receives undue prominence. The great fault of the work, as a whole, is indeed a certain lack of proportion; many essential points receiving scant attention, while valuable space is occupied to smaller advantage by long descriptions of less important subjects—such, for instance, as the Westinghouse air-pump. Nevertheless, the book should prove a valuable reference work for managers of works, or students of dyeing, to whom it can be heartily recommended.

WALTER M. GARDNER.

OUR BOOK SHELF.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. "Moths," Vol. iii. By G. F. Hampson. (London: Taylor and Francis, 1895.)

WE have already noticed the two preceding volumes of this work in some detail; and it is therefore unnecessary to say more respecting the general execution of this volume than that the letterpress is arranged in a similar manner, and that the execution of the woodcuts is equally good. The present volume includes the last two subfamilies of the *Noctuidæ*, the *Focillinæ*, and the *Deltoidinæ*, and one or two small families of the *Geometridæ*. Respecting the *Deltoidinæ*, Mr. Hampson remarks: "It exhibits a gradual development from forms with straight palpi fringed with hairs above, such as *Hypenæ*, which is closely allied to the *Sarrothripinæ*, and to the ancestors of the *Noctuidæ* and *Nolinæ*, through forms with oblique palpi, to a group possessing palpi of an extremely curved sickle-shaped type; from this group arose the stouter-built, more typically noctuiform and nocturnal *Focillinæ* and *Quadrifinæ*." We seriously doubt the advisability of speaking in such a positive manner on questions which cannot, in the present state of our knowledge, be anything more than very doubtful inductions, at the best.

After the *Noctuidæ*, Mr. Hampson places the families *Epicopiidæ*, *Uraniidæ*, *Epiplemidæ*, and *Geometridæ*, for the last of which he has followed Mr. Meyrick's classification. Under the *Uraniidæ* he includes a considerable number of genera, most of which, except *Nyctalemon*, were included by previous authors in the *Microniidæ*, and other families of *Geometridæ*. A fourth volume is to conclude the Indian *Macro-Lepidoptera*, and to contain the *Pyralidæ* and a supplement; and we are glad to learn that Lord Walsingham is working at the *Micro-Lepidoptera* of India.

Mr. Hampson speaks of the difficulty of the sub-family *Boarmiinæ* in the *Geometridæ*; and under the genus *Boarmia* itself he includes no less than eighty-five species, divided into several sections, to some of which sub-generic names are applied. As, however, no less than twenty-eight generic names are included as synonyms of *Boarmia*, we think it would have been better to have treated some, at least, as provisionally entitled to generic rank. And this leads us to a consideration of the most serious defect in all Mr. Hampson's work, which has already been pointed out in more than one quarter. He is too much inclined to place forms together as varieties, and then to treat them as actual synonyms. It is true that in a few instances in the present volume he discriminates between named varieties; but far more frequently he gives a description of a species in a few lines, preceded by a string of half-a-dozen or more names, without any hint of how far these names represent distinct forms, or which names represent his idea of the species he is describing, even when he notices that the species is variable. While making allowance for exigencies of space, this is hardly fair to those who will use his books; for even if we assume that Mr. Hampson is always correct in his views as to which forms are entitled to specific rank, and which are only to be regarded as varieties, it is not to be supposed that every one will take exactly the same view of a doubtful case; and we greatly fear that if an entomologist meets with an insect which does not correspond with the description of a species given by Mr. Hampson, he will at once describe it as new, and, in many cases, redescribe one of the forms which Mr. Hampson has rejected, with a light heart, as a mere synonym.

Apart from this serious defect, we can recommend the book as a most useful and, indeed, quite indispensable manual for all who are interested in East Indian Moths.

W. F. KIRBY.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Origin of the Cultivated Cineraria.

RETURNING from abroad, I have just seen Mr. Dyer's letter in NATURE, March 14. Of the matters there treated I ask leave now to deal with one only, that numbered (18). This is a point of fact—the origin of the cultivated Cineraria. At a meeting of the Royal Society, on February 28, Mr. Dyer exhibited a specimen of *Cineraria cruenta* from the Canaries, side by side with a plant of the common cultivated form. With the object of minimising the value of "sports" in evolution, this exhibition was made to illustrate what can be done "by the gradual accumulation of small variations." Mr. Dyer stated, if I rightly understood him, first, that of the two forms exhibited, the one had been produced from the other; secondly, that, as far as is known, this process of evolution had been accomplished by the gradual accumulation of small variations, and not by the selection of "sports" or seedlings presenting notable and striking variations. That in the case of a plant much modified by gardeners in recent times such a history would be highly unusual, Mr. Dyer will, I think, admit.

Doubting this account, and searching records of the early culture of the Cineraria for my own satisfaction, I found a good deal of miscellaneous information on the subject. The history is not yet quite complete; but as Mr. Dyer's account has now appeared in print, the following notes may be of use.

In the ordinary manuals (*e.g.* Burbidge, *Propagation* &c., 1877, p. 250) it is said that the florists' Cinerarias are *hybrids*, obtained by crossing and recrossing several species of *Cineraria* (or more strictly *Senecio*). As to the exact parentage, there is not entire certainty. Burbidge gives *C. cruenta, aurita* and *lanata* as the parents. Other writers mention *C. maderensis, multiflora, tussilaginis* and *populifolia* as having contributed (*cp. Jour. d'hort.* Gand, ii. 1846, p. 231). General statements of a like nature are made by many. For the account given by Mr. Dyer I find no authority except one, an article by Rolfe (*Gard. Chron.* 1888 (1), p. 653). Here *C. cruenta* is given as the sole parent, and a figure of this species raised at Kew, from wild seed, is shown beside two extreme flowers of the modern type. Excepting this statement, it seems agreed that the species originally concerned are at least four: *cruenta, aurita, populifolia* and *lanata*. The first three have comparatively small flowers in corymbs or cymes. Those of *cruenta*, introduced from Canary by Masson to Kew in 1777, are purple. This species was originally described from Teneriffe by L'Héritier, *Sert. Angl.* 1788, pl. 33, and is figured *Bot. Mag.* t. 406, and elsewhere. The lower surface of the leaves is purplish. The petioles have auricular expansions. *C. aurita*, sent to Kew from Madeira 1790, figured by L'Héritier, pl. 31, and *Bot. Mag.* t. 1786, is a somewhat different plant, of more slender habit, said to be more akin to *populifolia*. The flowers are purple. Ray-florets few and irregular. Petiolar expansions variable, mostly much smaller than in *cruenta*. *C. populifolia* L. Hér., Canaries, brought by Masson from Teneriffe 1780, is a form with yellow flowers. *C. lanata*, L'Hér. pl. 30, and *Bot. Mag.* t. 53, is a plant very different from any of the others. It bears large purple flowers, some two inches across, only one to a peduncle. The leaves are cordate-subrotund and sept-angular, and woolly underneath. L'Héritier gives it as from Teneriffe. The *Bot. Mag.* wrongly says it had been introduced from Africa (perhaps confusing with *lanosa*, DC. = *lanata* Thunb.). The large flowers and peculiar leaves at once distinguish this species from the rest.

It should be added that *populifolia* in its native state showed considerable diversity in the forms of its leaves, three varieties being specified by Decandolle, *Prodr.* vi. p. 409. A natural variety of the same species with *white* flowers was brought from Teneriffe by Webb. This is the β. *leucanthus* DC. It is figured in *Flor. Cab.* i. p. 73, from a specimen grown in Birmingham Botanic Garden. As to these species, references to further information may be found in Decandolle, *Prodr.*, and in Webb, *Phytogr. Canar.*, &c.

These four species with others were at the beginning of this century pretty generally distributed in greenhouses in England, France, and Germany. They are enumerated in most of the horticultural treatises of the period, with directions for their propagation. *C. lanata* was thought the best. "It far exceeds all others cultivated here in the beauty of its flowers. . . . It is valuable on account of its hardiness, its readiness to flower, and the facility with which it may be propagated." Rees' *Cycl. of Arts and Sci.* viii. 1819. Others speak to like effect.

The first mention I have found of any distinct garden form is that of Willdenow, who in "Enum. Pl. Berol." 1809, p. 893, gives *C. hybrida*, saying that this plant is grown in gardens under the name of *C. cruenta*, but that it in reality differs much from the latter, and has flowers almost like those of *C. lanata*.

Between 1820 and 1830 definite efforts were made to improve the Cineraria. The first published is that of Bouché. Writing in the "Verh. zur Beförd. d. Gartenbauer, Berl.," i. 1824, p. 139, he says that having grown *C. lanata* L'Hér., *C. cruenta* L'Hér., and *C. hybrida* Willd., and noticed that the first two seeded freely, it occurred to him to try to raise varieties or sports (*Spielarten*), and at the same time to test the distinctness of these species. His seedlings flowered in the following year. Those from *C. cruenta* had the flowers rose-red, except one which was quite white, the flowers of the parent being dark red. The seedlings from *C. hybrida* varied so much that they might be mistaken for separate species. His words are as follows:—"Unter denen von der Cin. hybrida zeichneten sich besonders fünf Abänderungen aus, welche eine ganz eigenthümliches Ansehen bekommen haben, und leicht von Botanikern, denen die Entstehungsart derselben nicht bekannt ist, für neue, noch unbeschriebene Arten dieser Gattung gehalten werden könnten." His description follows. In particular, the foliage had varied greatly from the parent form, somewhat resembling *lanata*, suggesting to Bouché that there may have been hybridisation with that species.

About the same time Mr. Drummond, then Curator of the Botanic Garden, Cork, published a paper in the *Gard. Mag.* ii. 1827, p. 153. He says that Cinerarias are favourites with him, especially *cruenta*, "for besides the great beauty and variety in the flowers, its fine purple blossoms form a beautiful contrast, &c." "We seldom see it cultivated to the extent it merits. The following account of the method I have followed for some years of growing this plant. . . may turn the attention of your readers to the cultivation of the *C. cruenta*, the effects of which *will, in all probability, be the production of fine double and single varieties of different colours, as it sports greatly from seed.* [Italics are mine.] Except in cases when it becomes desirable to preserve any particular variety for its superior beauty, I prefer raising the *C. cruenta* from seeds. . . . Care should be taken to select the finest varieties, and those that produce the largest and finest heads or corymbs of flowers." "The other greenhouse species I cultivate are *lanata, hybrida, geifolia* and *amelloides*. These I increase by cuttings, &c."

It happens that in the same year (1827) of the *Gard. Mag.* p. 446, there is a reference to Bouché's paper. Not improbably Drummond may have read the latter, for in Loudon's *Ladies' Mag. of Gard.* 1842, p. 111, I find this passage: "Most of the purple Cinerarias are varieties or hybrids of *C. cruenta*. . . . It was long a favourite in greenhouses, and was generally propagated by dividing the roots; but about 1827, Mr. Drummond, Curator of the Botanic Garden in Cork, having raised it from seed, and found the seedlings vary considerably, conceived the idea of hybridising it with *C. lanata, C. geifolia* and *C. amelloides*. The trials, however, with *C. geifolia* [a true Cape Cineraria] and *C.* [*Agathæa*] *amelloides* do not appear to have succeeded; but between *C. cruenta* and *C. lanata* some handsome hybrids were raised. Since that time numerous experiments have been made and hybrids have been raised, &c." A summary follows.

Soon after this a number of definite seedlings or "sports" came into existence. Of some of these there are good records. I will mention four which are represented by good coloured plates. *C. waterhousiana* is said to have been a hybrid, the result of the seed of *C. tussilaginis*, fertilised by the pollen of *cruenta* (*Paxton's Mag. of Bot.* iv. 1838, p. 43, and *Ladies' Mag. l.c.*). In general appearance it rather resembled *tussilaginis* (one of L'Héritier's species which had died out, and was introduced again in 1832 by Webb. See *Bot. Mag.* t. 3215.) This must have been a very fine plant. It had large *red* flowers, about two and a half inches across, with long narrow ray-florets something like *lanata*.

The next case I shall take is a plant which first flowered in a garden near Belfast, called var. *cyanophthalmus* in *Bot. Mag.* 1840, t. 3827. It had long white rays and a *blue* disc. Sir W. J. Hooker says of it: "Notwithstanding the very unusual colour of the flowers for one of the Compositæ, I have little hesitation in referring it to . . . the old *C. lanata* of our gardens. The foliage is the same, and the structure of the flowers; but the colour of the blossoms is very different, and in our variety of a most unusual character." He then recalls Decandolle's well-known remark that *yellow* in Compositæ may vary to red or white, but not to blue, and, on the other hand, that *blue* may vary to red or white, but never into yellow. He adds: "Not only in our plant is the lilac-coloured ray of the flower changed to white, and the deep lilac or blood-red purple of the ray [disc] changed to a very bright blue, but the stigmas, which are deep orange in the original stock, are also intensely blue, and the anthers are purple-black."

Another seedling of a very different type, famous in its day, was *webberiana*. It was figured in *Paxt. Mag. Bot.* ix. 1842, p. 125. The flowers were of a deep blue, the rays being short and wide, compared to those of *waterhousiana*, for example. "It was raised from seed ripened promiscuously on a number of plants of various kinds blooming together, &c." In the *Gard. Chron.* 1842, it was advertised at 10*s.* 6*d.* a plant.

Another sport, pinkish and white, is figured in the *Botanist*, v. 1841, No. 215. "It came up accidentally, some years ago, from self-sown seeds, in one of the pots of the greenhouse, so that I cannot say anything certain about its parentage." The writer conjectures it to be a hybrid between *lanata* and *populifolia*, var. *leucanthus*.

If any one will look at the plates to which I have referred, he may satisfy himself of the astonishing diversity of these forms. In *Gard. Mag.* 1839, p. 430, is an early record of the appearance of the new seedlings at shows. At the Caledonian Horticultural Show, the Cinerarias "were very brilliant, and partook of novelty." The names of the seedlings successful, including *waterhousiana*, are given. At the beginning of the forties the named kinds became very numerous, and were at first offered at high prices in the trade advertisements. Henderson and Ivery were the two chief English cultivators at that time.

During this period, 1830–1840, the progress was very rapid, and there can be no doubt that the florists' Cinerarias came into existence within some ten or twelve years. Such a plate as that in *Jour. d'hort.* Gand, 1846, shows the ordinary kinds much as we know them. From those plants up to the perfected plants of ten years ago, the change was undoubtedly slow and gradual. The alterations have consisted chiefly in increase in size and symmetry of the flower, and in promotion of compactness of habit (see, *e.g.*, Glenny, *Ann. of Hort.* 1850, p. 37, also *Gard. Chron.* 1879 (1), p. 532).

The next point is of some interest. As compared with other "improved" herbaceous plants, the Cineraria is a little peculiar in the fact that it is now generally raised from seed. This is done partly to ensure that the plants shall not be overgrown, and partly to avoid green fly, a pest to which these plants are specially liable. In consequence of this, the old "named" kinds, that is to say, kinds propagated by asexual methods, went out of fashion, though till lately they still had supporters. It was found that seeds of good strains could be fairly relied on —not, of course, to reproduce the form of their particular parents, but to give fine plants. For instance, Henderson, *Scot. Gard.* i. 1852, p. 22, says: "in raising seedlings you should select three or four dwarf varieties, which number is quite sufficient to produce all the different colours." In *Gard. Chron.* 1887 (1), p. 549, are some interesting particulars of the methods used by Mr. James, to whom the later improvement of the plant in England is largely due. The plants of each colour are grouped in blocks, and the bees are freely admitted to the houses. It is not found necessary to separate the plants further, and in saving seed all the colours are mixed together. In the case of the Cineraria therefore, as in that of Calceolarias, Begonias, and other plants much grown from seed, it is desirable not only to create a fine variety of which the stock can at once be multiplied asexually, but also to raise a good strain of which the seedlings come fairly true. The latter process may undoubtedly often take time.

Even in recent times a "sport" has been recorded. In *Gard. Chron.* 1880 (1), p. 277, it is stated that Mr. James "has succeeded in obtaining a new 'break' that promises to be the forerunner of another host of new flowers. The colours of the flower do not shade off into one another, as is usually the case, but are arranged in bold and well-defined belts. . . . We understand that it flowered for the first time last season, and that it has reproduced itself from seed." A figure is given.

To these particulars might be added many more, relating to the origin of double varieties, variations in the foliage, and other matters. The foregoing notes of the history must, I think be taken to show (1) that the modern Cinerarias arose as hybrids derived from several very distinct species; (2) that the hybrid seedlings were from the first highly variable; (3) that "sports" of an extreme kind appeared after hybridisation in the early years of the "improvement" of these plants; (4) that the subsequent perfection of the form, size and habit has proceeded by a slow process of selection. Mr. Dyer's statement that the modern Cinerarias have been evolved from the wild *C. cruenta* "by the gradual accumulation of small variations" is therefore, in my judgment, misleading, for this statement neglects two chief factors in the evolution of the Cineraria, namely, hybridisation and subsequent "sporting."

I have ventured to deal with this case because it seems to be generally supposed by those not acquainted with the facts, that the origin of the modern florists' flowers has in general been very gradual. As a matter of fact it would, I believe, be more true to say that the new departures have in general been at first very rapid, subsequent improvement being commonly slow. "Sporting," usually after hybridisation, has been the chief factor in the production of these new developments, just as in the case of the Cineraria. To speak of no more, I may refer to the new forms of Begonia, of Gladiolus, and of Erica now so familiar. With what special propriety the Cineraria was chosen by Mr. Dyer to support his contention is not evident to me.

Whether any of these sports exhibit the phenomenon of organic stability I cannot now discuss. W. BATESON.

St. John's College, Cambridge, April 17.

The Age of the Earth.

IN Dr. Hobson's letter on this subject, he confuses the argument by the introduction of a new factor (never alluded to in the former discussion, or in my theory as stated in "Island Life"), the *bulk* or *volume* of the matter deposited. This has nothing whatever to do with the practical problem, because it is admittedly impossible to form *any* estimate of the total bulk of all the stratified rocks of the earth during all geological time; while it is equally impossible to form any estimate of the total bulk of the denuded matter, since we have no clue whatever to the number of times the same areas have been again and again denuded. But the maximum *thickness* of the same rocks, compared with the average *rate* of denudation, and the coincident maximum *rate* of deposition, *do* furnish materials for an estimate, since they can all be approximately determined from actual observation; and the result is what I have given. If Dr. Hobson had referred to the former discussion he would have avoided imputing to me "fallacies" which I never made. I never said a word about "equal bulks" of material being deposited in less time than they were denuded. But, as the only available data are those of *thickness*, not bulk, then it is clear that, if the area of deposition is one-nineteenth of the area of denudation, the *rate* of deposition of a known *thickness* of rocks will be nineteen times as great as the known *rate* of denudation. It was necessary for me to point this out when first discussing the subject, because one eminent writer had made the rate of deposition *less* than the rate of denudation, because the water-area is greater than the land-area of the globe; while an eminent geologist has quite recently taken the rates of denudation and deposition as being *equal*. If, however, the area of deposition is very much *less* than the area of denudation, which is now admitted to be the fact, then the *rate* of deposition *per foot of thickness* will be many times *greater* than the *rate* of denudation.

I should not have thought it necessary again to state this very obvious conclusion, had not Prof. Sollas, while so clearly pointing out Dr. Hobson's misconception as to the area over which the maximum thickness of the strata extended, omitted to refer to the confusion he has now for the first time introduced into the problem, by references to the *bulk* or *volume* of the sedimentary rocks, a factor which all previous writers have seen to be wholly beyond even an approximate determination.

ALFRED R. WALLACE.

So little is really known about the earth's age that any additional mode of approximating to it, however rough, may possess some value. The following method of finding a lower limit is, with one or two alterations, the same as that given in a paper in the *Geological Magazine* for 1887 (p. 348). It depends, not on the rate of denudation, but on the rate of subsidence within the area of sedimentation.

Part of the sediment brought down by a river is used for keeping the surface of the delta close to the level of the sea; and the fact that the deposits formed from it are generally shallow-water deposits, shows that the amount of sediment is, as a rule, sufficient or more than sufficient for the purpose. The remainder of the sediment is carried out seawards, and enlarges the delta laterally.

If there were no surplus sediment, it is evident that the mean rate of subsidence over the delta would be obtained by dividing the volume of the sediment brought down annually by the river by the area of the delta. But if there be an excess of sediment, then the same quotient will give a value greater than the mean rate of subsidence, for only part of the sediment is used for keeping the delta-surface in shallow water. In the case of the Mississippi, the amount of sediment brought down annually is 7,459,267,200 cubic feet, and the area of the delta 12,300 square miles, or 342,204,320,000 square feet; so that the mean rate of subsidence is not greater than $\frac{1}{46}$ of a foot per year, or 2·18 feet per century.

Prof. Sollas estimates the total maximum thickness of the different layers of sediment since the beginning of Cambrian times at 164,000 feet (NATURE, vol. li. p. 534). If these layers tapered off uniformly in either direction from the region of maximum deposit, the total mean thickness would be half this, or 82,000 feet; and if the mean rate of subsidence were never greater than 2·18 feet per century, the total time required for the accumulation of Cambrian and post-Cambrian rocks would be not less than 3¾ millions of years. But there may have been long unknown gaps in the process of their accumulation; the outer margin of the deposits may have extended far beyond the area of subsidence, and the mean rate of subsidence may have been at all times considerably less than the upper limit given above. On these accounts, as well as on others that might be mentioned, it seems possible that much more than 3¾ million years has elapsed since the beginning of the Cambrian period.

Birmingham, April 8. C. DAVISON.

The Burmese Chipped Flints Pliocene not Miocene.

IN the *Geological Magazine* for November of last year, p. 525, is a review by Prof. T. Rupert Jones, of the important paper, published in the *Records of the Geological Survey of India*, by Dr. Fritz Noetling, the Palæontologist of the Survey, "On the occurrence of Chipped (?) Flints in the Upper Miocene of Burma." Another paper, by Prof. T. R. Jones, on "Miocene Man in India," appeared in *Natural Science* for the same month.

From the fact that the mammals *Rhinoceros perimensis* and *Hipparion antelopinum*, of which bones were found associated with the flint chips, have only been found in India in Pliocene beds, and from a slight acquaintance, gained, it is true, more than thirty years ago, with the Burmese strata in which Dr. Noetling's most interesting discovery was made, I felt assured that there must be some error in believing that the flint chips occurred in Miocene deposits, and I wrote to Dr. Noetling on the subject. I have just heard from him in reply. In a letter from Upper Burma of March 11, he tells me he has now definitely ascertained that the bed containing the chipped flints is Pliocene.

Further particulars will, I hope, be published before long by Dr. Noetling; and I should not have written on the subject but that a serious error is caused by its being supposed that "Miocene Man" has been shown to have existed in India, and it is desirable that this error should be corrected without delay. The importance of the discovery is in no way diminished by the correction of the geological date to which the flint-bearing stratum is referred. W. T. BLANFORD.

April 17.

The Mandrake.

WITH regard to Prof. Veth's exhaustive account of the mandrake (referred to in NATURE of April 11, p. 573), it may be useful to students of folklore to call their attention to the occurrence in the Chinese literature of a similar superstition, wherein *Phytolacca acinosa* (Shang-luh) takes the place of *Mandragora officinarum*. Sie Tsai-Kang's "Wu-tsah-tsu," written about 1610 (Japanese edition, 1661, tome x. p. 41), contains the following passage:—"The Shang-luh grows on the ground beneath which dead man lies; hence its root is mostly shaped like a man.[1] . . . In a calm night when nobody is about, the collector, offering the owl's flesh roasted with oil, propitiates the spirit of the plant until *ignes fatui* crowd about the latter; then the root is dug out, brought home and prepared with magic paper for a week; thus it is made capable of speech. This plant is surnamed 'Ye-hu' (*i.e.* Night Cry) on account of its demoniacal nature.[2] There are two varieties of it: the white one is used for medicine; the red one commands evil spirits, and kills men when it is internally taken by error." KUMAGUSU MINAKATA.

April 16.

[1] Here the author says: "It is popularly called 'Chang-liu-Kan' (= Witch-tree-root)." The name shows that the root was used in witchcraft, similarly with that of the Mandragora (*cf.* Hone, "The Year-Book," *sub.* "December 28").

[2] Another explanation suggested for this name is that, as long as the fruit of the Phytolacca remains unripe, the cuckoo continues to cry every night (Sie Tsai-Kang, *ubi supr.*). However, seeing that the belief in the shrieks of the Mandragora was once current among the Europeans ("Encyclopædia Britannica," 9th ed. vol. xv. p. 476), it would be more just to derive the Chinese name "Night Cry" from an analogous origin.

A Claim for Priority.

I SEND you, under separate cover, a copy of an address, "Radiant Matter," &c., delivered at the International Electrical Exhibition, held in Philadelphia in 1884, reprinted from the *Journal* of the Franklin Institute, September 1885, and would call your attention to the description of the method of preparing films of gold and other metals of extreme thinness, far exceeding in tenuity those described in NATURE as novelties in metallurgical methods (prepared in identically the same manner), and exhibited at a conversazione of the Royal Society, June 13, 1894. The first published note regarding this subject may be found in the *Proceedings* of the American Phil. Soc., vol. xcix. February 16, 1877. Later and fuller notices will be found in *Journ. Franklin Institute*, April 1877, June 1877, September 1885, and September 1894. In addition to the above, the process was fully described in *U.S. Patent*, 198, 209, December 18, 1877. ALEX. E. OUTERBRIDGE.

Philadelphia, April 5.

AN IMPROVED METHOD FOR THE MICROSCOPIC INVESTIGATION OF CRYSTALS.

A MEMOIR of considerable importance to all who are interested in the microscopic determination of the characters of crystals, is contributed by Prof. Klein to the *Sitzungsberichte* of the Berlin *Akademie der Wissenschaften* for January 31, 1895. The two essential points of the communication are that a form of stage goniometer is described, which permits of the most complete examination of many of the principal zones of the crystal with one and the same setting of the crystal upon its holder, and that the crystal is immersed during the observations in a liquid whose refractive index is about the mean of the refractive indices of the crystal. The idea of the "Universaldrehapparat," as the new stage goniometer is termed, appears to have suggested itself almost simultaneously to Prof. Klein and to Herr von Federow, for the former described an earlier form of it in the *Sitzungsberichte* of April 1891, while the latter published a description of an "Universaltischen" for the microscope in the *Zeitschrift für Krystallographie* of May in the same year. Herr von Federow had previously contributed to the *Zeitschrift* a remarkable memoir concerning a theodolitic universal goniometer, and the application of the principle of that instrument to the microscope goniometer followed naturally therefrom. The present memoir of Prof. Klein affords so admirable a description of the improved instrument, which has been constructed for him by the well-known Berlin crystallographical optician, Herr Fuess, and likewise of the mode of employing it in connection with the immersion method, that readers of NATURE may find a brief account of it not uninteresting. Unfortunately this description cannot well be illustrated, as Prof. Klein's illustrations are photographic reproductions which are unsuitable for further reproduction.

The microscope should of course be one of the petrological type, fitted with the usual accessories for the examination of crystals in parallel and convergent polarised light. The particular instrument constructed for Prof. Klein is somewhat similar to the largest Fuess model. It is so arranged with respect to the centre of gravity that it can be rotated into the horizontal position whenever desired, a point of some importance with regard to the use of an immersion liquid. The stage is of course circular, and is divided so as to read with the aid of a pair of verniers to single minutes; it is further provided above with two graduated rectangular traversing movements, one of which is supplied with a micrometer registering 0·01 m.m., while the other is capable of much more rapid motion. The advantages of the simultaneous rotation of the polarising and analysing nicols, as adopted in the microscopes made by Mr. Swift under the direction of Mr. Allan Dick, have been so well appreciated by

Prof. Klein, that this has been arranged for in the new Fuess instrument. The carriers of the nicols are each furnished with a toothed flange capable of gearing with a smaller pinion, and the two pinions are arranged at the ends of a connecting rod furnished at a convenient height near the upper pinion with a milled flange by means of which rotation can be effected. Provision is made for the lengthening of the connecting rod when the focussing of the microscope by the rack and pinion or by the fine adjustment is effected, and care is also taken that the rotation by means of the connecting rod shall occur without dead-space or backlash. Prof. Klein sta tes that some important details in connection with improvements in the mode of carrying out this simultaneous movement of polariser and analyser will shortly be published by Herr Fuess. Provision has likewise been made for correcting at any time the setting of the nicols in their carriers, experience having shown that the setting invariably alters slightly in course of time. In addition to the eyepiece nicol capable of being connected with the polariser in the manner just described, there is likewise provided the usual nicol capable of sliding in or out of the microscope tube just over the objective. Above this, and just below the eyepiece, a Bertrand lens for observing interference figures in convergent light is capable of sliding in and out of the tube, and is intended to be employed in conjunction with a converging system of lenses capable of being carried in a tube attachment beneath the level of the stage. The remaining details of the microscope are the same as are usually supplied with the No. 1 Fuess instrument.

The stage goniometer is intended to be employed with the microscope arranged horizontally, as it is found inconvenient to employ an immersion liquid with a vertical arrangement. The base-plate of the goniometer, consisting of a stout metal plate with fairly large central aperture, is fixed by a suitable clamping arrangement upon the now vertical stage of the microscope. The plate is continued into a short arm on that side which is uppermost when fixed in position, and this arm carries near its end, and at right angles to it (horizontal when in position), a projecting piece terminating in the supporting cone for the goniometer circle, and which also carries the vernier reading to five minutes and the fine adjustment. The circle is hollowed in its upper central part, and perforated with a central aperture; this permits of the sliding movement within the hollow, for centering purposes, of a disc which carries the axis of the instrument. To the lower end of this short axis are attached the movements for adjusting the crystal, and the lower of which carries the crystal. The adjusting movements are a pair of circular quadrants arranged at right angles to each other and graduated. They are simpler in construction, and lie much closer together than those of the best forms of goniometer now in use for ordinary goniometric and spectrometric work, and are therefore particularly suitable for use in connection with the microscope. The upper quadrant is fixed to the axis; over it a slider is capable of moving, which carries a vernier, and below it the lower quadrant, which in turn is fitted with a slider terminating in the holder which carries the crystal cemented by wax. The verniers enable readings of five minutes to be obtained, the same degree of accuracy as in the case of the circle.

The glass cell containing the immersion liquid is supported in position normal to the axis of the microscope by means of a stand with an adjustable arm placed to the left of the microscope. It is recommended to have a series of cells, ready for filling with various media of the most frequently required refractive power. The advantages of Adams' method of determining optic axial angles may also be combined with those of the method now described, by use of a cell consisting of an upper cylindrical portion terminating below in a sphere filled with the liquid. As regards suitable liquids, an admirable list is given by Herr Pulfrich in his book descriptive of the construction and use of the total-reflectometer recently devised by him (p. 64). Two errors in that list, however, are corrected by Prof. Klein; he has been unable to prepare the solution of mercuric iodide in aniline and quinoline of refractive index 2·2, and the refractive index of the phenyl sulphide kindly supplied by Prof. Klein's colleague, Prof. Emil Fischer, is only 1·56 instead of 1·95. If the dangerously poisonous and inflammable liquids are excluded, the list consists chiefly of oils, the well-known Thoulet solution, monobromnaphthalene, and methylene iodide. The solution of iodine in the latter frequently renders it insufficiently transparent for the purpose.

The determination of the true angle, 2V, between the optic axes within the crystal, supposing it to be biaxial, can at once be determined with the aid of the new apparatus, by immersing the crystal in a liquid whose refractive index is equal to the β (the intermediate) refractive index of the crystal. The condensing system of lenses is first inserted between the polarising nicol and the stage, and the Bertrand lens above the analyser; as objective, either the ordinary wide angle combination usually employed for convergent light work, or a specially constructed one supplied for the particular purpose of convergent light observations through an immersion liquid, is employed. This objective is so constituted that as large a field of vision as possible is afforded, while the distance between objective and crystal is considerably greater than with the ordinary systems in use. The apparent angle of the optic axes in air, 2E, may first be measured, if desired, after adjustment of the crystal by means of the adjusting movements, by bringing the hyperbolic brushes to the cross wire of the microscope eyepiece in the usual manner. The immersion cell not being in position while this is being achieved, the objective can be approached nearer to the crystal and one of the ordinary forms of convergent light objective employed, which affords a larger angle of vision, reserving the special objective for the determination of the true angle of the optic axes. If, however, the Adams spherical cell is employed, there is no necessity even here to use the special objective, as the older wide angle form serves admirably. With the parallel sided cells it is preferable to use the special objective. The Adams sphere is not supported similarly to the rectangular cells, but is conveniently held by its cylindrical neck in a small support directly attached to the lower quadrant of the adjusting apparatus. The measurement of the true angle of the optic axes is then carried out in the usual manner, similarly to the determination of the apparent angle in air, while the crystal is immersed in the liquid contained in one or other of the two forms of cell. Monochromatic light should of course be used in making the observations, a sodium flame some little distance in front of the polariser being employed by Prof. Klein.

The great advantage of this method of determining the true inner angle between the optic axes lies in the fact that it is totally unnecessary to prepare section-plates of the crystal, the whole crystal itself being employed, and thus material saved. Prof. Klein does not claim for it the highest attainable accuracy, and for the class of work such as that with which the writer of this article has become identified, the determination of the crystallographic characters of series of isomorphous compounds closely resembling each other, where every endeavour must be made to attain the upper limits of experimental accuracy, such a method is of course inadequate. But for the ordinary description of minerals and the crystals of isolated chemical preparations unlikely to be injured by the immersion liquid, and particularly for laboratory teaching, the method is one of the simplest and most interesting yet described. The accuracy depends entirely upon the closeness of the approximation of the refractive index of the liquid to the β index of the crystal. Of course it will rarely happen that coincidence of these values will occur for all colours of the light employed, the dispersion of the crystal and the liquid in general being different. So that although the values may be coincident for sodium light, they would in all probability be different for other colours. But if the observations are only conducted for sodium light, a process which is frequently sufficient for the purpose in view, then this objection entirely disappears. Moreover, the errors introduced by the discrepancy for different wave-lengths of light would not be sufficiently large in most cases, if observations for other colours were made, to materially reduce the value of the method for the purposes for which it was designed.

A consideration of the simple formulæ connecting the optic axial angle with the β refractive index and the refractive index of an immersion liquid will at once render the value of the method, within the above specified limits, clear. Representing as usual the real semi-acute angle between the optic axes within the crystal by Va, the semi-obtuse angle by Vo, and the apparent semi-acute and obtuse angles in the immersion liquid by Ha and Ho respectively, the refractive index of the medium for light of the same wave-length being n, then:

$$\text{Sin Va} = \frac{n}{\beta}\text{ sin Ha and sin Vo} = \frac{n}{\beta}\text{ sin Ho.}$$

These two equations are of the same kind, for both Va and Vo are less than 90°; and the only variables are n sin Ha and n sin Ho, for β, sin Va, and sin Vo are constant quantities for this wave-length of light. If, now, the sum of the angles 2Ha and 2Ho is greater than 180°, the common factor n must, in order to bring the sum of these angles down equal to 180°, be increased, that is, a liquid of higher refractive power be employed. Conversely if the sum is less than 180° the refractive power of the liquid must be diminished in order to bring the sum of the angles up to 180°. For the specially interesting intermediate case where $n = \beta$, the sum of 2Ha and 2Ho will be exactly 180°, and sin Va = sin Ha and sin Vo = sin Ho, when also Va = Ha and Vo = Ho.

From the above theoretical considerations one can immediately deduce the course to be taken to render the immersion liquid exactly equal to the β index of the crystal; if the measured values of 2Ha and 2Ho add up to over 180° a liquid of higher refraction must be obtained, and *vice versa* if the sum is less than 180°. There are, however, several ways of determining the closeness of approximation of the indices without going to the trouble of actually making preliminary measurements. In the first place the crystal will disappear in the liquid, that is to say, will be invisible, provided that it is colourless, when its refractive power is equal to that of the surrounding medium, especially when the line of the observer's vision lies in the plane of the optic axes. This is very beautifully observed when calcite is immersed in monobromnaphthaline, and particularly when it is arranged so that the observer looks along the direction of the vertical axis of the crystal; under these conditions the latter is completely invisible. In the second place, instead of hyperbolic curves passing through the positions occupied by the optic axes, the brushes will take the form of almost straight lines when the refraction of crystal and liquid is about the same.

In choosing crystals for observation by the new method, Prof. Klein recommends that individuals or fragments should be selected which are equally thick in two perpendicular directions in the plane of the optic axes, that is, such as are almost cylindrical in appearance, and not too thick to prevent the interference figures being observed. When immersed in the liquid, it is as if at each moment, and for every position during rotation of the crystal, a parallel section-plate were being examined, the natural faces of the crystal—however rich in faces the zone may be—not entering into consideration whatever.

The advantages of the use of an immersion liquid of equal refractive power in the examination of crystals have been pointed out by several previous observers, as Prof. Klein is careful to state. So long ago as 1841 Biot, in his memoir concerning lamellar polarisation, describes the use he made of it. The method has long remained dormant, however, as far as is known from the literature of this branch of study. In the eighth edition, however, of the *Lehrbuch der Physik und Meteorologie* of Joh. Müller, edited by L. Pfaundler in 1879, it is stated that if the refractive index of the liquid in which a plate perpendicular to one of the medium lines is immersed is equal to that of the crystal, the true angle between the optic axes is at once afforded. Latterly, however, the evident advantages of the method have suggested themselves to several crystallographers. M. Fouqué mentions it in his memoir in the *Bulletin* of the French Mineralogical Society of 1894 on the felspars.

The writer of this article has frequently made use of the method for certain specific purposes, and it may be of use to other workers to give a brief indication of one or two modes of extending its sphere of usefulness not touched upon by Prof. Klein. In the course of the investigation of the normal sulphates of potassium, rubidium, and cæsium, the results of which were laid before the Chemical Society last year (*Journ. Chem. Soc.* 1894, 628, and *Zeitschrift für Krystallographie*, 1894, xxiv. 1), a difficulty was found in determining the true optic axial angle of rubidium sulphate by means of the very accurately orientated section-plates prepared by use of the new grinding goniometer described to the Royal Society (*Phil. Trans.* 1894, Series A, 887) earlier in the same year. The difficulty, which is one not uncommonly met with, was owing to the fact that the extremely low double refraction, necessitating the use of very thick section-plates, combined with the slight separation of the optic axes, rendered it impossible to measure the obtuse angle in monobromnaphthaline, and so to calculate the true angle by means of the formula $\tan \text{Va} = \frac{\text{Sin Ha}}{\text{Sin Ho}}$. The difficulty was surmounted, as fully described in the memoir referred to, by measuring the acute angle by means of section-plates perpendicular to the first median line immersed successively in two liquids, benzene and cedar oil, whose refractive indices were nearly, and the mean of them exactly, equal to the mean refractive index of rubidium sulphate. The two series of values obtained for six wave-lengths of light (the monochromatic light producer recently described by the writer, *Phil. Trans.* 1894, Series A, 913, being employed) were almost identical, differing only by a very few minutes, and the mean for each wave-length was taken as representing the true angle of separation of the optic axes for that particular wave-length. The method is applicable to all cases where it is found impossible to see the hyperbolic brushes through a section perpendicular to the second median line on account of the slight separation of the optic axes. The suggestion to employ it was made to the writer by Mr. Miers, of the British Museum, who has had a goniometer constructed for the express purpose of studying the use of an immersion liquid.

Another case in which observations in such a liquid are of great value is when it is found desirable to confirm, in some independent manner, the mode of dispersion of the optic axes for different colours indicated by the calculated values of 2Va obtained from the formula last quoted. Several of the compounds which the writer has lately been engaged in studying exhibit very low dispersion of the optic axes, and the calculated values of

2Va for five wave-lengths, obtained from the measurements of the apparent acute and obtuse angles in monobromnaphthalene by the use of accurately orientated section-plates, are so close together that it was considered advisable to ascertain in some other manner whether the order of dispersion was truly represented; that is, whether the angle for one end of the spectrum was really very slightly greater than that for the other end, or whether the amount of dispersion thus indicated did not really fall within the limits of experimental error, thus leaving it possible that the dispersion might even be of the contrary order. By immersing a plate perpendicular to the first median line in a liquid of refractive power equal to the medium refractive index of the crystal, the interference figure in white light usually at once indicates, by the colours exhibited on the margins of the axial brushes, the order of dispersion, and measurements of the axial angle for the two extreme wave-lengths afford an immediate check upon the accuracy of the calculated angles. It is a considerable source of satisfaction to be able to confirm such calculated optic axial angles in so simple a manner.

Prof. Klein further describes how admirably the new apparatus is adapted for the determination of the extinction angles upon the various faces of a zone, in parallel polarised light. For this purpose the converging lenses are removed, and the eyepiece analysing nicol is employed, so that the polarising and analysing nicols may be arranged for simultaneous rotation. The measurements are carried out while the crystal is immersed in the liquid as in case of the determinations of optic axial angle. The only precaution necessary is that the crystal should be uniformly illuminated in order that the exact position of extinction may be ascertained by use of one of the usual half-shadow stauroscopic plates.

The memoir concludes with a description of the general mode of investigating a biaxial crystal immersed in a liquid of equal refractive power, indicating how the principal planes of optical elasticity may be found, the positions of the optic axes ascertained, and the true internal angle of the latter measured. One of the most important advantages of the method is the simplification which it introduces into the study of triclinic crystals, hitherto almost dreaded by the crystallographer for the trouble they involve. It would appear that their optical investigation by the immersion method offers but slightly more difficulty than that of crystals of higher symmetry, the positions of the optic axes being readily found, and the true angle at once afforded. This alone would entitle Prof. Klein to the thanks of crystallographers and mineralogists for perfecting so admirable an aid to investigation.

A. E. TUTTON.

MICROBES AND METALS.

THE effect of metals on the growth of bacteria has been examined by Miller, Behring, and others, and another contribution to this subject has lately been published by Dr. Meade Bolton, in the December number of the *International Medical Magazine*. According to Uffelmann, who smeared the surface of copper coins with liquefied jelly-cultures of cholera bacilli, the latter were destroyed in seventeen minutes; whilst on a brass coin they were alive after thirty hours, but dead after sixty hours. Bolton employed Miller's method of inoculating a tube of melted jelly with particular microbes, and pouring the contents out on a sterilised glass-plate, after which bits of the metal under examination were laid on the jelly whilst it was still soft. If the metal has an inhibitory action on the microbes, then a clear zone is left around the metal after the colonies have developed in the other parts of the jelly. The width of this zone, Dr. Bolton found, varied very considerably with different organisms, as well as with different metals. Thus carefully purified bits of silver produced in the case of cholera bacilli a clear zone 5 millimetres broad, in the case of typhoid bacilli a zone of about 1 millimetre, whilst with the closely allied colon bacillus a zone of about 5 millimetres was produced. In the case of purified gold, no inhibition was observed with the staphylococcus pyogenes aureus, colon bacillus, typhoid bacillus, or cholera bacillus. Freshly "glowed gold" had invariably no inhibitory action; and in the few cases where inhibition was observed, the gold had not been glowed for several weeks. Pure nickel, platinum wire, and platinum black aluminium, silicon, and niobium, again, also failed to give any reaction with most of the microbes examined. Throughout the investigations it was found that those metals that are resistant towards chemical reagents in general, failed to produce any effect on microbes; whilst, on the other hand, those metals which are readily attacked by chemical reagents, all exhibited a marked inhibitory action upon the growth of bacteria. This result is probably due to a solution of the metal taking place in the medium. The length of time it is necessary to leave the metals in contact with the jelly, to produce an effect on the microbes present, was tried with brass, copper, cadmium, and zinc, on the staphylococcus pyogenes aureus. The metals were put on and removed at various intervals. When cadmium was left on for a minute, there was a clear space underneath where it had rested, which extended to 1 millimetre round; when it was left on for three or four minutes, the clear space usually extended over 3 millimetres. Very similar results were obtained with zinc. With brass no effect was produced when it was left on thirty-six minutes, but after this there was more and more marked inhibition up to fifty minutes; but to produce a clear space, it was necessary to leave it on for still longer. Copper produced no visible effect under thirty-six minutes, and fifty minutes was required to produce a clear space.

G. C. FRANKLAND.

PROFESSOR JAMES DWIGHT DANA.

BY the sudden death of Prof. J. D. Dana, from heart-failure, on April 15, America has lost a veteran man of science, who in his time has not only played many widely varied parts, but has reached the highest excellence in each. As a mineralogist he published, so long ago as 1837, the first edition of a "Descriptive Mineralogy," which by reason of its completeness and accuracy soon became a standard work of reference throughout the civilised world, and of which the sixth edition (1134 pages), issued in 1892 under the superintendence of his distinguished son, Prof. Edward Salisbury Dana, still maintains the high reputation attained by the original work. As a geologist and palæontologist, he published in 1863 a similarly excellent and well-illustrated "Manual of Geology," having special regard to the geology of the North American continent, and of which the fourth edition (1087 pages) was issued only two or three months ago. Of his work as a zoologist, we may cite as example his elaborate report on the zoophytes, collected by an expedition in which he took a very active part. The report is illustrated by 61 plates, and in it are described no fewer than 230 new species. Attainments so diverse belong only to the few.

James Dwight Dana was born on February 12, 1813, at Utica, in the State of New York, U.S.A., and was therefore in his eighty-third year at the time of his death. He was educated at Yale College, New Haven, Connecticut, receiving there a sound training in mathematics, physics and chemistry, which was of the greatest service to him in his subsequent career; he proceeded to his degree in the year 1833. His appointment as Instructor of Mathematics to the midshipmen of the United States Navy gave him splendid opportunities for the study of nature in various parts of the world, particularly in France, Italy, and Turkey, opportunities of which he was not slow to avail himself; more especially was his attention attracted to the study of volcanic phenomena by an ascent of Vesuvius, a sight of Stromboli, and an excursion in the Island of Milo in the year 1834. Settling down for a short time, he acted as chemical assistant at Yale College to his old teacher and friend, Prof. Silliman (1836–38); but an opportunity again presenting itself of making a long voyage of marine observation, he accepted the appointment of mineralogist and geologist to the United States exploring expedition, which was to proceed round the world. This expedition, under Charles Wilkes as Commander, was admirably equipped for the objects in view, and consisted of two sloops-of-war, a store-ship, and a brig; the cruise extended over four years (1838–42), and the scientific staff included, in addition to Dana, Pickering, Couthoy, and Peale as zoologists, Rich and Breckenridge as botanists, and Hale as philologist. The memory of the events, scenes and labours of this cruise was a constant joy to him during the remaining fifty-three years of life. On at least two occasions, however, he was in imminent peril: at one time his vessel narrowly escaped destruction on the rocks of Southern Fuegia, when the sea was dashing up the cliffs to a height of two or three hundred feet, and all the anchors had given way; at another time his party had to take to the boats empty-handed, and some hours afterwards they saw the last vestige of the vessel which had been their home for three years disappear beneath the waves.

The study of the material collected by the expedition and the preparation of his reports occupied all the available time during the next thirteen years. The first two or three years were spent at Washington, but after his marriage to the daughter of Prof. Silliman he removed back to New Haven, where he passed the rest of his life. In 1850 he was appointed Silliman Professor of Geology and Natural History at Yale College. In 1846 Mr. Dana had become associate-editor of the *American Journal of Science*, and after the death of Prof. Silliman, in 1864, he became the principal editor of that important scientific organ.

Dana gave special attention to corals and coral islands, and also to volcanoes. The Wilkes expedition of 1838–42 followed in part the course taken by the *Beagle* in 1831–36, and even where it diverged from that route visited coral and volcanic islands such as have been carefully described by Charles Darwin. When the Wilkes expedition reached Sydney in 1839, Dana read in the papers a brief statement of Darwin's theory of the origin of the atoll and barrier forms of reefs; this mere paragraph was a great help to him in his later work, and he afterwards regarded Darwin with feelings of the deepest gratitude. A visit to the Fiji Islands in 1840 brought before him facts such as had been already noticed by Darwin elsewhere; but there they were on a still grander scale and of a more diversified character, thus enabling him to speak even more positively of the theory than Darwin himself had thought it philosophic to do. On other points the conclusions arrived at by Darwin and Dana, independently of each other, were for the most part the same, and differed only in comparatively unimportant details. Dana's special labours relative to corals ceased with the publication of his report on the zoophytes collected by the expedition, but an elaborate account (406 pages) of Corals and Coral Islands was prepared by him and issued in 1879: this was an extension of his expedition-report on Coral Reefs and Coral Islands, which had been separately published in 1853. In 1890 appeared another considerable work (399 pages) entitled "Characteristics of Volcanoes, with contributions of facts and principles from the Hawaiian Islands," which placed on record much useful information collected by him during his travels.

In addition to these larger works, he was the author of about two hundred separate papers. Some of them are of a physical character: his first paper, published as far back as 1833, dealing with the connection of electricity, heat and magnetism; subsequent papers treated of galvano-magnetic apparatus and the laws of cohesive attraction as exemplified by crystals. Other papers, of a purely crystallographic character (1835–52), treated of the drawing and lettering of crystal figures, of crystallographic symbols, and of the formation of twin growths; a series of volcanic papers discussed both lunar and terrestrial volcanoes, the latter including those of Vesuvius, Cotopaxi, Arequipa, Mauna Loa, and Kilauea (1835–68); a set of coral papers treated of the temperature limiting the distribution of corals, on the area of subsidence in the Pacific as indicated by the distribution of coral islands, on the composition of corals and on fossil corals (1843–74).

About forty papers are on mineralogical topics: many of them are descriptive of particular mineral species; others treat of general subjects, such as nomenclature, pseudomorphism, homœomorphism, the connection between crystalline form and chemical constitution, and the origin of the constituent and adventitious minerals of trap and the allied rocks. As illustrations of the variety met with in his geological publications, we may cite his papers on the origin of the grand outline features of the earth, the origin of continents, mountains and prairies, the early condition of the earth's surface, the analogies between the modern igneous rocks and the so-called primary formations, on erosion, on denudation in the Pacific, on terraces, on southern New England during the melting of the great glacier, on the degradation of the rocks of New South Wales, and the formation of valleys. The remaining papers, about seventy in number, deal with biological subjects, both recent and fossil, and have a similarly varied character; some being descriptive of species, others treating of classification and similarly general problems.

The importance of this scientific work was widely recognised, and many marks of distinction were conferred upon him, both at home and abroad. He was an original member of the National Academy of Sciences of the United States, and in the year 1854 occupied the presidential chair of the American Association for the Advancement of Science. In 1851 he was elected a Foreign Member of the Geological Society of London, and in 1872 received from that Society the Wollaston Medal, the highest compliment the Geological Society can pay to the man of science; in the same year the University of Munich honoured him with the degree of Ph.D.; in 1877 he was the recipient of the Copley Medal of the Royal Society, and in 1884 was elected one of the foreign members; in 1886 Harvard conferred upon him the degree of LL.D.; he was also an honorary member of the Academies of Paris, Berlin, Vienna, St. Petersburg and Rome, and of the Mineralogical Societies of England and of France.

NOTES.

WITH the École Normale at Paris, which has just celebrated its centenary, the names of a number of distinguished men of science are associated. At the present time, no less than twelve of its old students are members of the Academy of Sciences. Pasteur left Lille to become the director of scientific studies at the school, and carried on, while in connection with it, the researches which have made his name known throughout the world. M. Bertrand, the Perpetual Secretary of the Academy, is an old student of the school, and among other eminent names included in the list of its alumni are MM. Darboux, Joubert, Serret, Hermite, Puiseux, Briot, Bouquet, Giard, Baillaud, Chaive, Floquet, Pellet, Tisserand, Appell, Picard, &c.; while the teaching staff now contains such men as Goursat, Tannery, Gernez, Dufet, Houssay, Constantin, Raffy, Violle, Joly, and Wallerant.

AN influential committee has been formed for the erection of a monument to the late Prof. Hermann von Helmholtz, the German Emperor having promised 10,000 marks and a free site for the purpose. The committee is international and thoroughly representative, as shown by the names of Berthelot, Blaserna, Boltzmann, Geikie, Holmgren, Kékulé, Kelvin, Lippmann, Lubbock, Pictet, Rayleigh, Roscoe, Sidgwick, Siemens, Tait, Thalén, Virchow, Weber, and others among the 180 distinguished men of science forming the committee. Funds will be collected in Germany and in other countries, and may be sent to any member of the committee, or to Messrs. Mendelssohn and Co., Berlin W., Jaegerstrasse 49 and 50. Letters may be sent to Prof. Dr. A. König, Berlin N.W., Flemmingstrasse 1. The appeal issued by the committee concludes as follows: "Friends and admirers of Hermann von Helmholtz, far and near, unite with us! Bear witness to the homage paid by science, which knows no frontiers, to one of its heroes; show your gratitude for the benefits which life has received from his scientific labours, and give expression to the love which his harmonious spirit won wherever he appeared."

PROF. HUXLEY's condition during the past week has caused his friends considerable anxiety, but we are glad to learn that a change for the better set in on Monday.

DR. JOHN H. REDFIELD, one of the founders of the American Association for the Advancement of Science, died recently at Philadelphia.

THE Prince of Wales has signified his intention to be present at the celebration of the jubilee of the Royal Agricultural College, Cirencester, on July 25.

THE sixty-seventh meeting of the Society of German Naturalists and Physicians will be held this year at Lübeck, September 16 to 21. The secretaries of the zoological section are already making preparations for this event, and will issue a preliminary programme of communications and demonstrations early in July.

THE London Geological Field Class will commence their series of Saturday afternoon excursions, under the direction of Prof. H. G. Seeley, F.R.S., next Saturday, when they will visit Otford and Eynsford. Further particulars can be obtained from the General Secretary, R. Herbert Bentley, 31, Adolphus Road, Brownswood Park, N.

MR. EDWARD CROSSLEY has signified his intention of presenting to the Lick Observatory the 3-foot reflecting telescope, with its dome, which now form part of his private observatory at Halifax. This information comes to us directly from the Lick Observatory, together with an expression of high appreciation of Mr. Crossley's most generous gift.

APPLICATIONS for appointment to the Medical Research Scholarships of the Grocers' Company must be sent in before the end of this month. The Scholarships are three in number, each of the value of £250, and are open only to British subjects; they were instituted by the Company as an encouragement to exact research into the nature and prevention of important diseases.

AT Stevens's sale room on Tuesday, a fine and well-preserved specimen of the Great Auk, from the collection of the late Sir William Milner, was put up to auction. About eighty skins of the bird are known to be in existence, of which twenty-four are in Great Britain, ten of these being in museums, and fourteen in private hands. The bidding for the specimen offered for sale by Mr. Stevens started at 100 guineas, and went up slowly to 350 guineas; but as this was lower than the reserve price, the bird did not change owners. A Great Auk's egg, offered at the same sale, reached the price of 180 guineas, while an egg of *Æpyornis maximus* was sold for 36 guineas.

A PARTY, consisting of Dr. Geo. Becker, Prof. W. H. Dall, and Mr. Parington, of the U.S. Geological Survey, will leave Washington on May 16 for Alaska, and will be away until September. Congress recently directed an examination of the gold and coal deposits of the territory to be made, and this will be the work of the party; directed more especially towards an estimate of the economic value of the known deposits, rather than toward a search for new ones.

THE new system—the "Système français"—proposed by the French Société d'Encouragement to regulate the pitch of screws, and the metric wire gauge—the "Jauge décimale métrique"—in which the number of a wire is the same as the diameter expressed in tenths of millimetres, have been adopted in the French Navy by the Minister of Marine. The approva thus officially shown to the new scales will greatly assist the Society in its efforts to establish uniform gauges for wires and screw-threads.

THE news that the office of Superintendent of Agriculture, held by Mr. C. A. Barber in the Leeward Islands, has been abolished, and that the Department of Agriculture, as such, no longer exists, is altogether surprising. The Department was only opened towards the end of 1891, but, under Mr. Barber's direction, the four botanical stations in connection with it, at Antigua, Dominica, St. Kitts, and Montserrat, have done a large amount of work, which is daily becoming more and more known and appreciated. No agricultural community can afford to be without scientific advice in these days of competition and plant disease. Why the local Legislature should dispense with this advice just when the Superintendent of their Department of Agriculture had, by incessant stndy of the climatal and economic conditions of the islands, attained the position to give it authoritatively, is quite beyond our comprehension.

THE "Exposition annuelle" of the French Physical Society was held last week. Many new and ingenious pieces of apparatus, for use in all branches of physical investigation and instruction, were on view. Electrical instruments occupied a large share of the exhibits, but there were also to be seen new forms of barometers, thermometers, calorimeters, spectroscopes, dynamometers, balances, and other engines of research. M. Violle exhibited photographs of the electric arc, and MM. Loewy and Puiseux showed their lunar photographs obtained at the Paris Observatory. Useful accessories to micrometers for astronomical telescopes were shown by M. Maurice Hamy. There were also on view, among numerous other things, metals of new compounds prepared by M. Moissan in his electric furnace; a radiometer which turned in the opposite direction to that of the ordinary form of the instrument; M. Janssen's long-period meteorograph, designed for the Mont Blanc Observatory; M. Raoul Pictet's apparatus for the experimental study of the critical points of liquids; and the spectrum of argon. Visitors to the Exhibition must have derived considerable benefit from an inspection of the many physical instruments and devices which were to be seen.

Major Cardew's report on the inquiry which he has made into the circumstances connected with a series of explosions which occurred on February 1, on Southwark Bridge, has just been printed as a Parliamentary Paper. It will be remembered that there were four explosions; the first, and by far the most intense, occurred in the culvert under the pavement and roadway on the west side of the bridge, and it was immediately followed by three explosions in the street boxes of the Electric Lighting Company, on the east side of the bridge. On opening the ground over the culvert, shortly after the explosions, a large crack was found in the 3-inch gas main, out of which the gas was coming in volumes. How the gas was fired could not be exactly ascertained, but Major Cardew confidently asserts that it was not by means of the electric lighting mains. The most striking features about the accident seem to be: (1) The distance to which it appears that a series of explosions may travel along the electric mains which form a gigantic network under the whole of the streets of the city; and (2) the proof it affords of the insufficiency of any ordinary system of ventilation of these pipes and street boxes, if gas can find an easy access to them, and the necessity of exercising great care to make and keep the street boxes impervious to gas. In a former report it was recommended that "accumulation of gas should be prevented by thorough ventilation, by making the sides and bottoms of street boxes impervious to gas, and by filling up the boxes as far as practicable with incombustible material"; to this Major Cardew now adds—"by thoroughly plugging pipes and conduits at each street box to prevent passage of gas along the system," and he puts the filling up the boxes first, as the most simple and certain method of preventing danger of explosion. It is admitted that the main cause of the explosions was the defect in the gas-pipe, and this again directs attention to the very serious danger to the public arising from the condition of the gas-pipes in many districts, and the way in which they are laid and supported; a danger which is continually increasing, owing to the spread of the use of wood paving and other impervious surfaces, and which is temporarily intensified by every severe frost. No want of care on the part of the gas companies can, however, relieve electric lighting companies of the duty of sufficiently protecting their conduits and street boxes against an accumulation of gas, by acting on the recommendations made.

It is very commonly believed that in Ireland, on account of the mild climate, the Arctic or Mountain Hare does not turn white in winter, but remains in its brown summer fur. Writing in the *Zoologist*, Dr. R. F. Scharff brings evidence that there is no change in the colour of the Irish hare in most winters. But, on the other hand, Major-General Warrand states that—"At Finnebrogue, near Downpatrick, a very large number of hares are taken or killed every year, and it is found that a considerable number of them turn very white in the winter, while nearly all assume a much lighter shade of fur when the cold weather sets in." The editor of the *Zoologist* says that this view is supported by a number of sportsmen and good observers, and that he himself has shot several Irish hares in all stages of change from brown to white.

There is an interesting paper in the *Electrician*, by Messrs. Campbell and Lovell, on the supposed magnetic fatigue. Prof. Ewing has recently shown that in the case of good wrought iron, when subjected to very many reversals in weak magnetising fields, there is no perceptible change in the magnetic qualities. The authors have made use of strong magnetising fields, and have experimented on cast as well as wrought iron. The specimens to be tested were in the form of rings wound over with primary and secondary coils. A single B.H. curve was taken by the ordinary ballistic method, and then an alternating current of about 1·4 amperes at 83 alternations per second was kept passing through the primary coil for nearly a month. Another series of tests were then made, and it was found that the B.H. curve obtained coincided exactly with that given before the repeated reversals, both in the case of wrought and cast iron.

The current number of *Wiedemann's Annalen* contains a paper, by Herr A. Bock, on the ratio between the lateral contraction and the longitudinal dilatation (Poisson's ratio) in magnetised iron rods. In the method employed the rod under test is rigidly supported at its middle, so that it lies in a horizontal plane. At either end of the rod a cross-piece is attached, as well as a plane mirror. These cross-pieces serve as lever arms, from the ends of which weights can be hung. In this way the bar is both bent and twisted, the amount of bending and twisting being read off by means of a vertical telescope, two scales at right angles, and the mirrors attached to the ends of the rod. The difference of the readings on the scale parallel to the length of the rod (B) is proportional to the bending, while the difference in the readings on the scale at right angles to the length of the rod (T) is proportional to the twist. Then using Kirchhoff's formula, Poisson's ratio is given by $\mu = \frac{T}{B} \cdot \frac{s}{2l} - 1$, where s is the half length of the rod, and l is the length of the lever arm, at the end of which the deforming weight acts. Neither in the case of hard steel or soft iron (a magnetising coil being used in this latter case) was a difference in Young's modulus, or of the torsional rigidity greater than 0·5 per cent. observed. In the case of soft iron, the author considers that his experiments are sufficiently accurate to show that after magnetisation the torsional rigidity and Young's modulus both diminish. Since, however, B diminishes faster than T, the value of Poisson's ratio increases. The author finds that frequent magnetisation and deformation causes the differences in the elastic constants between the magnetised and unmagnetised states to diminish, and he therefore concludes that it is not possible to detect the effect on the elasticity of magnetisation in a rod by the change in the pitch of the note it emits when struck.

The field experiments now in progress in various parts of the country partake rather of the character of demonstrations than of incursions into the domain of original research. The experiments made in Carnarvonshire last year, in connection with the agricultural department of University College, Bangor, included a series in which a mixture of rye grass and clover seeds was pitted against mixtures containing the seeds of other grasses than rye grass, in addition to or exclusive of the latter. The crops were cut in July, and weighed green, when the crop containing clovers and rye grass only was found to be the heaviest. All the plots are to be grazed for the next three years, and it is obvious that considerable time must be allowed before definite conclusions can be arrived at. Experiments made in Anglesey "to test the best quantity of seed to sow for oats," appear provisionally to demonstrate that four or six bushels of seed (black Tartarian) broad-casted per acre, give better crops than are obtained from eight bushels of seed, the quantity sown under the usual practice of the island. In both counties comparative manurial experiments are in progress upon pasture land and field crops.

The work of the Aberdeenshire Agricultural Research Association in 1894 was largely concerned with an inquiry into "degeneration of rye grass and possible recovery." It is argued that, in permanent pasture, "starvation of plants, and non-utilisation of the plants when grown, are the features to be remedied, in order to secure permanent pasture of the valued rye grass." The supreme value of *Lolium perenne* in pastures, as demonstrated by Sir John Lawes and others a few years ago, appears to be steadily acquiring additional confirmation in different parts of the country, and the economic importance of the question is beyond all doubt. We are afraid that confusion is likely to arise from the adoption of a practice in vogue at some of the American experiment stations, where the word "legume" is used to denote "leguminous (papilionaceous) plant." In this report we read, "Legumes (*i.e.* tares, peas, clover, lucerne, &c.)." The word "legume" has already a definite meaning attached to it by English botanists, whilst in colloquial use in France it has another and a wider application. Exception should also be taken to the use of the term tubercules (or tubercles) to denote the structures on the roots of leguminous plants. Lawes and Gilbert have, with admirable consistency, adhered throughout to the word "nodules," and it is unfortunate that this example has not generally been followed. Students of agriculture are hearing more and more of tubercle in animals, and of the disease termed tuberculosis, and there is a tendency, at least on the part of beginners, to think that all tubercles must be alike. The general adoption of the word "nodules," as used by Lawes and Gilbert, would lessen the possibility of confusion.

MISS CHRISTINE LADD FRANKLIN publishes an interesting paper on "The Normal Defect of Vision in the Fovea" in the current number of the *Psychological Review*. Recent investigations of Königs on the relative absorption of different portions of the spectrum by the visual purple, the curve of which corresponds with the curve which expresses the distribution of brightness along the spectrum for (1) the totally colour-blind and (2) the normal eye in a faint light, suggest that vision both in (1) and (2) is conditioned by the presence of visual purple in the retina. But this visual purple is absent in the fovea. If this be so, the eye in (1) and (2) should be blind in that part of the retina. Careful observations and experiments were made to test the validity of this conclusion. "The blindness of the fovea for faint light did not at once reveal itself; the act of fixation means holding the eye so that an image falls on the part of the retina best adapted for seeing it, and hence it would involve keeping the image *out of* the fovea in a faint light, if the fovea were then really blind. But after the total disappearance of the small bright object looked at had several times occurred by accident, it became possible to execute the motion of the eye necessary to secure it at pleasure. It was then found that the simple device of presenting a group of small bright objects to the eye of the observer was sufficient to demonstrate the 'normal night-blindness of the fovea' without any difficulty—one or other of them is sure to fall into the dark hole of the fovea by accident." Observations on a totally colour-blind boy showed the blindness of his fovea. The function of the retinal purple is, it is suggested, for the reinforcement of waning light, and is especially adapted for the absorption of the faint green light of dense forests.

THE Calendar of Queen's College, Galway, for 1894–95, has just been published, and also that of the Royal University of Ireland, for the year 1895.

THE current number of the *Journal* of the Royal Agricultural Society of England contains a long report, by Sir J. B. Lawes, F.R.S., and Sir J. H. Gilbert, F.R.S., on "The Feeding of Animals for the Production of Meat, Milk, and Manure, and for the Exercise of Force."

A NEW edition has been published of "Stephens' Catechism of Practical Agriculture" (W. Blackwood and Sons), revised and largely rewritten by Mr. James Macdonald. The popularity of the book is vouched for by the fact that more than twenty-one thousand copies have been sold.

TWENTY-EIGHT short essays by Dr. Jean Rey, "On an inquiry into the cause wherefore tin and lead increase in weight on calcination," form the contents of No. 11 of the Alembic Club Reprints. The essays, which originally appeared in 1630, are interesting because they contain descriptions of experiments and results which anticipated, to some extent, the work done by Lavoisier a century and a half later.

PARTS of the first and second editions of Malthus' essay on the principle of population, have been published, in a handy volume, in Messrs. Macmillan's series of Economic Classics, edited by Mr. J. Ashley. Of the first edition, published in 1798, about one-third has been reprinted; but of the second edition, which contained about four times as much matter, the selected chapters are only one-twentieth of the whole work.

AN account of principles and practice of the methods adopted by Dr. T. Schott in the treatment of chronic diseases of the heart by means of mineral baths and exercises, has been written by Dr. Bezly Thorne, and published by Messrs. J. and A. Churchill, together with a description of the Nauheim baths, and of the therapeutic exercises. The volume is full of diagrams and other illustrations of interest to students of cardiac affections.

A GERMAN edition of Mr. Benjamin Kidd's "Social Evolution," with a preface by Dr. A. Weismann, has just been published by Gustav Fischer, Jena.

FIVE new volumes belonging to the "Encyclopédie scientifique des Aide-Mémoire" have come to us from the joint publishers, Gauthier-Villars and G. Masson, Paris. They are: "Le Fonctionnement des Machines à Vapeur," by G. Leloutre; "Des Marées," by P. Hatt; "Balistique des Nouvelles Poudres," by E. Vallier; "La Théorie des Procédés Photographiques," by A. de la Baume Pluvinel; and "La Distillation," by E. Sorel.

INDEXES to the literature of cerium and lanthanum, by Dr. W. G. Magee, have been published together as No. 971 of the "Smithsonian Miscellaneous Collections," in accordance with the recommendation of the Chemical Literature Committee of the American Association for the Advancement of Science. The difficulty and labour involved in the preparation of these indexes can only be fully understood by those who have attempted similar tasks. All chemists should be grateful to Dr. Magee for his very valuable bibliography.

A FULL notice of the life and numerous works of the late Mr. F. Buchanan White appears, with a portrait, in the April number of the *Annals of Scottish Natural History*. A report on the remarkable visitation of the Little Auk to Scotland, during the past winter, is contributed to the same number by Mr. W. E. Clarke. The whole of the records of occurrences of the bird from December 22, 1894, to February, are shown upon a map which accompanies the report, and are also precisely tabulated in chronological sequence.

DR. HENRY MAUDSLEY'S "Pathology of Mind" (Macmillan) has recently been published in such an altered and enlarged form, that it is virtually a new book, "for," to quote from the preface, "while old matter has been left out, and much fresh matter added, the whole has been recast, the form of the presentation changed, and the text entirely rewritten." The present contents of the work, as expressed by the new subtitle, constitute a study of the distempers, deformities, and disorders of the mind.

IN the third *Bulletin* of the Madras Government Museum appears a revised edition of Mr. Edgar Thurston's "Rámésvaram Island and the Fauna of the Gulf of Manaar." The situation of Râmésvaram, on the reef which, under the name of Adam's Bridge, almost connects Ceylon with the mainland of India, renders an account of its flora and fauna particularly interesting; and the present brochure, which is illustrated with several charts and photographs of the coast, furnishes a useful supplement to Haeckel's graphic pages upon the island of Ceylon. The observations recorded are admitted to be far from exhaustive of the biological features of the Gulf of Manaar, but they are more than sufficient to indicate the existence of a fauna well worthy of further examination.

THE Malacological Society of London, instituted for the study of the Mollusca and Brachiopoda, only came into existence in February 1893, but its performances up to now give every promise of a successful future. It publishes *Proceedings*, in which appear anatomical papers, and papers devoted to descriptions of recent and fossil shells. A valuable address by Dr. H. Woodward, F.R.S., dealing largely with scientific investigations of the sea and its inhabitants, appears in the fourth number of the Society's *Proceedings*, with a number of other papers. In this connection we notice that the *Journal of Malacology* contains a contribution, by Dr. J. C. Thresh, on "Oysters as Disseminators of Disease," and, together with several other communications and a bibliography of recent literature, an interesting note, by Mr. W. M. Webb, on "The Dimyarian Stage of the Native Oyster."

THE Natural History Societies in our public schools probably do more to foster scientific research than all the systematic instruction in lecture-room and laboratory; therefore every encouragement should be given to the work of observation and collection which is carried on by them. Increased demands of both school work and games on half-holidays leave little time to cultivate interest in natural things, and this accounts partly for the statement in the report of the Rugby School Natural History Society for 1894, that the interest shown in the Society by members of the school has decreased. Possibly, now that the new museum is completed, and the collections in it are being systematically arranged by Mr. Collinge, the Society will commence a new era of prosperity.

THE Danish Meteorological Institute and the Deutsche Seewarte have conjointly published daily synoptic weather charts of the North Atlantic Ocean and adjacent continents for a year ending November 1889. These valuable charts were first issued for September 1873 by the late Captain Hoffmeyer, of Copenhagen, and they afford excellent materials for tracing the connection between the weather conditions of the Atlantic, this country, and Western Europe. For some years past the charts have been accompanied by explanatory text, which greatly enhances their value. The discussion of the charts for the year in question is divided into two parts: (1) general investigations of the conditions over the North Atlantic, and (2) application of this knowledge to navigation; while the position and movement of the areas of high and low barometer, in interesting cases, are shown in forty special charts accompanying the text.

SEVERAL aromatic esters of arsenious acid have been prepared for the first time by Dr. Fromm, of Rostock. The new substances are either viscous liquids or crystalline solids, and are prepared with considerable facility. The first member of the series, the triphenyl ester, $As(OC_6H_5)_3$, is obtained by allowing arsenic trichloride diluted with ether to fall drop by drop into sodium phenylate suspended in ether. The reaction commences vigorously at the ordinary temperature, but the mixture eventually requires warming over a water bath in order to obtain the theoretical yield. The ethereal liquid is then allowed to stand until the finely-divided precipitate of common salt subsides, when it is decanted from the latter. The ether is then removed by distillation over the water bath, and the thick residual liquid subsequently subjected to distillation under reduced pressure. Arsenious triphenyl ester is a colourless viscous liquid endowed with an odour somewhat resembling that of phenol; it boils under a pressure of 57 m.m. at 275°. The liquid is remarkably sensitive to moisture, for water instantly decomposes it into arsenious oxide and phenol. Halogens do not form additive compounds with it, but chlorine and bromine convert it into arsenic trichloride or tribromide and trichlor- or tribromphenol. The second member, the para cresyl ester, $As(OC_6H_4CH_3)_3$, is similarly obtained, and is likewise an oily liquid, boiling at 290° under 20 m.m. pressure, and endowed with similar properties. The benzyl ester, $As(OCH_2C_6H_5)_3$, has also been isolated in an analogous manner, but is not quite so stable as the two esters just described, being more or less decomposed upon distillation *in vacuo*; it may be obtained practically pure, however, by heating the product of the reaction in an oil bath to 200° under low pressure. It reacts with water similarly to the two other esters. In addition to these liquid aromatic arsenious esters, the β-naphthyl ester, $As(OC_{10}H_7)_3$, has been prepared by the action of arsenic trichloride upon the sodium derivative of β-naphthol. As the sodium compound is in this case completely soluble in ether, the arsenic chloride reacts with great energy. The arsenious naphthol ester crystallises from the ethereal solution after decantation from the precipitated common salt, in colourless aggregated crystals, which melt at 113°–114°, and are readily soluble in alcohol and benzene in addition to ether. Water immediately decomposes them, and in boiling water the products of the decomposition, arsenious oxide and β-naphthol, dissolve completely.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*, ♀) from West Africa, presented by Miss Florence Greffin; a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. R. J. Davidson; two Polar Hares (*Lepus glacialis*) from Norway, presented by Mr. O. Gude; a Common Badger (*Meles taxus*) from Berkshire, presented by The Duke of Wellington; an Irish Stoat (*Putorius hibernicus*) from Ireland, presented by Viscount Powerscourt; two Antipodes Island Parrakeets (*Cyanorhamphus unicolor*) from Antipodes Island, New Zealand, presented respectively by Sir Walter L. Buller, K.C.M.G., and Mr. William E. Collins; two Scarlet Tanagers (*Ramphocœlus brasilius*) from Brazil, presented by Mr. Robert E. Graves; a Red and Blue Macow (*Ara macao*) from South America, deposited; two Griffon Vultures (*Gyps fulvus*) from Egypt, purchased; an Egyptian Gazelle (*Gazella dorcas*, ♂) from Egypt, received in exchange; a Great Kangaroo (*Macropus giganteus*, ♂), a Rufous Rat Kangaroo (*Hypsiprymnus rufescens*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE VARIABLE STAR Z HERCULIS.—This recently discovered variable star turns out to be one of exceptional interest. It was first suspected of variability by the Potsdam observers, and subsequent observations by Chandler and Hartwig seemed to show that it was a star of the Algol type. Early in the present year Dr. Dunér announced that the new variable was probably of the Y Cygni type with unequally bright components, since he found unequal minima alternating in periods of forty-seven and forty-nine hours. Returning to the subject (*Astrophysical Journal*, April), Dr. Dunér gives the data on which his conclusion was based, and derives some interesting results as to the probable constitution of the system. The normal magnitude of the star is 6·89; at principal minimum it falls to 8·05, and at secondary minimum to 7·35. Hence, the relative degrees of brightness at these times are 1, ⅝, and ⅜, and assuming that the eclipses are central, it is easily shown that the observed magnitudes may be explained by supposing that the two components are of equal size, while one is twice as bright as the other. The unequal duration of the minima further indicates that the orbit is an ellipse with an eccentricity of 0·2475, and it is calculated that the semi-axis major of the orbit is six times the diameter of the stars. The plane of the orbit passes through the sun, and the line of apsides is inclined at an angle of 4° to the line of sight. The stars revolve in this orbit in a period of 3 days 23 hours 48 minutes 30 seconds.

It seems probable that this variable may form a connecting link between Algol, which consists of a bright and a dark body, and Y Cygni, consisting of two stars of equal brightness.

THE DIAMETER OF NEPTUNE.—With the Lick telescope and an eyepiece magnifying 1000 diameters, Prof. Barnard finds the mean angular diameter of Neptune, when reduced to the mean distance from sun 30·0551, to be 2″·433. This corresponds to an actual diameter of 32,900 miles, which is from two to four thousand miles less than that stated in most of our text-books.—*Astronomical Journal*, No. 342.

INDUCED MAGNETISM IN VOLCANIC ROCKS.

AN interesting note by G. Folgheraiter, on the magnetism induced in volcanic rocks by the earth's magnetic field, appears in the *Atti della Reale Accademia dei Lincei* (vol. iv. part 5, March 3, 1895). The author has performed a number of experiments on volcanic rocks, in order to determine the amount of induced magnetism left when, after heating to such a temperature that they entirely lose their permanent magnetism, they are either allowed to cool slowly or are suddenly cooled, in each case under the influence of the earth's field. From such observations he hopes to be able to deduce some conclusions as to the conditions under which the rocks experimented on, which were originally permanently magnetised, became magnetised. The rocks are cut into small parallelopepedons weighing about 50 grams, and such that the length is about two or three times the depth or breadth, care being always taken to cut the rock so that the axes of these pieces were vertical when the rock was in its place in the earth. The intensity of magnetisation was in every case measured by the method of deflection; a freely suspended magnetic needle being deflected by the sample, which was placed with its length east and west. After measuring the intensity of magnetisation of the samples, they were heated to redness, and then either allowed to cool slowly, or are rapidly quenched with their axes vertical. Their magnetic moment was determined, first immediately they were cool, and then after they had stood under the influence of the earth's field for three months. The specimens of basalt examined may be divided into two groups: in the first may be placed those specimens which were originally only slightly magnetised, and in this case, after heating to redness, the magnetisation is always increased, but to a very different degree in the different specimens. The second group includes those basalts which were originally strongly magnetised, and in this case after heating the magnetisation was considerably reduced. In both groups the magnetisation underwent no change during three months, and sudden cooling gave the same results as slow cooling. Experiments have also been made on tuff and peperino. The results obtained with the first of these rocks are similar to those obtained with the first group of basalts. Peperino, however, differs in that, before being heated, its coercive force seems almost nil, the bar becoming only temporarily magnetised. After heating, the character of the rock is altered, as it can now become permanently magnetised and behaves just like the tuff. From this the author concludes that peperino has been formed at a low temperature, probably by the action of water on cinders, &c.

THE FREEZING-POINT OF DILUTE SOLUTIONS.

CORRECT determinations of the freezing-point of dilute solutions are of fundamental importance in connection with the general theory of the subject, and it is therefore anything but satisfactory to find that, in spite of the closeness with which the individual results of the same observer agree amongst themselves, the results of different observers are in many cases widely separated. For example, the following values have been given as the molecular depression of the freezing-point in the case of a 1 per cent. aqueous solution of sugar:—2·02, Arrhenius; 2·07, Raoult; 2·01, Pickering; 2·18, H. C. Jones; 1·81, Loomis. The results of Jones and Loomis, both of whom claim increased accuracy for the methods they employ, differ by some 18 per cent. The theoretical value of the molecular depression, calculated from the melting-point and heat of fusion of ice, is 1·86. The cause of these differences has given rise to much discussion. Pickering has attempted to show that Jones's results, wherein the temperature was read to the ten-thousandth of a degree, were affected by thermometer errors. Jones has replied that his thermometer was tested. Kohlrausch has drawn attention to probable sources of error in Jones's method, but is compelled to admit that the differences between the results of Jones and Loomis must, in the main, be due to some unknown source of error.

A definite step in the direction of clearing up this point is made in a recent number of the *Zeitschrift für physikalische Chemie*. Here Nernst and Abegg emphasise the fact that the observed freezing-point must in general be different from the true freezing-point, or the temperature at which solid and liquid are in equilibrium. They point out that a partly-frozen liquid, uninfluenced by the temperature of its surroundings, will strive to reach the true freezing-point at a rate which, at any instant, may be taken as proportional to the difference between its actual temperature and the true freezing-point. Again, in practice, on account of the limited amount of substance employed, and the effect of the temperature of the surroundings, &c., unfrozen liquid strives to reach a definite temperature, which may be termed the "convergence temperature." On these assumptions it is easy to show that the observed freezing-point, or the temperature at which the thermometer becomes steady, will only be the true freezing-point if the "convergence temperature" is equal to the true freezing-point, or if R, the rate at which the temperature of the partly frozen liquid approaches the freezing-point, is infinitely great as compared with r, the rate at which the temperature of the unfrozen liquid approaches the "convergence temperature." If one of these conditions is not fulfilled, corrections determined experimentally have to be applied. For dilute solutions of alcohol and common salt the corrections were found to be inappreciable under the experimental conditions described in the paper. Here the value obtained for R, although, as is always the case, it was largely diminished by the lag of the thermometer, still was sufficiently large as compared with the value of r. In the case of sugar, however, R was so small that by varying the experimental conditions, a 1 per cent. solution gave molecular depressions varying between 1·6 and 2·1—limits which are even further apart than those given by the results of previous observers. On correcting the observed depressions in the manner described, they all gave practically the theoretical value.

Without these corrections, observed freezing-points are thus held to be functions of the size of the apparatus used, the temperature of the cooling-bath, the rate of stirring which largely affects the "temperature of convergence," &c.

Evidence is also given of the futility of expressing freezing-points to the ten-thousandth of a degree. It may readily happen that the above correction is as high as 0°·01, and as the mode of deducing it is but approximate, in such a case 0°·001 or 0°·002 would be a favourable estimate of the error of the end result, even if satisfactory corrections could be applied for the alteration in the concentration of the solution produced by freezing, and the ordinary sources of error incidental to the method of experiment.

J. W. RODGER.

THE EXAMINATION CURVE.

IF the results of the examination of a mixed body of candidates be plotted out on the graphic method, they will be found, in accordance with a well-known law of statistics, to approximate to a curve having a more or less rapid gradient at either end, and a mid-region of gentler ascent. Fig. 1, for example, shows the results of an examination of 27 students in physical geography, the scale of marks running vertically from 10 to 90, the examinees being arranged horizontally at equal distances apart from the lowest to the highest. The larger the number of candidates the more flattened does the mid-region of the curve tend to become. Again, in any series of examinations, the mean results of which are plotted out, the more uniform the standard of difficulty of the papers set, the flatter is the mid region of mediocrity. Fig. 2 shows the mean results of ten separate examinations, of different students conducted by six examiners, in history, English literature, geography, physical geography, physics, botany, arithmetic, and Euclid. They are taken without special selection from the returns of class examinations in University College, Bristol. The standards were somewhat markedly different; in some the head, in others the tail, being excessive; hence the mid-region is not so flattened as it probably would have been had a larger series been taken. The results indicate, however, sufficiently well

Fig. 1.

the general nature of the examination curve. The total range of marks being from 17·5 per cent. to 84 per cent., 15 out of the 30 students fall within the mid-region of from 40 per cent. to 60 per cent.

It is not my purpose to attempt to determine how far the form of the lower end, or tail, of the curve is due to incapacity on the one hand, or to sheer idleness on the other, and how far that of the upper end, or head, of the curve is due to exceptional ability on the one hand, or to industry and hard work on the other. Whichever cause preponderates, we may say that, at any rate with pupils who have got beyond the school-boy stage,

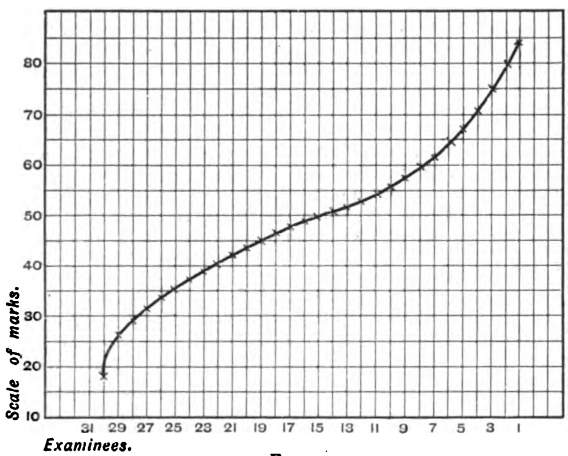

Fig. 2.

and very largely with them too, the teacher's chief field of influence is in the preponderant mid-region of mediocrity. Those in the tail of the curve either cannot or will not profit by his ministrations; those at the head of the curve may be trusted to do well without his aid, or even in spite of his interference. It is on the body of the curve that he can do his best work.

It is, at first sight, somewhat remarkable that the general form of the curve persists as we ascend through a series of graded examinations. It might well be supposed that the tail would be eliminated in the lower examinations; and the results of my own observations show that the tail does tend to flatten out and become raised as we ascend. But it is by no means got rid of. It flattens because we have eliminated the hopelessly idle and those who have altogether mistaken their vocation. It persists because at each stage there are those whose limits of capacity have been reached. A student whose capacity may bring him into upper mediocrity in matriculation, may drop hopelessly into the tail when he proceeds to work for the degree. I was informed, on good authority, at the Cape, that whereas the Kaffir lads were often ahead of white boys in the early stages of education, the limits of their capacity were soon reached, and they were left behind by those whom they had before easily beaten. At each stage there are pupils for whom the work is beyond their powers; and they inevitably fall into the tail.

In the traditional division of candidates into three classes, the most rational method is to place in the first class those at the head of the curve, the mediocrities in the second class, and the tail in the third class. For many years it has been my custom as an examiner to plot out on the graphic method the results of each examination. The advantage of doing so is that one thus sees at a glance the distribution of the examinees. One can also more readily see where the divisions should run between the several classes. It is irrational to fix beforehand some arbitrary number of marks to form the limiting line above which the candidates are to be called first class, those below this and above another arbitrarily chosen number being ranked in the second class. The limit must be determined—and even then it is often only determined with difficulty—by an inspection of the curve. The form of the curve, and the level of mediocrity in the scale of marks, enable one to decide whether the paper has been too hard or too easy. If too hard, the level of mediocrity will be low, and the tail inordinately large; if too easy, the level of mediocrity will be high, and the head not well differentiated from the body.

The examination curve may be commended to the special consideration of those who have to deal with large numbers of candidates in connection with the Education Department and that for Science and Art. And I would recommend to the consideration of those who have the control of Civil Service and Army Examinations the excellent suggestion made by Dr. J. Venn, in a paper on the "Correlation of Mental and Physical Powers," contributed to the *Monist* for October 1893. In these examinations large numbers of candidates compete for a limited number of vacancies. Let the results be expressed in an examination curve. It will have a well-marked head, a longish body of mediocrity, and a decided tail. We may cheerfully eliminate the tail; it consists of duffers intellectually. We may select the head for entrance; it consists of men of marked intellectual superiority, so far as the examinations are an adequate test thereof. If the head exhausts all the vacancies, well and good. But if the number of vacancies involves an extensive incursion into the body of mediocrity, then it will be found that the lower selected candidates will be very little superior intellectually to the higher rejected candidates. The last ten selected, and the ten seniors among the rejected, will probably be separated by a comparatively small number of marks. Moreover, it is a well-known fact, *experto crede*, that, if, after an extensive set of papers has been looked over and carefully marked, an interval of time be allowed to elapse, and then the papers are gone over again, the result of this re-examination is that the head and tail remain practically unchanged, but that there is not a little redistribution among the mediocrities. Furthermore, if a different examiner look over the papers, the head and tail of his curve will not differ markedly in arrangement or form from those of his predecessor; but among the mediocrities there will be not a little shifting of places. While, therefore, such an examination as that for entrance to Woolwich or Sandhurst serves to select the intellectual head, and to reject the intellectual tail, it is by no means so effectual in classifying the candidates who fall within the body of mediocrity.

Now if the same body of candidates be further examined by some physical test (and Dr. Venn regards lung-capacity and breathing power the best single physical test), it will be found that in this respect there will be a curve with well-marked head, a mediocre body, and a rapidly descending tail. But the intellectual head and tail will not include the same candidates as the physical head and tail. Let us therefore select from our intellectual mediocrities those who fall within the head of the physical examination curve. If we must admit intellectual mediocrity, let us, at any rate, secure that we have, in compensation, physical excellence.

In practice this would necessitate the preliminary testing, when they are undergoing their medical inspection, of all candidates by means of the spirometer; neither a difficult nor a lengthy operation. No doubt, as Dr. Venn points out, breathing power may to some extent be improved by practice, and candidates would all flock to a "spirometer-crammer." But probably all of them would be the better for some physical cramming in this way.

C. LLOYD MORGAN.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. W. Watson Cheyne, F.R.S., has been appointed an additional Examiner in Surgery for the present term.

An inter-collegiate Examination in Mechanical Science and Engineering, for candidates for the Mechanical Sciences Tripos, will be held, under the direction of Prof. Ewing, at the end of this term, commencing on June 4.

THE Somerset County Education Committee have adopted a resolution in favour of establishing in the county a fixed Dairy Farm School for adults of both sexes. Instruction in cheese and butter making, and in subjects allied thereto, would be given. Provision is made for granting thirty scholarships, giving free board and tuition at the school for two months, to farmers' sons and daughters engaged in dairy work. The Committee have agreed that it is desirable to set up an agricultural side to one or more of the existing secondary schools in the county. It is hoped that in due course an agricultural college for the West of England will be provided by the combined efforts of the local counties.

WITH the view of acquainting teachers with a course of experiments in accordance with the British Association Committee's programme for the teaching of Chemistry in schools, the Evening Schools Code, and the syllabus for Major Scholarship examinations recently prepared by a committee of the Incorporated Association of Head Masters, Prof. Armstrong, F.R.S., will give a series of demonstrations at the City and Guilds Central Technical College, on Saturday mornings, in May. The special object of the course will be to explain the exact method to be followed in carrying out a carefully arranged series of very simple qualitative and quantitative experiments calculated to impress the chief and most generally useful facts of chemistry on children's minds whilst developing their powers of observing and reasoning.

IT has often been urged against the educated natives of India, that they are admirable at adaptation, but are altogether at a discount where original research is concerned. The Hon. Mr. A. Cadell commented upon this failing in a recent address to Convocation of Allahabad University. His advice was that debating societies, which are so common a feature of student-life, should give place to natural history societies; the object would be to foster the true scientific spirit in the native mind. In this connection, some remarks (which we quote from the Allahabad *Morning Post*), made by Prof. Ingram, of the Madras Educational Service, indicates that the complaint as to the want of scientific research by natives of India is not without foundation. In a recent contribution he says:—"Now, if India is not helping in this work, if she is supplying no additional information, and is offering no aid towards the consummation of this unity, her claim to be regarded as in any sense a scientific country, is null and void. No matter how assiduously her students may devote themselves to studying the science course of their University curriculum; if it all end there, it is nothing. But need it end there? What country could offer greater facilities for scientific research than India? Here is a country teeming with animal and plant life; but the systematic biology of India is still in a nebulous condition. Why are no students devoting themselves to collecting and collating, and studying the plants of their districts, or the insects that abound within their walls? It would be hard, too, to find a country better suited than India, with her clear atmosphere and cloudless skies, for the study of the stars or of other atmospheric phenomena. In these ways, and in a thousand others, we might be advancing the cause of knowledge. But we can scarcely be said to have begun yet." By way of remedy, Prof. Ingram suggests the formation of an Indian Royal Society, or some such association as would serve the same purposes here as the British Association does at home. It is possible, however, without going to that length, to utilise the resources already at hand. India is not without its scientific societies. There are the Asiatic Society of Bengal, the Indian Science Association, and the Bombay Natural History Society, all of which are amply sufficient for the purposes of scientific research.

SCIENTIFIC SERIALS.

American Journal of Science, April.—Niagara and the Great Lakes, by F. B. Taylor. By a correlation of the abandoned shore lines, moraines, and outlets, and the gorges, recently-submerged shores, and rivers of this region, the author is led to the view that the lakes were at first glacial and ice-dammed, falling by stages as the outlets changed on withdrawal of the glacier-dams. By the withdrawal of the glacier the Niagara river was opened, and the upper lakes became united. The land was gradually depressed at the north, and finally led to the opening of Nipissing outlet, which was then brought down to the sea-level, and marine waters filled the three upper lakes, the Ontario, St. Lawrence, and Winnipeg basins. The subsequent raising of the Nipissing outlet made the upper lakes fresh again. Then followed the stage of the second Lake Algonquin and that of the second (present) Niagara lakes. Lake Superior became independent. The Great Champlain uplift took place at the north-east, and the formation of the St. Clair delta began, and continues to the present day.—Disturbances in the direction of the plumb-line in the Hawaiian Islands, by E. D. Preston. There appears to be a disturbance of more than a minute in the direction of gravity at the south point of Hawaii. At Kohala the plumb-line is deflected half a minute towards the south, and at Kalaieha nearly as much towards the north, the disturbance being in both cases towards the mountain. The deflection at the south point is also northward, and is caused by the great masses of Mauna Loa and Mauna Kea.—Structure and appendages of *Trinucleus*, by Charles F. Beecher. The three posterior thoracic endopodites are very similar, and in a general way closely resemble those of *Triarthrus* from the same region of the thorax. They are, however, comparatively shorter and stouter, and could not be extended beyond the ends of the pleura. The two distal joints are cylindrical, with well-marked articular surfaces and ridges. The joints preceding these proximally become much wider, flattened, and produced into transverse extensions which carry large tufts of setæ at the end. The exopodites seem to be composed of slender joints, the distal exites being long and slightly curved outwards. They carry very long, close-set, overlapping lamellose fringes, which evidently had a branchial function. The characters of the appendages indicate an animal of burrowing habit, which probably lived in the soft mud of the sea-bottom, much after the fashion of the modern *Limulus*. In addition to its limuloid form, the absence of eyes seems to favour this assumption. So does the fact that many specimens have been found preserving the cast of the alimentary canal, showing that the animal gorged itself with mud, like many other sea-bottom animals.

Wiedemann's Annalen der Physik und Chemie, No. 3.—Electric conduction and convection in feebly conducting dilute solutions, by E. Warburg. The alteration of conductivity produced by a current in bodies like aniline, the phenomena of convection exhibited by them, and their apparent deviations from Ohm's law, can all be explained on the supposition that their conductivity depends upon an electrolyte of which the body is a very dilute solution. Bodies were investigated whose conductivities went down to 5×10^{-15}. The similar behaviour of still worse conductors, like xylol, benzol, oil of turpentine, is probably due to the same cause.—Ratio of sectional contraction to longitudinal dilatation of iron rods during magnetisation, by A. Bock. By magnetisation the constants of elasticity of soft iron are altered to an extent not exceeding 0·5 per cent. The observations indicate that flexure diminishes, torsion also decreases, and the ratio of sectional contraction to longitudinal expansion increases. Iron becomes more incompressible in the magnetic field (see p. 614).—Freezing points of some binary mixtures of heteromorphous substances, by Albert Dahms. Eutectic mixtures give no uniform crystallisation product, but always a heterogeneous mechanical mixture, consisting of solid solutions of the components in each other, and in the limiting cases of the components themselves. The composition of eutectic mixtures—*i.e.* those mixtures of two bodies which have the lowest fusing points—does not correspond to simple molecular proportions of the components. In eutectic mixtures the process of solidification is in general more complicated than in chemically homogeneous bodies, owing to complex supercooling. Equimolecular solutions often show approximate correspondence of fusing points, also for the higher concentrations. Menthol, $C_{10}H_{19}OH$, exists in two modifications, which explains the divergences of the freezing points of even the most dilute solutions in menthol.—On glow discharge in air, by C. A. Mebius. Straight lines representing the relation between strength of current and difference of potential for different distances between the electrodes, are not parallel, the divergence increasing with the extent to which the air has been modified by the current. The fall of potential gradually decreases with a constant or an increasing current. These changes are probably due to the formation of nitric oxide, as was proved with the spectroscope.

Bulletin de l'Académie Royale de Belgique, No. 2.—On a new class of ethers: methylene lactate, by Louis Henry. Methylene monolactate, $CH_2.CH_3\ C_2HO_3$, obtained by heating lactic acid with polymerised methanal, is a colourless mobile liquid, with a strong odour resembling methanal, and an extremely pungent taste. Its density is 1·1974 at 2·5° C., and it boils with remarkable regularity at 153° to 154°.—Comparison of the astronomical coordinates referred to the instantaneous (astronomical) pole and the (geographical) pole of inertia respectively, by Ch. Lagrange. The discovery of the sensible character of the variations of latitude and longitude is not of such a nature as to render necessary the substitution of geographical axes to instantaneous ones in astronomy. The mean values of the latitude and the longitude will be the geographical characteristics of the spot. But for the points of the heavens, the result of the substitution of geographical for instantaneous axes would have the eminent disadvantage of affecting all their coordinates with diurnal variations 300 times greater. This is a simple geometrical consequence of the fact that every day the geographical and the instantaneous axes describe a cone about the resultant, and that the geographical cone is 300 times more open than the instantaneous cone.—Critical temperatures of mixtures and of water, by F. V. Dwelshauvers-Dery. The critical temperature of water was obtained by finding the critical temperatures of aqueous mixtures of alcohol or acetone containing more and more water. The limiting value for water, as derived from the acetone results, was 638° C., from the results with alcohol, 641° C.—Action of heat upon carbon bisulphide, by Henryk Arctowsky. Carbon sesquisulphide, CS_3, which is obtained by exposing the bisulphide to the voltaic arc, may also be obtained by keeping it at 250° C. for some time. It is this body whose presence in small quantities in commercial CS_2 gives this product its pungent odour.

THE number of the *Journal of Botany* for April is occupied almost entirely by papers on descriptive botany, viz. on African species of *Eriosema*, on South American species of *Polygala*, on British *Rubi*, on hybrid *Epilobia*, and others on special species or genera.

The Bulletin of the Minnesota Botanical Studies for March contains a paper on a period of growth in the fruit of *Cucurbita Pepo*, by Mr. A. P. Anderson, accompanied by an elaborate series of tables and plates of curves. The other articles in the same number refer exclusively to the Flora of Minnesota.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 21.—"Experiments upon the Influence of Sensory Nerves upon Movement and Nutrition of the Limbs." (Preliminary communication.) By Dr. F. W. Mott and Dr. C. S. Sherrington, F.R.S.

Claude Bernard first showed, by experiments upon frogs, the impairment of movement in a limb deprived of sensation by cutting the posterior spinal roots. The authors have, by an extensive and varied series of experiments on the monkey, demonstrated the important *rôle* played by sensation in the performance of voluntary movements.

The experiments deal separately with the upper limb and the lower limb. The phenomena do not essentially differ, but are more striking in the former.

Summary of Experiments.—The limbs were deprived of all sensation, superficial and deep, by cutting the "whole series" of posterior spinal roots. For the upper limb, 4th cervical to 4th thoracic inclusive. For the lower limb, 2nd to 10th post-thoracic inclusive.

Animals with a limb thus *deprived of all forms of sensation* from the time of operation onwards, even up to four months, have never been observed to use it in any finer and delicately adjusted movements. For example: the foot is not used in climbing or grasping, nor is the hand. The animal does not use the hand to defend itself, or even to satisfy hunger, when prevented from picking up food by any other way, than by using the desensitised hand. It must be concluded, therefore, that there is *actual inability* to perform the movements in question. Occasionally in struggling, coarse movements of the shoulder and elbow take place; but, as a rule, the arm hangs down helplessly. The movements abolished are those most literally represented in the cortex cerebri. Damage to the pyramidal tract is not the cause of the loss of movement, because degeneration is not found in the spinal cords; moreover, stimulation of the cortex cerebri evokes movements in the desensitised limb even more readily than the normal.

The effect of section of the "whole series," except the *one root* which supplies the *apex* of the limb, produces only a very slight impairment of movement. Any trophic changes that occur are due to pressure and microbic infection.

"Is Argon contained in Vegetable or Animal Substances?" By George W. MacDonald and Alex. M. Kellas.

At Prof. Ramsay's suggestion, experiments were undertaken by the authors to see whether argon could be obtained from nitrogenous vegetables or from animal tissues.

It is concluded that there is no appreciable quantity of argon in peas (or at least that the argon cannot be obtained with the nitrogen by Dumas' method).

An experiment with regard to the presence of argon in animal tissues was also negative in its results. Mice were selected for the experiment, because the nitrogen from the whole animal could be conveniently collected by Dumas' method.

Chemical Society, March 21.—Dr. Armstrong, President, in the chair.—The following papers were read:—The volumetric determination of sugars by an ammoniacal cupric solution, by Z. Peške. The author has devised a modification of Pavy's method of estimating sugars, and gives tables showing the reducing power of ammoniacal cupric solution for solutions of various sugars.—The action of hydrogen sulphide on antimonic acid solutions, by O. Bošek. The author demonstrates the existence of compounds of the composition SbX_4; he has obtained the tetrasulphide Sb_2S_4, and a double compound of the composition $3KCl, 2SbCl_4$.—Action of hydrogen sulphide on antimonic, arsenic and telluric acids, by B. Brauner.—The atomic weight of tellurium, by B. Brauner. From its position in the periodic table, tellurium should have an atomic weight between 123 and 125, whilst the number actually obtained is 127·71; for this and other reasons the author concludes that tellurium is not a simple substance, although attempts to effect a separation of its constituents have failed. The author suggests that tellurium is a mixture or compound of two elements, one of which occupies the position of tellurium in the periodic table, and the other of which is the hypothetical "triargon."—The hydrolysis of maltose by yeast, by G. H. Morris.—Studies in isomeric change. Part iv. Ethylbenzenesulphonic acids, by G. T. Moody. The sulphonation product of ethylbenzene yields only one sulphonic acid, and not two, as stated by Chrustschow. The para-acid is obtained thus: the ortho-acid can be prepared by sulphonating and subsequently reducing ethylbromobenzene. — β-Ethoxynaphthalenesulphonic acids. The arrest of isomeric change at an intermediate stage, by A. Lapworth. During the sulphonation of ethoxynaphthalene at a low temperature the 2:1-sulphonic acid is the first product. On allowing the mixture to stand, however, this spontaneously changes into the 2:1'-acid.—Some oxypyridine derivatives, by Miss A. P. Sedgwick and N. Collie. Starting from γ-chloro-αα'-dimethylpyridine and αγ-dichloro-α'-methylpyridine, the authors have succeeded in preparing a number of new oxypyridine derivatives.—On the colouring principle of *Toddalia aculeata* and *Evodia meliæfolia*, by A. G. Perkin and J. J. Hummel.—Some ethereal derivatives of sarcolactic acid, by P. Frankland and J. Henderson. The molecular rotations, molecular deviations and asymmetry products of a number of alkylic salts of sarcolactic acid and its acidic derivatives have been investigated.—Electrolysis of potassium allo-ethylic camphorate, by J. Walker and J. Henderson. The chief products of the electrolysis of potassium allo-ethylic camphorate are salts of allo-campholytic acid, $C_9H_{14}O_2$, and allo-camphothetic acid, $C_{18}H_{30}O_4$.—Trimethylsuccinic acid, by W. A. Bone and W. H. Perkin, jun.—New isomeric sulphonic chlorides derived from camphor, by F. S. Kipping and W. J. Pope. The authors describe two isomeric chlorocamphene-sulphonic chlorides and their derivatives.

Royal Meteorological Society, April 17.—Messrs. F. C. Bayard and W. Marriott communicated a paper on the frost of January and February 1895 over the British Isles. The cold period which commenced on December 30 and terminated on March 5 was broken by a week's mild weather from January 14 to 21, otherwise there would have been continuous frost for sixty-six days. Temperatures below 10° F., and in some cases below zero, were recorded in parts of England and Scotland between January 8 and 13, while from the 26th to the 31st and from February 5 to 20, temperatures below 10° occurred on every day in some part of the British Isles. The coldest days were February 8 to 10. The lowest temperatures recorded were: −17° at Braemar and −11° at Buxton and Drumlanrig. The mean temperature of the British Isles for January was about 7°, and for February from 11° to 14° below the average, while the mean temperature for the period from January 26 to February 19 was from 14° to 20° below the average. The distribution of atmospheric pressure was almost entirely the reverse of the normal, the barometer being highest in the north and lowest in the south, the result being a continuance of strong northerly and easterly winds. The effect of the cold on the public health was very great, especially on young children and old people. The number of deaths in London due to diseases of the respiratory organs rapidly increased from February 2 to March 2, when the weekly number was 1448, or 945 above the average. Rivers and lakes were frozen, the ice being more than 10 inches thick. The frost will long be remembered for its effect on the water-pipes all over the country, in many cases householders being without water for more than nine weeks. As the result of inquiries the authors find that mains have frozen which have been laid as low as 3 ft. 6 in. from the surface of the ground to the top of the pipe. It appears, however, that the nature of the soil had far more to do with the depth to which the frost penetrated than the intensity of the frost itself. From a comparison of previous records, the authors are of opinion that the recent frost was more severe than any since 1814.—Mr. Birt Acres read a paper on some hints on photographing clouds.

Mineralogical Society, April 2.—A paper was read by Mr. Spencer upon *enargite*. Several new forms were discovered upon the specimens of this mineral examined. The parameters calculated from the measurements were

$$a : b : c = 0{\cdot}8694 : 1 : 0{\cdot}8308,$$

numbers which differ somewhat from those previously given by Dauber. The habits of the crystals and their mode of twinning were fully discussed, and the fact pointed out, bearing upon the possibility of the identity of clarite with enargite, that measurement of cleavage fragments of clarite gave angles identical with those existing between the prism cleavages of enargite when three crystals are twinned together.—Mr. A. E. Tutton exhibited his new instrument for cutting, grinding, and polishing accurately orientated section-plates and prisms of mineral or other crystals, and demonstrated the readiness with which the cutting disc or grinding or polishing lap may be driven by a small electric motor. Mr. H. A. Miers suggested the possibility of simplifying the instrument somewhat for the commoner purposes of the mineralogist, by employing only one driving gear and making the cutting disc and laps interchangeable; he also suggested the experiment of using carborundum for the cutting edge instead of diamond dust.—Mr. Miers exhibited a crystal of *lorandite*, the new arseno-sulphide of thallium discovered by Kreuner; also a fine crystal of *clèveite*, the mineral which had, at his suggestion, been examined for argon by Prof. Ramsay. The specimen exhibited was from the neighbourhood of Moss, and this variety, as well as that from Arendal, had been found to yield the spectrum of helium.

EDINBURGH.

Royal Society, January 21.—Prof. Sir W. Turner, Vice-President, in the chair.—Drs. Gulland and Noël Paton communicated a paper on the absorption of carbohydrates from the intestine.—Prof. Ewart read a paper, by Dr. J. D. F. Gilchrist, on the torsion of the molluscan body.—Prof. Tait communicated a note on a curious property of determinants.

February 4.—Prof. J. G. M'Kendrick, Vice-President, in the chair.—Prof. Crum Brown communicated a note on normal nystagmus.—Sir W. Turner read a note on M. Dubois' account of pithecanthropoid remains recently found in Java. The remains are a skull, a third molar tooth, and a left femur. They were found in a bank of a river in Java, at some distance from each other, and at different times. M. Dubois supposed that he had established the existence of a connecting link between the ape and man, and he named it the "erect ape man," in recognition of the differences from man and the ape. Sir W. Turner remarked that it was not at all certain that the three bones belonged to the same creature. A comparison of the skull with several specimens of the skulls of aboriginals, left him unconvinced that it might not have belonged to a human being. The features of the femur could all be made out in a large collection of human thigh bones, and the tooth had quite as much resemblance to the tooth of a human being as to the tooth of an ape. He considered that the remains were of a low human type.

February 18.—The Hon. Lord M'Laren, Vice-President, in the chair.—Prof. Chrystal discussed a theorem regarding the equivalence of systems of ordinary linear differential equations with constant coefficients, and its application to the theory of such systems.—Dr. C. G. Knott communicated a note on volume-changes in iron and nickel tubes when magnetised. He dealt specially with the effects which are caused when the tubes are closed by a non-magnetic cap instead of a cap of the same metal as the tubes themselves.—Dr. W. Peddie compared the case of yellow-blue blindness, described by him some weeks ago, with the case recently described by v. Vintschgan and Hering. In the present case, unlike the latter, the whole range of the spectrum is visible. So far as the tests have yet been carried out, the presence of red seems to be very easily recognised, but all other colours seem to be nearly, or entirely, grey. Only one neutral point (near D, in the yellow part of the spectrum) seems to exist.

March 4.—Sir Douglas Maclagan, President, in the chair.—At the request of the Council of the Society, Dr. Munro gave an address on lake-dwelling research. Whatever was the object of these dwellings, or the causes of their development, it is certain that they were for centuries the characteristic dwellings of the early tribes of Central Europe. Research on the subject began with the discovery of remains in a bog in Ireland, more than half a century ago. Another discovery was afterwards made in Switzerland, and gave new significance to the Irish discovery. Dr. Munro sketched the results of the investigations made in Switzerland and in other parts of Europe, especially Italy. Perhaps no part of Europe is more prolific in remains than the valley of the Po. The first great discovery made in Scotland was in a loch in Wigtownshire. When the loch was drained, several artificial islands were found, and evidences of early Scottish civilisation, previously unknown, were discovered. Among the articles found were canoes and Roman bronze dishes. Subsequent Scottish discoveries were described, and then the recent discoveries in Bosnia were dealt with. The coincidence of the style of art in the ornaments recently found at Glastonbury with that of the North German articles is peculiarly significant.

Scottish Meteorological Society, March 27.—Prof. Copeland, Astronomer Royal for Scotland, in the chair.—Mr. R. C. Mossman gave a paper on "The Frost of 1895," in which he pointed out that the severe frost began on December 28, and ended about February 20, covering a period of fifty-four days. During this time the average temperature of the British Isles as a whole was 8° below normal, the greatest deficiency being in the central highlands of Scotland and the midland districts of England. At the same time barometric pressure was highest in Scandanavia, Lapland, and West of Russia, and lowest about Spain; an almost exact reversal of the normal winter distribution. Thus cold, dry, and therefore heavy, air was drawn from the north-east over the British Isles, not only lowering the air temperature directly, but clearing the sky of the usual winter cloud layer, and thus allowing free radiation at night, with consequent low night temperatures in valleys where the chilled air can accumulate and lie stagnant. Places thus situated recorded temperatures below zero Fahrenheit, the lowest being − 17° at Braemar, and − 11° at Drumlanrig. At western sea-coast places the frost seldom lasted for more than twenty-four hours without a break; while at inland stations, such as Kingussie and Braemar, the temperature never rose to the freezing point for fifteen consecutive days in February. No very low temperatures were recorded on Ben Nevis, the lowest being 2° above zero. On February 18, 19, and 20 the temperature on Ben Nevis averaged 18° higher than that at Fort William, 4400 feet below it, showing that the summit was in the down draught of the anticyclone then lying over Scotland; while at sea level the warmth and dryness of this upper current was not felt. The cold extended all over Europe, including the South of Spain and the Riviera, but scarcely touched North Africa. Though snow fell in Tunis, Algeria was beyond the cold area, the winds there being mostly westerly. To the north Iceland was the only part of Europe outside the influence of the north-east winds, and the winter there has been mild and open.—Mr. A. G. Herbertson presented an interim report on hygrometric work at Ben Nevis. He also gave an account of the Meteorological Observatory at Montpellier, France, describing many of the instruments employed there, and also pointing out the excellent results got from regular phenological observations.—Mr. Mossman gave some notes on "Auroras in the North-east of Scotland 1773 to 1894," mainly taken from data at Gordon Castle (Banffshire) and Inverness. The average number of auroras in this district for the 122 years is seven per annum, but the numbers vary from fifty cases in 1870 to none at all in sixteen years of the record. An intimate connection was shown between sun-spots and auroras; maximum sun-spot periods being the time when auroras were frequent and brilliant, while with the absence of sun-spots there were few or none. No aurora was observed in any year between May 23 and July 22, that is, within four or five weeks of the summer solstice; and the rest of the year shows two maxima, a primary in October and a secondary in February.

Dublin.

Royal Dublin Society, January 23.—Prof. J. Mallet Purser in the chair.—Mr. G. H. Carpenter read a paper on a collection of Lepidoptera from Lokoja, West Africa.—Prof. A. C. Haddon and Mr. J. E. Duerden described some species of Actiniaria from Australia and other countries. Ten species, most of them new to science, were described anatomically, and their relationship to other members of the group discussed.—Prof. Haddon then gave a paper on a branched worm-tube.—Mr. Duerden followed with some notes on the Hydroida and Polyzoa collected during the Royal Dublin Society's Fishery Survey on the West Coast of Ireland. In this paper the author describes two new species of *Perigonimus*, and records the occurrence of *Campanulina panicula*, G. O. Sars, for the first time for the British seas.—A voluminous monograph of the marine and freshwater Ostracoda of the North Atlantic and of North-Western Europe (Sections ii.-iv.: Myodocopa, Cladocopa, and Platycopa) was presented (through Prof. A. C. Haddon) by Dr. G. S. Brady and the Rev. A. M. Norman.—At the meeting held February 20, Prof. Grenville A. J. Cole in the chair, the following papers were read:—Dr. V. Ball, C.B., F.R.S., made a communication in which he gave an historical account of the gold nuggets found in the county Wicklow.—Prof. W. J. Sollas, F.R.S., read a paper descriptive of the systems of Eskers in Ireland. Some beautiful photographs of nebulæ and clusters of stars, taken at Daramona, co. Westmeath, were afterwards exhibited by Mr. W. E. Wilson.—At the meeting of March 20, Prof. G. F. Fitzgerald, F.R.S., in the chair, Prof. Sollas read a paper upon the age of the earth.—Prof. James Lyon demonstrated some of the errors that arise from the imperfect alignment of the slide lathe. If the line joining the centres of a slide lathe is not parallel to the line of motion of the saddle, the path of a cutter fixed in a bar which is rotated between the centres is a plane which is not perpendicular to the direction of motion. Any piece of material being bolted to saddle, and having a hole bored in it by the cutter, would be traversed by a hole the shape of which would be the projection of the cutting circle on a plane perpendicular to the line of motion of saddle—i.e. an elliptic cylinder would be the result. In the second case, if the poppet-head centre be higher than the fixed centre, and a bar of material be turned between the centres by means of a tool placed in the saddle at a height above the bed about equal to the height of the centre point of the axis of bar above the bed, the result will be a hyperboloid of revolution, since the surface is generated by a straight line (the path of the tool), which is always at a fixed distance from a given axis, is not parallel to it, and does not intersect it.

Paris.

Academy of Sciences, April 16.—M. Marey in the chair.—Observations on argon, its fluorescence spectrum, by M. Berthelot. The fluorescence of argon, when charged with benzene vapour and submitted to the action of the silent discharge, is described at length. It is noted that, with the second sample of gas supplied by Prof. Ramsay, and under the conditions of the experiment, the condensation taking place amounted to only 6 to 10 per cent. The author cannot yet explain the different behaviour of the first sample as regards condensation. The following approximate measurements have been made in the spectrum of the fluorescent light: A yellow line at λ 579 corresponding to the 575 argon line and 578 of the aurora borealis; a green line at λ 547 corresponding with Crookes' group 549 to 555, and perhaps with 557 of the aurora; violet lines 438 and 436 corresponding with Crookes' 433 and 430, and with an important aurora line.—A contribution to the study of variability and capacity of transformation in microbiology, as illustrated by a new variety of anthrax bacillus (*Bacillus anthracis claviformis*), by M. A. Chauveau and M. C. Phisalix. The cultivation obtained from the lymphatic ganglion of a guinea-pig inoculated with attenuated anthrax bacilli consisted of a new type which retained only in a very slight degree the immunising power of the attenuated culture, and no longer had any toxic action beyond that evidenced by a certain rise in temperature of the inoculated subject. The authors believe the *Bacillus anthracis claviformis* to have been certainly derived from virulent *Bacillus anthracis*, but they have not as yet succeeded in bringing back the new variety to the original virulent form.—On the minimum temperatures observed this winter at the summit of Mont Blanc, by M. J. Janssen. A description is given of the mounting of the minimum thermometers. The following minima have been recorded: Mont Brévent − 26° C.; Mont Buet − 33° C.; Mont Blanc − 43° C.—Secular variation and ephemerides of terrestrial magnetism, by General Alexis de Tillo.—Researches on assimilable nitrogen and its transformations in arable land, by M. Pagnoul. The conclusions are drawn that: (1) Abundant rains may carry off from rich soils considerable amounts of nitric nitrogen. (2) Plants growing on the soil are able to prevent this loss. (3) Carbon disulphide arrests the action of the nitric ferment temporarily without killing it. (4) The ammoniacal form is a transition state for organic nitrogen passing into the nitric form; carbon disulphide causes the temporary suspension of the action at this stage. (5) The nitrous form is also an unstable transition state.—On the products of combustion in the electric arc, by M. N. Gréhant. Carbon monoxide is produced and, in confined spaces, has produced illness among the workmen employed in electric light stations.—On a question concerning the singular points of algebraical left-handed curves, by M. G. B. Guccia.—Summation of series by means of definite integrals, by M. Petrovitch. On types of groups of substitutions of which the order equals the degree, by M. R. Levavasseur.—On the theory of the system of differential equations, by M. A. J. Stodolkievitz.—On Rondelet's rule for woods, and beams loaded on end, by M. C. Maltézos. Rondelet's rule is reduced for wood to a parabolic formula. The curve of limit loads for wood, iron, and brass, between wide limits for the ratio of length of beam to smallest side of transverse section, may be replaced by an arc of a single parabola.—Electric discharge by illumination of substances which are mediocre conductors, by M. Edouard Branly.—On a new method for the measurement of temperatures, by M. Daniel Berthelot. The author proposes the determination of density of gases, by means of their refractive indices as investigated by interference fringes, as a basis for measurement of temperature by a property of gases independent of the envelope.—On the presence of helium in clèveite, by M. P. F. Clève. A letter in which the author gives the wave-lengths of lines observed in the spectrum of gas obtained from clèveite by heating with potassium bisulphate. The argon lines were not observed.—On the definite combinations of metallic alloys, by M. H. Le Chatelier.—On the aliphatic aldehydes $C_nH_{2n}O$, by M. Louis Henry.—Action of halogens on pyrocatechol, by M. H. Cousin.—On the drying property of fatty matters in general and their transformation into elastic products analogous to linoxine, by M. Ach. Livache.—On the composition of some French and foreign oats of the 1894 crop, by M. Bolland.—On the existence of abnormal variations of pressure with the height, a vertical gradient, by M. L. Teisserenc de Bort.

BERLIN.

Physiological Society, March 1.—Prof. du Bois Reymond, President, in the chair.—Dr. Weintraud spoke on the formation of uric acid in man. After the view that the excretion of uric acid is in direct relationship to the proteids of the food had found no support from the experimental side, the theory had been propounded that it is related to the breaking-down of leucocytes. This view was supported by experiments in which the administration of nuclein and xanthin to man had increased the output of uric acid; but, on the other hand, similar experiments on dogs had always yielded negative results. The speaker had experimented on several individuals by substituting thymus gland, rich in nuclein, for the ordinary flesh of the food. The increased excretion of phosphoric acid in the urine showed that the nuclein was largely resorbed, and a constantly large increase in the excretion of uric acid was at the same time observed; the latter disappeared again at once when ordinary flesh was substituted for the thymus gland. Apart from theoretical considerations, it appears that foods rich in nuclein or xanthin should be avoided by patients suffering from excessive formation of uric acid.—The President and Dr. Sklarek made some communications as to argon, recently discovered by Lord Rayleigh and Prof. Ramsay.

March 15.—Prof. H. Munk, President, in the chair.—Prof. Liebreich stated that he had found in propyl alcohol a means of separating the cholesterin fats of the skin into those with a high and those with a low melting point. The former exhibit all the characteristics of a wax, and are distinguished by their fixed melting point and by their containing cerotic acid. By extracting human nails and vernix caseosa he had obtained a quantity of cholesterin fats which resembled in all points the cholesterin ethers of the skin. He further demonstrated a new chemical reaction which shows the existence of the inert region on the surface of fluids and in capillary tubes in which chemical changes are taking place. It consists in the interaction of chloral hydrate with sodium carbonate and gold chloride, and since all these reagents are solid it is evident that evaporation has no effect on the production of this inert space.—Dr. E. Flatau exhibited two series of nerve preparations, the first consisting of isolated ganglion cells and neurons prepared, by a modification of Golgi's method, partly from the cerebrum and partly from the cerebellum and medulla. The second series, prepared by Marchi's method, was intended to show that in the Wallerian experiment on degeneration, not only does the peripheral stump degenerate after the section, but that the central end also undergoes a secondary degeneration after the break-up of the now inactive ganglion.

Meteorological Society, March 5.—Prof. Hellmann, President, in the chair.—After the President had presented the fourth number of the *Reprints* containing the oldest charts of terrestrial magnetism, Dr. Süring gave an account of his observations on the temperature and humidity near a surface of snow. They were made last winter on the Brocken, and this winter in Potsdam, and in the following manner. One thermometer was placed on the snow, and another at the usual height above the surface, either exposed or protected, while at the same time an aspiration-thermometer placed 1 cm. above the snow recorded the temperature of the air. It was found that the size, shape and position of the thermometer lying on the snow, as well as the condition of the snow-surface, &c., had a considerable influence on the temperature recorded by this instrument; the observations had therefore been restricted to a determination of the difference between the temperature of the snow and that of the air above it, in its relations to clouds and to the motion and temperature of the atmosphere. It was found that the difference was lessened as the sky became more clouded, and when the sky was completely clouded during a fall of snow the temperature of the snow's surface was higher than that of the air. As the temperature of the atmosphere fell, the difference became greater, but was lessened as the motion of the air increased in rapidity. On the whole, the difference was much less on the Brocken than in Potsdam. As to the influence of the snow-surface on the humidity of the air, the speaker had arrived at the result that evaporation from the snow is much more frequent than condensation from the air, but that they are about equal in amount. Prof. Hellmann spoke on the, as yet, uninvestigated velocity of the wind in Berlin, basing his remarks on the indications during ten years of a self-registering anemometer placed at a height of 33·5 metres above the ground in the tower of a house which was originally quite isolated. In later years this house was surrounded by others, but this fact did not in any way affect the working of the anemometer, whose constants were determined at the marine observatory at Hamburg and the central observatory at St. Petersburg. Taking a year as a whole, the maximum rate was observed in March, the minimum in September, and during these months the variations were least. The average for the year is 5·1 metres per second. The above-named periods of maximum and minimum have also been observed at a number of other stations, viz. Paris, Munich, Prague, Vienna, and Cracow. Winds with a velocity less than the average are more frequent than those with one above the average. The frequency of storms, as measured in hours, is greatest in January and March; it increases in October, and sinks rapidly in April. The daily period of greatest velocity lies between one and two o'clock p.m.

Physical Society, March 8.—Prof. du Bois Reymond, President, in the chair.—After Prof. Lampe had referred to the death of their late member, Prof. Worpitzky, Dr. W. Wien spoke on the testing of pyrometers made, according to Le Chatelier, of platinum and platino-rhodium, and connected with an apparatus constructed by Keiser and Schmidt for measuring not only the voltage of the thermo-electric currents, but also the corresponding temperatures. The testing was carried out by determining the melting-points of copper, silver, platinum, palladium, and nickel, which, as fine wires, formed the solder-joints of the platinum and platino-rhodium thermo-elements. These were heated in porcelain tubes, and the current was broken when the respective wires melted. In these experiments platinum must be protected from carbon, copper from oxygen, and palladium from hydrogen. It is impossible here to enter into all the details referred to by the speaker.—Dr. W. von Uljanin gave an account of his experiments on polarisation by oblique radiation from silver, platinum, and black glass. Assuming that the radiation from the heated plates is determined by the refraction of their substance, it was found that the curves thus arrived at corresponded in the case of silver very closely with those obtained experimentally. In the case of platinum, whose surface is very easily altered by heating, the experimental values were always less than those required by theory; in the case of black glass the correspondence of the values was greater, but not so complete as in the case of silver.—Dr. Raps introduced an improvement in his automatic air-pump, designed to facilitate the filling and emptying of the mercury, and at the same time to protect the pump from the consequent risk of breakage. The result was arrived at by means of a chamber for the expansion of air.—Prof. Vogel demonstrated the experiment, already described in NATURE, whereby a half black and half white disc with black patches on it produces different colours, when rotated at a moderate speed, according to the direction of the rotation.

March 22.—Prof. Planck, President, in the chair.—Dr. Rubens exhibited several galvanometers, and explained in detail the arrangement and advantages of one he had constructed for the measurement of reversing currents, but which can also be readily adapted for currents in one direction.—Dr. Raps spoke on a new regulator for synchronous motion, especially as required in telegraphy, explaining its principle and construction on a model.

AMSTERDAM.

Royal Academy of Sciences, December 29, 1894.—Prof. van de Sande Bakhuyzen in the chair.—Mr. MacGillivray communicated the results of an investigation made by Mr. D. MacGillivray in the Boerhaave Laboratory at Leyden, and which proved that the germs of tuberculosis are not destitute of the power of locomotion, but possess this power, if the conditions of life are favourable.

February 23, 1895.—Prof. Hubrecht brought forward a new hypothesis to explain the origin of the amnion. Birds and reptiles have been looked upon as possessing the normal type of amniogenesis from which that of the Mammalia had to be further derived. The primitive Insectivores offer far better starting points. In the development of the hedgehog's amnion, another path is found along which it is easy to connect both the higher Mammalia and the Sauropsida. The hedgehog allows a comparison to be made between the trophoblast with the outer layer of the amphibian ectoderm. Thus it would be possible to trace the first origin of the amnion in the Anamnia.—A paper containing full particulars, and accompanied by several plates, was presented for publication in the Academy's *Verhandelingen*, under the title: "Ueber die Phylogenese des Amnions und die Bedeutung des Trophoblastes."—Mr. Suringar read a paper on "family relations in the vegetable kingdom," as set forth in a sketch in the form of a genealogical tree, designed by the author to illustrate his University lectures.—Mr. Franchimont presented, on behalf of Dr. P. van Romburgh, two papers. (*a*) On some nitro derivatives of dimethylaniline. By nitration of dimethylaniline in a great quantity of sulphuric acid, as well as by treating metanitrodimethylaniline with diluted nitric acid, two dinitro derivatives were obtained: a yellow one fusing at 176°, and a red one fusing at 112°. In the yellow one there is a nitro group that may easily be substituted. By further nitration it yields two trinitro derivatives: a yellow one melting at 154° and an orange-coloured one melting at 196°. The red dinitro derivative yields only the orange-coloured trinitro derivative. All of them are finally converted into the same tetranitrophenylmonomethylnitramine, viz.:

$$C_6H.(NO_2)_4\ (2,\ 3,\ 4,\ 6)\ (N.CH_3.NO_2)\ (1).$$

From their relations or properties the following structure is deduced:

Trinitro Dimethylaniline.

$$154° = C_6H_2N(CH_3)_2\ (1),\ (NO_2)_3\ (2,\ 3,\ 4).$$
$$196° = C_6H_2N(CH_3)_2\ (1),\ (NO_2)_3\ (3,\ 4,\ 6).$$

Dinitro Dimethylaniline.

$$176° = C_6H_3N(CH_3)_2\ (1),\ (NO_2)_2\ (3,\ 4).$$
$$112° = C_6H_3N(CH_3)_2\ (1),\ (NO_2)_2\ (3,\ 6).$$

(*b*) On addition products of symmetrical trinitrobenzol. Hepp has found that with aromatic amines S. trinitro-benzol yielded coloured addition products. With brucine, Dr. van Romburgh arrived at the same result: it formed brownish red needles fusing at 158°; strychnine did not do so under the same circumstances. With trinitro-benzol, indol yielded gold-coloured needles melting at 187°, skatol, orange-coloured ones melting at 183°, and pyrrol, gold-coloured ones melting at 95°; the last-mentioned gave off the pyrrol to the air in a few hours (at 25°). All these compounds consisted of one molecule to one molecule of trinitrobenzol. Pyridine and quinoline did not form such compounds; the former caused trinitrobenzol to crystallise in large crystals. Piperidine, nicotine and phenylhydrazine gave rise to red tints, but crystallised compounds could not be obtained. With other nitro compounds, too, as: $C_6H_3.NMe_2.NH_2.NO_2$ (1 : 3 : 4), and $C_6H_3NMe_2.NHMe.NO_2$ (1 : 3 : 4), trinitrobenzol yielded crimson products, melting respectively at 130° and 144°, and being composed of a molecule of each of the constituents.

March 30.—Prof. Van de Sande Bakhuyzen in the chair.—Mr. Bakhuis Roozeboom has, in conjunction with Dr. Hoitsema, investigated the behaviour of hydrogen to palladium, from 0° to 190°, and from 0 to 6 atm. pressure. It results from the observations that, contrary to the opinion of Troost and Hautefeuille, there exists no such compound as Pd_2H, neither can the phenomena observed be explained by admitting the existence of two solid solutions. The absorption proceeds gradually, as if there exists but one solid solution. There is, however, at low temperatures a period in which the concentration rises much more rapidly with the pressure of hydrogen than before or afterwards. This behaviour presents an analogy to the conduct of gases near their critical temperature.

GÖTTINGEN.

Royal Society of Sciences.—In the *Nachrichten*, part 1, for 1895, appear the following contributions in the department of mathematics and physics:—

December 1894.—I. R. Schütz: Complete and general solution of a fundamental problem in the theory of the potential.—Robert Fricke: On the theory of ternary quadratic forms with integral complex coefficients.—J. Orth: On bacterial disorders of excretion in the renal medulla.

January 1895.—I. R. Schütz: Extension of Maxwell's law of the distribution of velocities, deduced from the principle of the minimum path.—E. Ehlers: On the viscera of *Lepidosiren*.—Ludwig Rhumbler: Sketch of a natural system of classification for the *Thalamophora*.—Hermann Wagner: The area of the land surfaces of the earth according to zones.—R. Dedekind: On the basis of the theory of ideals.—Heinrich Burkhardt: Contributions to researches on the foundations of geometry.—Franz Meyer: On the structure of the discriminants and resultants of binary forms. — Wilhelm Hallwachs: On an aperiodic amagnetic quadrant-electrometer, free from residual action.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Royal University of Ireland, Calendar 1895 (Dublin, Thom)—Société d'Encouragement pour l'Industrie Nationale, Annuaire 1895 (Paris).—Land-Birds and Game-Birds of New England; H. D.
